- is transparent (the residual lives and characterisation factors should be publically available);
- is applicable to different levels of economic activity;
- permits data to be aggregated and disaggregated;
- uses input data that is available, i.e. data needed for EN15804 compliant EPDs;
- is easy to communicate (measure of quantity and availability).

6.3 As materials are combined into particular units that are built into infrastructure and buildings with additional materials to make them function (e.g. the example pipe described) true comparisons cannot and should not be made at the product level.

6.4 Water-use should have its own indicator and it is proposed that the net water-use is multiplied by a characterisation factor related to scarcity and impact on other users.

6.5 Land-use should be included as an indicator when an agreed method for taking this into account.

6.6 Recyclability at the end of life is more a matter for the designer of the structure than the product supplier.

6.7 Environmental compatibility is covered by BRCW3.

6.8 To avoid incorrect assessment, all three pillars of sustainability should be included in the assessment of the sustainable use of natural resources.

Short Summary

Life Cycle Impact Assessment (LCIA) is a phase of the Life Cycle Assessment that aims to evaluate the magnitude and significance of the environmental impacts of a product system throughout the life cycle of the product. LCIA is the weakest but the most important phase of the method due to uncertainties of the components and approach differences between methods.

Spatial differentiations are effective in evaluating and determining the significance of environmental impacts. Therefore, most countries have created LCIA methods aimed at assessing their own environmental situations. In addition, some countries have created LCA tools that evaluate the environmental impacts of building materials and developed LCIA methods. There are different approaches between LCIA methods. One of the important differences is the point that environmental categories evaluated quantitatively in the system. Accordingly, mid-point (problem-oriented approach), end-point (damage-oriented approach), and methods which combine two approaches have been developed. There are a lot of controversy that assess benefits and shortcomings of each approach. The methods are also different in specific aspects, such as the quantity and the concept of selected impact categories, the environmental models developed for the characterization phase, normalization and weighting factors.

This study aimed to evaluate and compare current LCIA methods for building materials such as BEES (Building for Environmental and Economic Sustainability), Bre- Environmental Profiles (Building Research Establishment), BPIC / ICIP (Building Products Innovation Council -Industry Cooperative Innovation Programme), ATHENA Impact Estimator, BEPAS (Building Environmental Performance Analysis System) and BELES (Building Environment Load Evaluation System). These comparisons are based on the ISO 14040 standard framework. As a result of the study, differences in the methods are seen in the selected impact categories and category numbers, the point which environmental categories evaluated quantitatively, selected category indicators and models, normalization factors and weighting methods like panel method, distance to target method and willing to pay method. This study emphasizes that continent or country specific LCIA methods for building materials need to be created.

Keywords: Life cycle impact assessment methods; building materials; environment; locality

1. Introduction

High production quantities of the building materials in the building construction and the use of them in a wide area in the world make the environmental impacts of the building materials important. Not only properties, types, application conditions and performance of the building materials but also the environmental effects should be known by the architects. Factors like decisions, transportation, technology, labor, legal arrangements, patterns of use may be decisive in the formation and the control of the environmental impacts of the building materials. Assessment of these impacts provides the reduction of their harmful effects on the environment and the selection of environmentally friendly materials. Life Cycle Assessment (LCA) is a tool that evaluates

environmental impacts of the products including the building materials or services in the entire life cycle defined as cradle to grave. LCA consists of four phases according to ISO 14040. These are goal and scope definition, life cycle inventory analysis (LCI), life cycle impact assessment (LCIA) and interpretation [1]. In the study of Junnila, it is stated that there are still uncertainties in the components of LCA despite the common use of it; data analysis phase contains atleast uncertainty and LCIA phase is one of the most vulnerable phases [2].

LCIA aims to evaluate the magnitude and the importance of environmental impacts of a product throughout the life cycle. In LCIA phase consisting of mandatory and optional elements, the selection of environmental impact categories, category indicators and the characterization models, classification of these categories, calculation of category indicator results according to the selected characterization model are the mandatory elements. Normalization, grouping and weighting are the optional elements. Spatial differentiations are effective in assessing of environmental impacts and determining the degree of importance of the effects in LCIA methods. Therefore, most of the countries which have created LCIA methods aimed at assessing their own environmental situations.The study of European Commission Joint Research Center provided an analysis of existing methods for assessing the potential environmental impacts from emissions and resource use that can be attributed to specific products in the LCA [4]. Besides, in the study of Menoufi, LCIA methods as midpoint approach methods, endpoint approach methods and other methods were analyzed [5]. In addition, some countries like America, England, Australia have created LCA tools that evaluate the environmental impacts of the building materials and have developed LCIA methods.This study focuses on LCIA methods which evaluate environmental impacts of the building materials unlike other studies about LCIA methods.

In this study, it is aimed a comparative analysis of the life cycle impact assessment methods of BEES (Building for Environmental and Economic Sustainability), Bre- Environmental Profiles, BPIC (Building Products Innovation Council)/ ICIP (Industry Cooperative Innovation Programme), Athena Impact estimator, BEPAS (Building Environmental Performance Analysis System) and BELES (Building Environment Load Evaluation System) models, the determination of variables among methods and thus, it becomes a guide to the future LCIA methods that assess environmental impacts of the building materials. Comparisons based on ISO 14040 series standards are made in terms of mandatory and optional elements in LCIA methods. Differences in the methods are primarily seen in the point which environmental categories are evaluated quantitatively. Accordingly, the methods become different as endpoint approach methods, midpoint approach methods and the methods which combine two approaches methods. Other variables are the types and the numbers of the selected environmental impact categories. Differences in the methods are also seen in the selected characterization models, category indicators, normalization factors and weighting methods.

2. Life Cycle Impact Assessment for Building Materials

The building materials, which are the components of the building, change the environmental performance of the building and fulfil their functions after having been installed in the building. The life cycle of the building materials consists of a series of phases, such as raw material acquisition and preparation, manufacturing, packaging, transportation, use, re-use, recycling, disposal [Fig. 1]. Each phase in the life cycle of materials brings with a number of environmental impacts.

Natural resource depletion, energy consumption, water consumption, waste generation, alteration of habitat and their impacts on the health and the environment are the major environmental issues at material acquisition and at the preparation stage. At manufacturing and fabrication stage; energy consumption, water consumption, and waste generation are the major environmental issues. Construction, use, and the maintenance stages include transportation of the product to the site plant, installation of the material in the building, maintenance requirements, durability and anticipated life span of the material. The major issue at this stage is the effect of installation and of the material itself on indoor air quality. Waste is also a concern in these stages. At recycling, reuse, and disposal stages; the building materials constitute an enormous solid-waste problem. Some building materials contain hazardous materials. The stages in the building material life cycle are defined below.

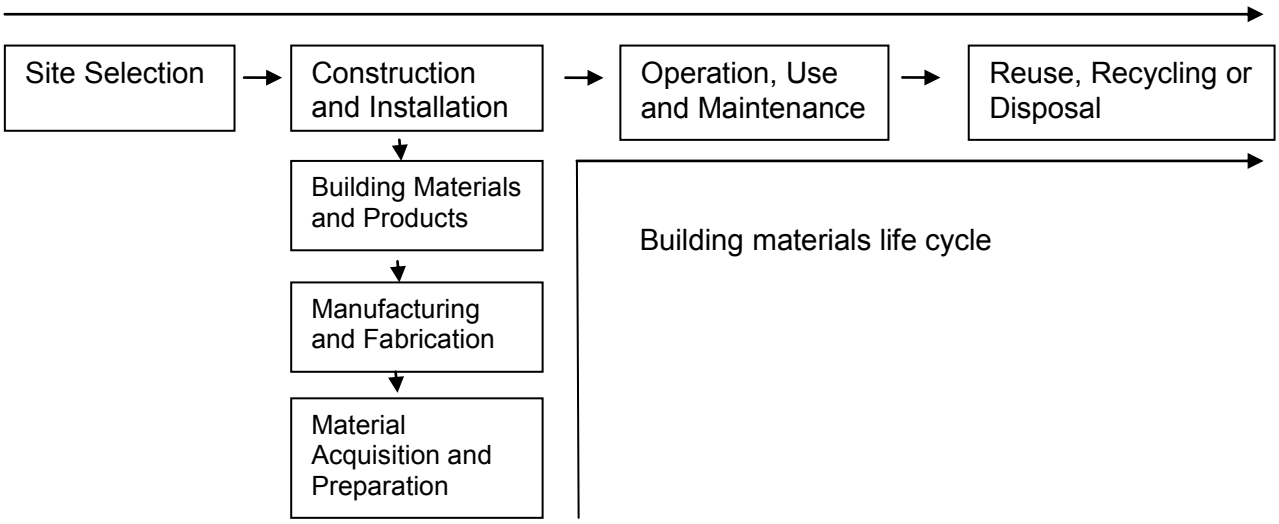

Fig.1: Facility and material life cycle [6]

In the process of material acquisition and preparation, type and quantity of the materials used in the process, type (coal, natural gas, petroleum, nuclear, hydro, wind energy etc.) and quantity of process energy, quantity of process water as inputs become important for LCIA. In addition, short or long transportation distances and transportation types (truck, rail, air, ship etc.) are also important in terms of environmental impacts. The type and the quantity of the materials in the construction process, durability and the useful life of the building materials, the effect of the building materials on building energy consumption like lighting, heating and cooling, type, and frequency of the maintenance are effective. In the disposal process, disposal methods like landfill, incineration etc., the volume and weight of the material and transportation become important. Finally, recycling and reuse properties of the building materials are very effective for LCIA.

The green building community has used LCIA methods to measure environmental performance of the building materials. There are differences among the methods. In these methods, different impact categories are taken into account; different environmental models and equivalence factors are used for the characterization; different reference points are used during normalization; and different ways are used while conducting the weighting phase. In this study, six models used for LCIA for the building materials are compared in terms of these differences.

3. Analysis of existing LCIA Methods for Building Materials

BEES (USA), Bre- Environmental Profiles (England), BPIC/ ICIP Project (Australia), Athena Impact Estimator (Canada), BELES (China) and BEPAS (China) are compared in terms of the mandatory and optional elements according to ISO 14040.

3.1.1 Approach Differences

LCIA methods are divided into three approaches as midpoint approach methods, endpoint approach methods and methods, which combine midpoint and endpoint approach methods. Midpoints are considered the links in the environmental mechanism of an impact category, prior to the endpoints, at which characterization factors or indicators can be derived to reflect the relative importance of emissions or extractions. This approach is referred as a problem-oriented approach. Endpoints are the terminals of the impact chains, which the environmental impacts are quantified. This approach is referred as a damage-oriented approach. There have been many discussions assessing the benefits and shortcomings of each approach [7]. Endpoint approach methods are accepted as more uncertain because of the high modelling and parameter uncertainties, whereas midpoint approaches are accepted as more precise because of the less modelling, the lower parameter uncertainties [8]. UNEP/ SETAC LCA Entrepreneurs proposed to benefit from the

advantages of both approaches; as a result, the methods combining two approaches have developed [9].

BEES, Bre- Environmental Profiles, BPIC/ ICIP, Athena IE, BELES are based on midpoint approach. In these methods, the potential environmental effects are assessed according to the midpoint impact categories like global warming potential, ozone depletion, acidification, eutrophication etc. BEPAS is based on endpoint approach by selecting human health, ecosystem damage, resources, and energy consumption.

3.1.2 Selection of Environmental Impact Categories

In the first or classification part, the emissions and resources in the LCI are assigned to the impact category or categories. Midpoint approaches include global warming, ozone depletion, eutrophication, acidification, photochemical ozone formation, human toxicity, ionizing radiation, ecotoxicity, land use, resource depletion etc. Endpoint approaches include energy, resources, ecosystem etc.

As a result of the examination of the methods, it is seen that all midpoint approach methods assess global warming potential, ozone depletion, eutrophication, acidification, fossil fuel consumption, photochemical smog formation. Mineral resource consumption, land use, water consumption, and ecological toxicity are mostly assessed. Waste, airborne suspended particulates, human toxicity, indoor air quality, ion radiation, noise, and transport pollution are environmental impact categories evaluating at least. BELES assesses human health, ecosystem damage, resources, and energy consumption as the endpoint categories [Table 1].

Table 1: Environmental impact categories and numbers in the methods

	Global Warming	Ozone Depletion	Eutrophication	Acidification	Fossil Fuel Depletion	Smog Formation	Mineral Resource	Land use	Water Depletion	Waste	Ecological Toxicity	Airborne sus.	Human Toxicity	Indoor Air Quality	Ionizing Radiation	Noise	Transport Pollution	Human Health	Ecosystem Damage	Resources	Energy Depletion	**Numbers of the categories**
BEES	x	x	x	x	x	x	x	x	x		x	x		x								**12**
Bre- En.	x	x	x	x	x	x	x		x	x	x		x				x					**12**
BPIC/ICIP	x	x	x	x	x	x	x	x	x		x		x	x	x	x						**14**
BEPAS	x	x	x	x	x	x	x		x	x	x	x										**11**
Athena	x	x	x	x	x	x		x														**7**
BELES																		x	x	x	x	**4**

3.1.3 Selection of Environmental Impact Category Indicators

In the characterization part, the relative effects of all the environmental interventions associated with each of the different impact categories are compared to one another. A reference unit is defined for each impact category as well as the corresponding characterization factors.

For global warming category, Global Warming Potential (GWP) is used and all greenhouse gases are expressed with CO_2 equivalent in the midpoint approach methods that are assessed. There is a consensus on this issue among the methods. For ozone depletion, all midpoint methods are based on World Meteorological Organization Model (WMO), and CFC11 equivalent is used; for acidification, H+ or SO_2 equivalents are used; for eutrophication, there is no consensus among the methods. N, NO_3, PO_4 equivalents are used for the characterization factors; for fossil fuel depletion kg., MJ, SCE or tons of oil equivalents (toe); for smog formation NO_X, ethane, ethylene equivalents

are used. Litre or m^3 for water consumption, kg or tonne for waste and mineral resource consumption, hectare year or the density of endangered and threatened species for land use are used in the methods. Only BEES method assesses indoor air quality with quantity of total volatile organic compounds (VOCs). There is no method for noise among the methods [Table 2].

In BEPAS method, human health is expressed with Disability Adjusted Life Years (DALY) /m^2; ecosystem damage is expressed with Potentially Disappeared Fraction (PDF) of species/ m^2.year; resources are expressed with Fe/ m^2 and energy consumption is expressed with Ce (coal amount converted by heat value) / m^2 [Table 2].

Table 2: Category indicators in the methods

	BEES	Bre-Env.P.	BPIC-ICIP	BEPAS	Athena	BELES
Global Warming	GWP	GWP	GWP	GWP	GWP	
Ozone Depletion	CFC-11 eq.	CFC-11 eq.	CFC-11 eq.	CFC-11 eq.	CFC-11 eq.	
Eutrophication	N eq.	PO_4 eq.	PO_4 eq.	NO_3 eq.	N eq.	
Acidification	H+ eq.	SO_2 eq.	SO_2 eq.	SO_2 eq.	H+ eq.	
Fossil Fuel D.	Kg	Toes	MJ	SCE(standard cool energy)	MJ	
Smog Formation	NO_x eq.	Kg. ethane	Kg. NMVOC	Ethylene eq.	NO_x eq.	
Mineral Resource	Kg	Tonne	Kg	Kg		
Land Use	TED		Hectare. year		TED	
Water Depletion	Litre	Litre	Kilo Litre	m^3		
Waste		Tonne		Kg		
Ecological Tox.	2,4D		kg.1,4-DB	Pb		
Airborne Sus P.	MicroDALYs			Kg		
Human Toxicity		Kg toxicity	1,4-DBeq. DALY'			
Indoor Air Q.	Total VOCs emissions		No methods			
Ionizing Rad.			Kg U235			
Noise			No methods			
Transport Pol.		Tonne. km				
Human Health						DALY/ m^2
Ecosystem Dam.						PDF.m^2. year
Resources						Fe/m^2
Energy Dep.						Ce/m^2

3.1.4 Normalization

In normalization, the results of each impact category are divided by a reference value. Thus, all environmental impact categories are made dimensionless. The major topic here is to use local data as a reference value. This data changes due to the diversification of values,such as population, area, emission rates etc., which depends on the countries.

Reference values used by the methods are shown below. BEES, Bre- Environmental Profiles, BPIC/ ICIP and Athena use the amount of emissions per person per year in the selected region as normalization factors. Unlike the other methods, BELES uses the total environmental load per unit building area of China as a normalization factor. BEPAS does not contain the normalization phase [Table 3].

Table 3: Normalization factors in the methods

BEES	The amount of emissions per person per year in the US
Bre- Environmental Profiles	Annual environmental impact created by a British citizen
BPIC / ICIP	The environmental impact per person per year in Australia
Athena Impact Estimator	Total annual emissions in Canada / Canadian population
BELES	The total environmental load per unit building area of China
BEPAS	Normalization is not used.

3.1.5 Weighting

In the weighting phase, important degrees of the environmental impact categories are specified according to the region or country in which the method is developed. There are different weighting methods such as panel method, distance to target method and willing to pay method.

In panel method, a group of experts representing different stakeholders are created for evaluating environmental impact categories in the order of priorities. In willing to pay method, weighting factors are expressed according to the estimated economic damage or monetary costs required in order to prevent damage for an impact category. In the method of distance to target, weighting factors are usually calculated in accordance with the target values based on political decisions.

It is seen that all midpoint approach methods use panel method. Analytic Hierarchy Process (AHP method), Delphi method, and eco-points method are used for the analysis of the results in the panel method. BEPAS uses willing to pay method for weighting phase [Table 4]. All LCIA methods for building materials include weighting phase.

Table 4: Weighting methods

BEES	Panel method- AHP method, user-defined, considered to be equal to all the effects.
Bre- Environmental Profiles	Panel method-- Eco-points system
BPIC / ICIP	Panel method-- Delphi method
Athena Impact Estimator	Panel method
BELES	Panel method
BEPAS	"Willing to pay" method

3.2 Discussion and conclusions

LCIA methods that vary by countries or even regions are used in order to assess environmental impacts of building materials. Considering the spatial differentiations in LCIA methods, continent or country specific LCIA methods for building materials need to be created.

Most of the methods evaluated in the scope of the study are based on midpoint approach methods. One of the advantages of using midpoint approach is the reduction of the uncertainties in the method. The other is to enable to develop a method that combines with midpoint and endpoint approaches.

Considering environmental impacts of building materials during the life cycle, the effects on air quality such as global warming potential, acidification, photochemical ozone formation, ozone depletion etc.; the effects on water quality such as eutrophication, acidification, etc.; soil effects as alteration of soil, besides, the consumption of non-renewable resources becomes important. Different environmental impact categories are assessed in the LCIA methods discussed. Waste, human toxicity, indoor air quality, dust and noise are at least evaluating the environmental impact categories. However, environmental and human health effects of these categories are great in the life cycle of the building materials. For example, indoor air quality is crucial for the protection of building occupant health and comfort, and the increasing of productivity. Some building materials release toxic gases. Dust affects worker and building occupant health in the material acquisition,

manufacturing, construction and demolition stages. Formation of odours is not assessed as the environmental impact categories in the LCIA methods for building materials. In the material acquisition manufacturing and demolition stages, formation of odours affects air quality. These environmental impact categories should be considered in the life cycle of building materials.

When examined the characterization factor used in the calculation of environmental impacts, there is a consensus for global warming category used CO_2 equivalent, for ozone depletion category used CFC11 equivalent. However, there is no consensus on globally representative characterization models for regional impact categories. For people who study on building and building materials, it is difficult to decide which equivalents are better for characterization factors. A recent comprehensive study of Hauschild M., Goedkoop M. and their friends can be the source on this issue. In this study, it is aimed to identify the best among the existing characterisation models in LCIA. Accordingly, baseline model of 100 years of the IPCC for global warming and World Meteorology Organization (WMO) model are recommended and satisfactory. Other environmental impact categories are evaluated as recommended but in need of some improvements or recommended but to be applied with caution [10].

The amount of emissions per person per year is mostly used as normalization factor in LCIA methods for building materials. Geographic coverage and time coverage are important in order to calculate the factors.

For LCIA of building materials, it is necessary to determine the importance degree of environmental impact categories for a region or a country, because the impact of the environmental category with a high weighting coefficient will be more important in the country that is evaluated, while two environmental impact categories have the same impact score. Although weighting is an optional phase according to ISO 14040, all LCIA methods for building materials include this phase. Panel method is mostly used in these methods. The disadvantage of the distance to target method is that weighting coefficient may change depending on the policy of countries. Only one method uses willing to pay method. Use of this method depends on the determination of economic values of the selected environmental damages for LCIA methods.

Potential environmental impacts and the importance of particular impacts can be quite significant between the countries or regions. Production and manufacturing processes can vary considerably from country to country, as can the types of fuel used, the source of raw materials, transportation distances, and the relevance of specific impact categories. The most accurate findings are usually obtained where product, process, technology, and location-specific data for a building material being studied is used.

Short Summary

The authors are hereby offering through experimental investigation a higher architectural design value for agro-fibres' usage and appliance in architecture. Through binding agro-fibres with bio-based matrices, green biocomposites of a wide variety of forms, textures and colours can be produced. These aspects are of a high importance in architectural applications and are the main key for such materials to compete with conventional fossil-based materials and non-annual wooden products that are still overwhelming the contemporary architectural products' markets. Cereal straw is here applied as the highest agricultural residue worldwide. This paper offers another perspective for agro-fibres biocomposites' applications in architecture.

Keywords:Biocomposites, Product Design, Ecological architectural products, Natural fiber composites, Agricultural residues, Agro-fibers.

1. Introduction

Using agro-fibers and applying them in the form of biocomposites, utilizing bio-based matrices based on renewable resources,can offer the opportunity to produce safe formaldehyde-free materials for interiors. Applying cheap and available natural fibers from the agricultural residues' source would offer not only an environmental balance reflecting society awareness, but also would open a new market for biocomposites' materials with lower prices and acceptable performances. Bio-based matrices binding industrial natural fibers generated from fiber crops cultivated especially for fiber generation leads mostly to products' price increase, leading to green-composites' market limitations. The option of choosing cheaper available fibers from another natural fiber source, as in the case of agro-fibers, is here suggested. The keys to provide attractive products using available production techniques and attractive product designs of higher architectonic qualities replacing the classic un-attractive agricultural residues applications in housing like baling systems, are here thoroughly illustrated.

2. Biocomposites Definition/Illustration

Biocomposites are composed of natural fibers combined by a bio-based matrix created from renewable resources, like linseed oils, or natural fibers combined with an oil-based matrix or artificial fibers bonded with a bio-based matrix. In this paper, biocomposites applied and meant are those green biocomposites composed of natural fibers and bio-based matrices. The authors here

discuss the green agro-fibers' biocomposites, where short natural agro-fibers are the types of fibers applied, which are retrieved from agricultural residues resources, and are bonded with bio-based matrices retrieved and manufactured from annual plant origins that aren't applicable in the feedstock industries.

Within biocomposites, the natural fiber provides extra rigidity to the composite that won't have been reached if the polymer/matrix alone has been applied. In addition, lower density, higher acoustic and insulation performances are always expected as a result of fiber incorporation with the matrix, due to the hollow capillary tubes within the natural plants tissues.
The material performance needs always to be tested and analyzed through the different qualifying techniques, whilst the processing itself can have a great reflection on the design value of the end product of the composite.

3. Alternative Natural Fibre Sources

Agricultural fibres are those natural fibres that are left over after the production of crops whether cereal crops, fruits, vegetables or nuts. The main interest in such annual crops' agriculture is the seed/fruit itself and not the residues left over after harvesting. That's why huge quantities of such residues are so often burnt after re-using relatively small amounts of them in conventional applications. On the other hand, and as the problems of conventional limited usages of stalks, straws, etc aren't completely been solved, fiber application industries are in great thirst to new available and cheap fiber types. Paper, furniture, boards and fiber reinforced composites' industries are examples of such industries that have long depended mainly on wood as a main source. The steady increase in the demand of wood fiber is gradually leading to a worldwide shortage of wood fiber supplies. Since the 1980's, depletion of the world's forests has steadily increased the price of raw wood and wood-based products [5]. One possible solution to this problem lies in the use of annual non-wood plants, where straw specifically is a direct available presenter of them. The following figure, Fig.1 , presents the non-wood natural fibre resources possibility to become a main ingredient in biocomposites with a short comparison showing the advantages when applying agro-fibres.

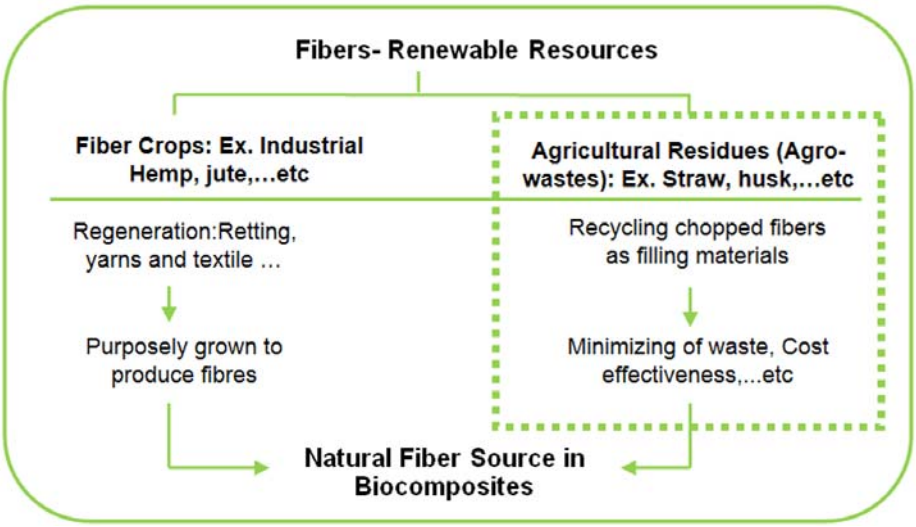

Fig.1 : Sketch illustrating the non-wood natural fiber sources, applicable in biocomposites' manufacturing

The most abundant type in agro-wastes, which is still not given enough that great attention except for feed stock and energy applications that still do not absorb all the available amounts, is the cereal straw. Cereal grains compose up to 72% of the world food of agricultural crops supply

according to the United Nations Food and Agricultural Organization, [7], which reflect the huge amounts of their residues.

Straw, the stem of the cereal plant that remains after the seed needed for nutrition is removed, composes about half the total dry weight of the crop [5]. For many centuries, straw has been utilized as animals feeding livestock, bedding and many other limited applications. However, these limited applications have never been enough to consume the huge straw amounts annually produced worldwide.

In addition, the drawbacks of the straw as an animal fodder increased dramatically the problems of its accumulation. The feed value (digestibility) problems are the main reasons for such drawbacks when used as a fodder due to the chemical structure of straw, [2].

Agricultural fibers' application in architecture is not a new discovered issue, but was already in use since the pheronic ancient Egyptian era when the rice straw was mixed with mud to form bricks that were used to build regular housing. In contemporary architecture, agro-fibers are re-discovered and re-applied, but still in limited applications. The hidden reason might be the un-attractive straw bales' look that still appears directly in our minds when talking about agricultural residues, making their applications next to their other technical difficulties, handling problems and aesthetic limitations, still un-desired from a lot of end-users worldwide, [6].

Therefore, it's discussed here within this paper another method of agro-fibers' appliance to reach a much higher architectonic design value and appearance, depending on renewable based matrices that can bind the agro-fibers in the desired forms, surface finishings and colours, reflecting their ecological nature to the end-user, according to the design required. In this case, and with extra further investigations, such products can compete with and replace existing fossil-based plastic and wooden products that are already present in the contemporary architectural-products markets, those which are applied in the same target applications like cladding, partitions, acoustic panels, etc.

4. Available Agro-fiber Biocomposites in Market and their Processing Possibilities

4.1 Agro-fibers' thermoplastic biocomposites

A lot of investigations took place in combining thermoplastic matrices with straw and husk fibers. Most of the available products in the market are combined fossil-based conventional PP, PE and PVC polymers with agro-fibres.From these commercial products: TerraFence™ and TerraDeck™ from recycled plastics and wheat straw, [14], in addition to Ricycled™ from recycled PVC and rice husk, [13]. Products from Resysta® are one of the rare examples of thermoplastic green composites made from mineral oils and rice husk of contents up to 60% by weight, [11].

The common compounding process takes place through the extrusion process, by heating the thermoplastic polymer whether externally or through the mechanical shearing of the inner screw(s), then feeding the chopped fibers according to specified fiber/matrix feeding procedures. Such processing is limited to the short fibers' compounding, which is the expected length that can be gained from the agricultural residues' resources. Long and continuous fibers in this case aren't yet applicable. The heating temperature should be carefully applied and not to exceed a certain limit (around 190-200 Degrees) [4], so as not to cause fiber rapid decomposition and hence failure by compounding and /or un-satisfactory composite performance.

After compounding, the composite can be either directly extruded into a final product through molding, or can be pelletized and packed for a reprocessing procedure through further extrusion or in-

jection in a separate process. These limited processing options leads to limitations in the application area as well. In such cases, non-structural applications are only to be expected.

In other types of plant natural fibers, that are not gained from the agricultural residues, other compounding methods can be applicable in case the fibers are produced long enough as in the case of flax, hemp, kenaf and cotton. In such cases, woven yarns, fleece and fabrics can be manufactured prior to the compounding process. Afterwards, manufacturing technologies possibilities of appliance are much higher. Examples of this are the pultrusion and comingling processes, which result in much higher performance composites. The composites are finalized through hot pressing of the compounded fibers/polymer, releasing and defusing the polymer within the fibers and resulting in a high performance composite.

4.2 Agro-fibers' thermoset biocomposites

Natural fibres are here bonded through thermoset polymers whether synthetic fossil-based or plant-oil bio-based ones.
Commercially, thermoset biocomposites are still not widely available. Inspite of this, high interest in such composites is in ascending demand, due to the known relative higher material performance of the thermoset composites than that of the thermoplastic ones. One of the examples of the successful products present in the market is the cladding products of Duralmond® from Avda. RegiónMurciana – Spain, [12], which is manufactured out of crushed almond husks and classic fossil-based thermoset matrices.
Manufacturing techniques as found in the classic composite industry, includes both 'open mould' (e.g. hand lay-up and spray-up) and 'closed mould 'techniques (e.g. resin transfer moulding, vacuum infusion and compression moulding). Limitations in the case of agricultural residues fibers are the relative short fibers that are normally won from such a source. Most of the compounding techniques are directed in the long fibers, fleece and fabrics direction. In case of thermosetting biopolymers' appliance, high curing temperature of the most current available ones is another limitation to the whole production process, [1].

Unlike classical methods of thermoset biocomposites' production, closed-press molding and open ones were applied and investigated using short free-oriented agro-fibres within the following examples to produce the desired designs. Short straw fibres were bonded with two different types of bio-resins of linseed oil epoxies. Each type of bio-polymer applied has its different processing method so as to reach the desired outcome.

5. Green agro-fibres biocomposites – Case studies

Inspite of processing difficulties, and limitations in both the molding techniques using short free-oriented fibers, as well as the high curing temperatures, two products of cereal straw short fibers were combined with two types of plant-based epoxy thermoset biopolymers. One of the types cured only in the presence of heat, while the other cured in room temperature. Difficulties were successfully overcome and the product design was correctly fulfilled and applied through choosing appropriate available production methods and enhancing all this into architectural applications.
The following case studies are products designed and produced by the authors and students of the third year in the faculty of architecture- University of Stuttgart within the framework of educational courses. The products are composed up to 40% by weight of fiber contents of cereal straw collected from different origins. The claddings were fixed as an interior and exterior application in an experimental pavilion named Eco-Pavilion which was fully constructed out of recycled materials, and was presented in the annual exhibition of the faculty of Architecture –University of Stuttgart in 2011.
The general criteria for designing the biocomposite, materials selection, processing techniques and their interaction is illustrated within the following sketch:

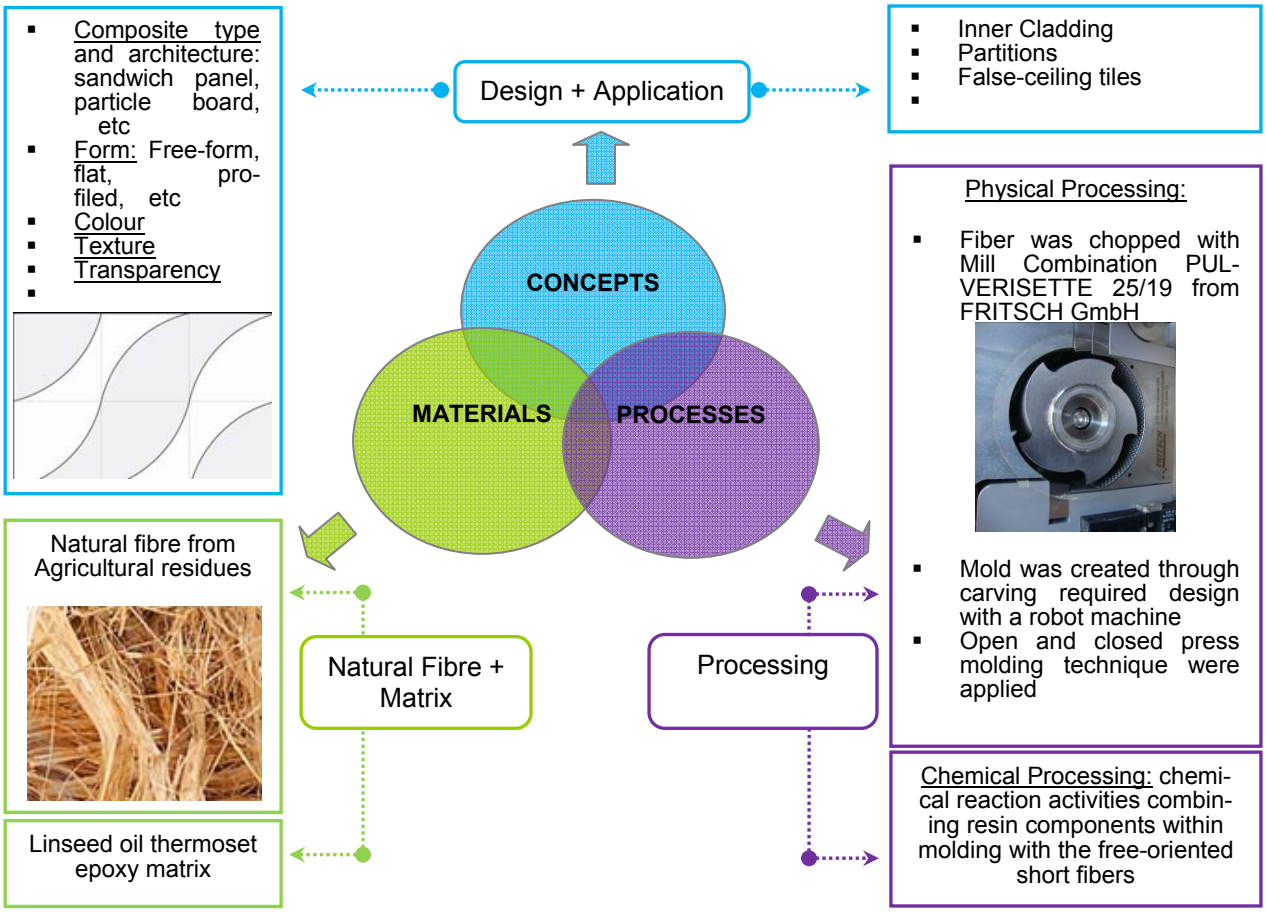

Fig.2 : Sketch illustrating the intersection between materials selection, processing possibilities to meet the desired design fitting into the required application

5.1 Case study – 1: TRAshell

Product description: Free-Form Façade Panels out of cereal straw short fibers and plant-based epoxy resin, 'TraShell', processed by press-molding (cold process).

5.1.1 Materials Applied

Rice straw and other agro-fibers were here applied, like coconut fibers of reddish brown colours and black ash recovered from sawdust and pellets burning to provide necessary colouring. Cereal straw was milled into 1 mm fiber length to maximize the polymer replacement percentage by weight uptill 40% by weight. Milling took place using a chopping machine integrated with a dust absorber, named Cutting Mill Combination PULVERISETTE 25/19 from FRITSCH GmbH. The previously mentioned reinforcing and active fillers were combined with a bio-based epoxy resin based on two components- Gripox® provided by Grizzly LeimGmBH, where component A (resin) is based on linseed oil epoxy and component B (hardener) based on a mixture of organic anhydrides (citric acid, oxalic acid etc) [8]. At room temperature, the fiber-matrix mixture cured in ~ 24 to 48 hours.

5.1.2 Product Design

The first sketch for a complete free-form cladded wall is presented as follows in Fig.3. The free-form panels were designed in two modules (A) and (B) as illustrated, to provide through their combination a desired 3D physical curvatures when the patterns combine as illustrated.

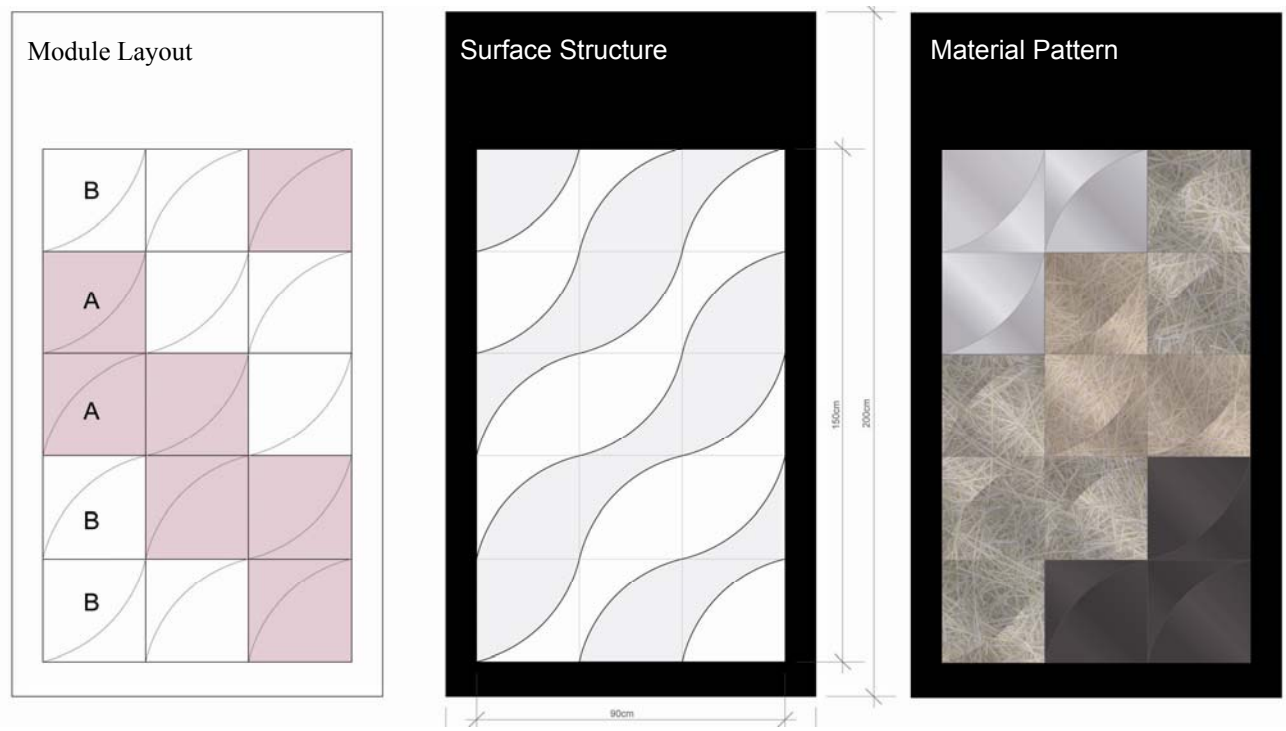

Fig. 3: Product design realized within the Seminar "Do it Yourself" in SS11, supervised by the authors. Students participated in this product: Susanne Hügel, Lousia Scherer, Kerstin Meyer

5.1.3 Mold making and molding technique:

For each designed module, a mold was separately manufactured. Each mold was composed of two pieces, a positive and a negative form. The negative forms were separately carved in a foam block material after a 3D digital drawing of the two design modules using a robot machine, and the negative sides of the molds were created in a different process using another resin and filling tiny stones.

After applying the necessary releasing materials, the mixture of agro-fibers and the bio-resin was distributed in the negative mold then pressed through the positive lid for at least 24 hours in normal room temperature. The hardened composite was then raised carefully from the mold, to harden completely in room temperature for another 24-48 hours.

5.1.4 Outcome:

The resulted panels were stable and fixed successfully on a pavilion's façade for experimentation-Fig.4. Panel surfaces contained no air gaps and the production of both mat and shiny surface finish was also possible. Free-form panels were of 4 mm thickness and 5 cm protrusion to the outside when measured horizontally.

The composite was tested for weathering conditions (according to Free Weathering Test-DIN EN ISO 877) for 12 months as well as mechanically tested. The results were satisfactory and have shown high stability of the material against UV rays and weathering conditions.
Mechanical testing showed comparable stiffness values with existing non-structural materials available in local markets that are applied in interior applications. This reveals the potential of replacing existing conventional materials with renewable resourced products based on agro-fibres and bio-based matrices. Further experimentations and designs should be proceeded by architects, designers and material engineers to reveal more attractive applications possibilities from agricultural residues.

Right- Down: Closing the upper positive mold with the negative one to create the shell composite. Photos: B. Miklautsch, H. Dahy

5.2 Case study – 2: 'BiOrnament'

Product description: Colored laser-cut flat panels (BiOrnament), processed by: hand lay-up open molding technique.

5.2.1 Materials Applied

Cereal straw fiber was applied and prepared using the same previous method in the first case study.

5.2.2 Product Design

The design sketch illustrates the idea of the pattern, that was applied depending on repating both the positive and negative cutting models that would result from the laser cutting procedures after the flat panels were separately manufactured. The product theme depended on the rhythm and diversity within unity using a repetitive pattern with different colourings after a specific design.

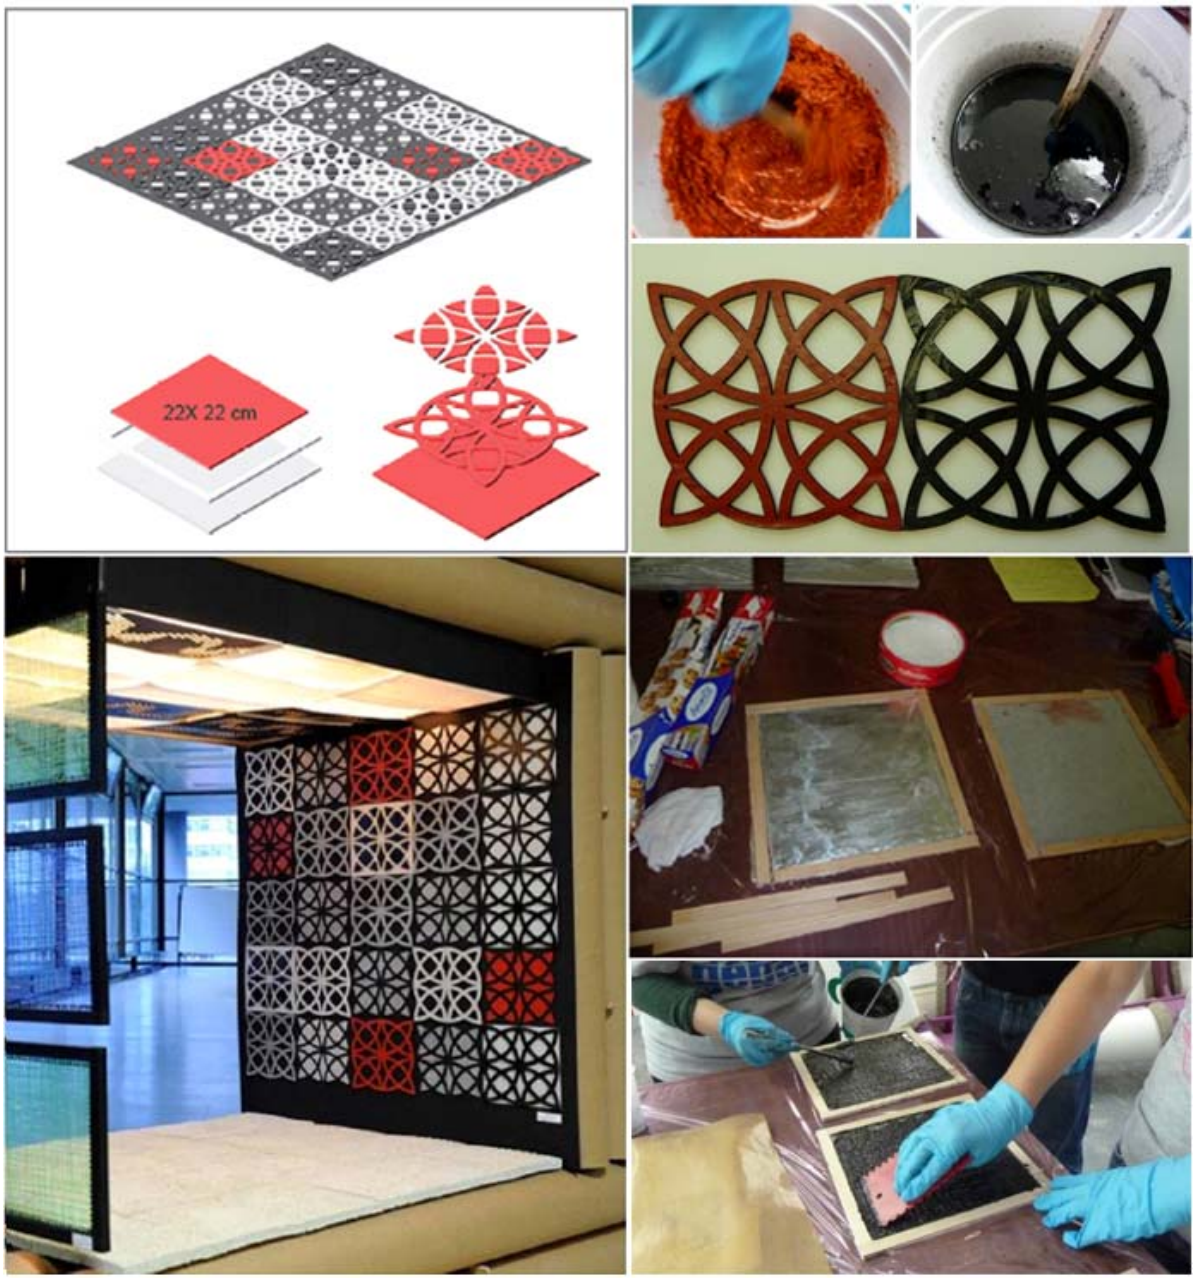

Fig. 5: Product design sketch, panel production stages and the final BiOrnament product after fixation on the experimental Eco-Pavilion (©ITKE). Photos: B. Miklautsch, H. Dahy.

The product and design were realized within the Seminar "Do it Yourself" in SS11, supervised by the authors. Students participated in this product: Anke März, Gregory Tarkhounian, Nora Woborny

5.2.3 Mold making and molding technique

The fibers were bonded with a linseed epoxy based thermoset polymer, PTP®-L provided by B.A.M. (Bio- Composites and More GmbH). The binder was prepared through a mixture of 3 components A, B and C, where Component (A): bio-based epoxy resin (concentration 55-65%), Component (B) hardener (concentration 35-45%) and Component (C) : additional PTP accelerator (concentration 2,5-5%), which is only activated by heat [9]. This is considered a disadvantage of the matrix in this case, for the extra energy usage.The mixture of the resin components reacted then rapidly after the fiber mixture uptill 40% by weight under high temperature (130° C) and finally polymerizes. The fiber should be dry enough to be properly bonded by the matrix.

The mold was composed of a metal flat plate surrounded by long flat edges, with extra openings on the edges for excess resin's release. After applying high temperature releasing agent to the mould, the fiber/matrix mixture was distributed horizontally and pressed. The final upper pressing of the mixture within the mold is not mandatory in this case.

5.2.4 Outcome:

The produced flat panels were cut by a laser machine according to an oriental design as shown in Fig.5 . The panels were from 2-4 mm thickness and of 25x25 cm dimensions. They were successfully colored through natural pigments that were applied during the mixing stage.The produced cladding panels were fixed as an interior application in the experimental pavilion. Samples were taken from the produced panels and free weathering was applied as declared in the previous case study. The visionary observation showed stability of the samples' appearances and colours after 12 months against UV rays and natural weathering.

-The outcome of the illustrated case studies show that the recycling of agricultural residues towards architecture and building industry still have so many potentials and beauty that need further work and investigations. Design possibilities are wide and open for further developments in the field, and the manufacturing of products of higher architectonic qualities that can compete in contemporary markets to replace conventional fossil materials is therefore applicable using agri-fibers.

6. Challenges illustration

6.1 Compatibility with polymers

Compatibility of the natural fiber with the thermoset resins in specific is still problematic due to the hydrophilic nature of the natural fibers in opposition to the hydrophobic nature of the resins. This causes plasticity nature during the compounding process that causes undesirable lower mechanical properties than expected. That's why alkali-treatment was the solution for many researchers to overcome the uncontrolled humidity in the natural fiber, through strengthening another aspect in the fiber-resin adhesion factors, which on the other side causes chemical wastes with recovery difficulties. On the other side, the fiber's combination with thermoplastics is pushed back with the limited processing temperature (maximum 200 degrees), otherwise the natural fiber would decompose. That's why the compounding of the natural fibers with thermoplastics are limited to plastics with relatively low-melting points like PP and PE [3].

6.2 Manufacturing techniques

6.2.1 Humidity control

One of the main problems is the humidity control, which is one of the main drawbacks of natural fibers. Chemical modifications can improve this problem to a great extent, however has its own problems concerning releasing chemical wastes and cost effectiveness.

6.2.2 Machining

Short agro-fiber composites are processed using the common plastic machinery, including extrusion, injection molding and thermoforming. In case of thermoset composites' processing, limitaions of short fibers' applications widely exist, as these techniques are mainly based on long fibers' processing. Technologies for production of straw mats should be further applied to increase the opportunity of the fiber's processing potentials and manufacturing possibilities, especially for agro-fiber thermoset composites.

6.2.3 Dust control during chopping

One of the main problems in the chopping process is the huge dust released causing dust clouds, with risks of lung diseases. Therefore, a milling/dust-absorber machine was applied in the fibers' preparation procedures, Fig.6, where the chopping system was integrated with a dust absorber and collector system, preventing dust clouds to exist.

Fig. 6: The chopping machine is integrated with the collector and dust absorber, supported by FRITSCH [10]

7. Conclusions

Current applications of straw-based biocomposites and boards are still in the early stages of development. Chemical modifications which are classically applied on the natural fiber before compounding to optimize the fiber/matrix interface quality releae toxic chemical wastes that are difficult to be treated. Hence, other compatible matrices with the natural fiber with the least

possible applied chemical modification should be further investigated. One of the suggestions would go further towards bio-based polymers which are derived from a much nearer to the natural fiers' base than a fossil-base. In this case, further investigations on life time of the final product and aging should be properly examined so as to suit different applications in building industry.

Straw can have much further applications when straw mats are applied in industry on much wider scales. In addition, the problematic transport problem when moving huge volume of the loose straw or even the bales themselves can be much decreased, especially when straw mats can be directly manufactured in fields and transported in this form to industrial applications. Furthermore, better waste management criteria to move straw towards more industrial applications, should take place.

In addition, further efforts are needed to take place to raise up the level of the architectural applications and reach up to much more attractive architectural products. Colouring, textures and forms are important keys in the architectural design of the products. With the help of natural pigments, laser cutting, free-form panels' manufacturing, more attractive products could be reached replacing the conventional ones based on fossil and non-annual wood available contemporary in the market.

Short Summary

The results from the investigation of the question whether insulating elements from components of the ETICS can be produced with sufficient static properties due to a new support structure as defined by wInterface to be produced as facade elements in a individualized industrial series production provide a new and significant solution to the challenge of deconstructing ETICS according to the Regulation (EU) No 305/2011 basic requirement for construction works No. 5, 6 and furthermost 7 Sustainable use of natural resources [1] which now has come into force.

Keywords: ETICS, ETIC, TICS, WDVS, Regulation (EU) No 305/2011, thermal refurbishment, EIFS, prefabricated cladding system, large panel system,

1. Introduction

The aim of this work is to investigate the question of whether it is possible to manufacture insulating elements from components of the ETICS, with static characteristics sufficient to be brought into use as prefabricated parts for exterior wall insulation in thermal renovation as well as new construction.

Only under this condition can the sensible use of individualized industrial series production of EIFS cladding panels be made possible on the basis of modern imaging methods of measurement. The use of this computer-based technology also enables the optimization over the entire manufacturing process.

Conventional EIFS facade insulation layers are produced directly and in conjunction with the existing facade in laborious hand work. To the cost driving disadvantages of difficult working conditions on the vertical wall and all the quality and time loss due to the barely controllable influences of the weather and to the long lasting burdens on the inhabitants by disturbing of privacy, noise and waste add the equally long-lasting obstruction of traffic especially in high-traffic roads in urban areas.

Through the conjunction with the facade these conventional ETIC systems cannot be dismantled. Thus they do not meet the basic requirement for construction works No. 5, 6 and 7 of the Regulation (EU) No 305/2011, which also prescribes the process of deconstruction at the end of use to be considered. Sufficient static properties provided prefabricated EIFS façade elements produced to accurate dimensions can be a possible solution to this challenge due to the possibility of their demounting.

2. EIFS insulation elements of the wInterface system

As an approach to solving this problem, EIFS elements for thermal insulation of buildings with a novel load-bearing structure have been defined by wInterface along with a method of manufacturing, which allows a customized industrial series production of precisely fitting EIFS façade elements.

In addition to the cost efficient EIFS made from EPS other EIFS have been accredited on the basis of insulation materials such as mineral wool, wood fibreboards or PUR / PIR showing accordingly different characteristics. Is to be noted that all components of these accredited EIFS are in principle suitable as component for the construction of these facade elements.

In contrast to the large, storey-high facade insulation elements in sandwich construction with window openings as it was developed in the Large Panel Insulation Technology (GEDT)[2] for thermal insulation improvement and renovation of old buildings and in distinction to the various forms of wood frame construction examined in the research program Haus der Zukunft and published in the project report plusFassaden [3], the wInterface insulation elements are usually arranged as simple rectangles between components like windows and balconies. The entire wood frame construction of such elements can be replaced by wood fibreboard when using the load-bearing structure of the wInterface insulation elements.

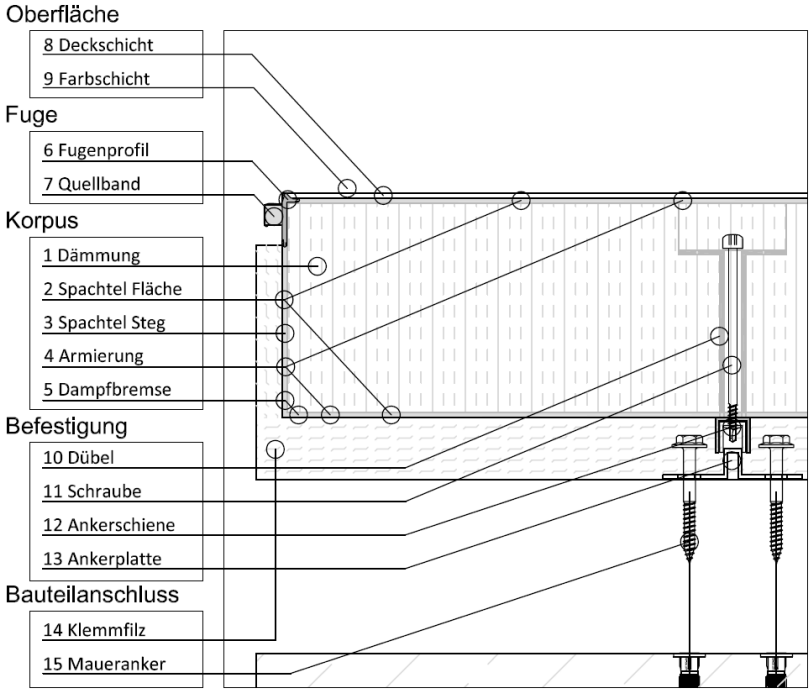

Fig. 1 Components of the EIFS insulation elements

2.1 System specification of the EIFS insulation elements:

Body of thermal Insulation (1): made from EPS, mineral wool and organic materials like wood fiber insulation or PIR
Adhesive (2, 3): Klebespachtel (4% organic compound) or Dispersionsspachtel; Option: Additive for quick setting; Addition to curing to dense vapor barrier on the inside.
Reinforcement (4): glass fibre, glass fibre; Option: diagonal in the fixed links
Surfaces (8): mineral or thin plaster; + pigment layer: Silicone resin dispersion,
Edges (6): Edge profiles made of plastic and metal
Gap to the wall (14): Mineral wool (Klemmfilz) on the inner surface of the EIFS elements directed towards the building to avoid ventilation

Vapour barrier (5): can be laminated on the inside against vapor diffusion or utilized as a coating or spraying of a suitable layer of vapor barrier in the course of production facilities. If possible, the element materials (as shown above at adhesive) should be tuned to each other so that an additional layer can be omitted and a high potential for dehydration is provided.
Formation of the joint (7): the gaps can be closed weather tight by a commercially available, pre-compressed sealing tape. There are for example pre-compressed multi-function bands made of durable elastic, fine-pored polyurethane foam for sealing to standard for defined gaps (Bauanschlussfugen) in a wide range usable with a water tightness proven to 600 Pa. The use of profiles for edge protection and joint edge profiles has also proved useful.

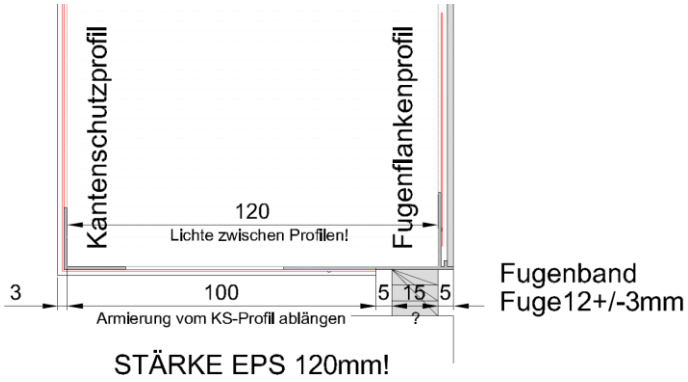

Fig. 2 Joint with pre compressed sealing tape and joint surface profiles

Fixing: The mounting of the insulating elements takes place by means of EIFS dowels (10) for a pointwise screw connection (11) to rails (12) which in turn are secured at their upper and lower ends via an anchor rail (13) to the wall. During assembly the rails (12) can be attached at their lower ends to the anchor rail (13) of the lower, already mounted elements and when dismantling single EIFS elements can be unscrewed through the joint (7) from the anchor rail. The rails (12) make an additional reinforcement of the system.

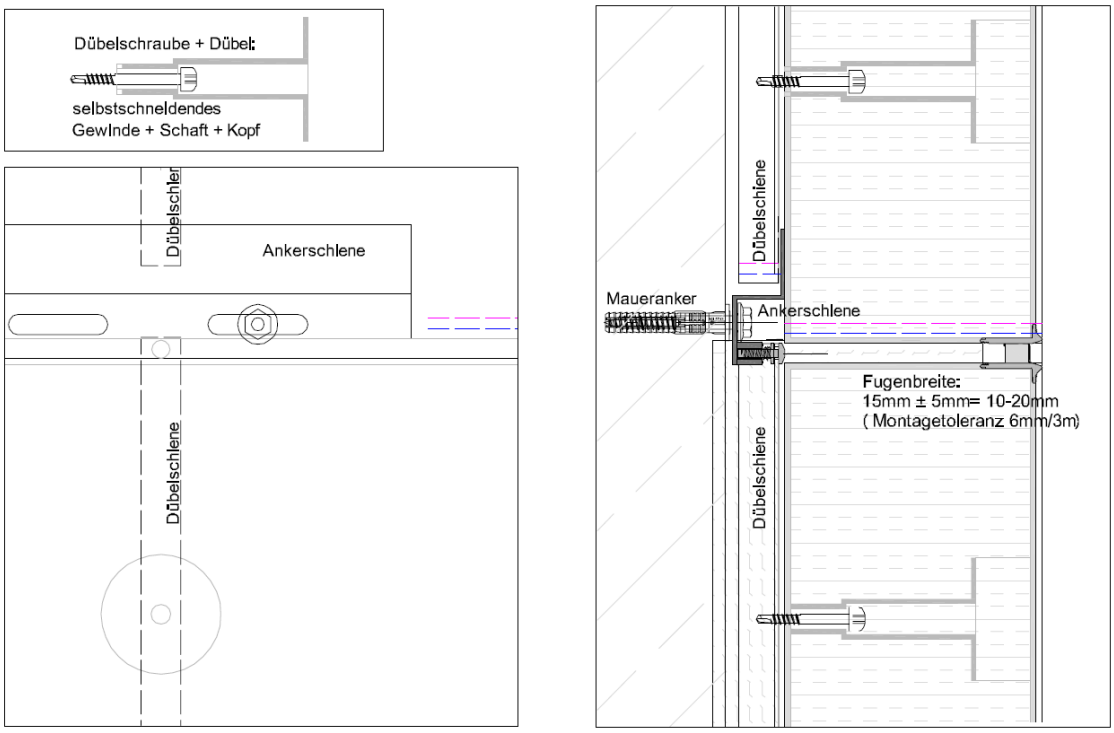

Fig. 3 Mounting system with ETICS anchor, anchor bolt, rail and anchor rail

2.2 Ensuring functionality and usability

Static sufficient properties will be stated in this work, when functionality and usability are demonstrated by the fact that under normal loading as wind suction on the order of 1,000 N/m², the deflection of the EIFS elements remains limited to the length-dependent maximum value of L/200 and that extraordinary loads such as wind suction on the order of 2,500 N/m² [4] and more do not lead to fracture of the EIFS elements or their mounting system.

3. Computational models of the deflection

The outer and inner stresses which may act on the elements must be detected to analyse the structural requirements of the elements. These are essentially dead weight, wind load, thermal stress and rain pressure.

In this survey of the basics a strong focus lies in the understanding of the interrelationships of important variables such as element thickness, insulation materials, coating materials (adhesives, reinforcements), fixings (dowels, fixing bars) on the achievable strength. The aim is to establish a computational model, by which three applications can be met:

- First, it serves to provide the proof of stability for individual projects. This is true both for the pilot projects as well as for future projects when the system is certified. Even then the stability analysis for each project must be provided by a structural engineer.
- Second, it provides the basis for the mathematical proofs in the context of certification and for the computational assessment of further developments.
- Third, the computational model is also the basis for the automated design (dimensioning and verification of stability) of the facades as part of the interface of the facade designing tool of the control software. The individually from the geometry derived facade elements must be automatically checked for stability. The same applies to manually by the designer adapted items.

The requirements for the static arising from external influences (weight, wind, temperature, etc.) are to be considered from two aspects: on the one hand, the failure of the element (eg, fracture) under extraordinary stress conditions (eg storm or fire), here it is important to know the load at which failure can occur. On the other hand, for the serviceability the deflection of the elements hast to be limited to a size-dependent maximum value under normal load conditions.

The study of the specific requirements for the statics and the survey of the basics was done in cooperation with Ingenieurgemeinschaft Kaufmann – Kriebernegg ZT-GmbH (IKK). The main findings are that exposure to wind in Austria lies normally in the range from 500 N/m² to 1,000 N/m², up to this load the maximum deflection of the elements must be less than a L/200. Higher loads (eg storms) fall into the category of extraordinary burdens, in which case the elements must remain intact as far as that no hazard to persons or property can occur. Furthermore, the shape changes due to temperature variations are expected in the order of less than 2 mm and thus can be easily absorbed by the joints.

For the calculation of the elements regarding the serviceability two computational models were developed. Basis of the deflection is the following formula:

$$f = \frac{5}{384} \times \frac{l^4 \times q}{E \times I}. \quad (1)$$

Where f is the maximum deflection and l represents the length of the component. The load is represented by the linear load q. The modulus of elasticity E is a material constant and I is the area moment of inertia that depends on the geometry of the component. In contrast to l and q, which are given for a particular component and a particular load, the modulus of elasticity and the area moment of inertia of the elements must be derived for the assembled components. Principally there are three options available for this approximation:

1. Hollow profile of adhesive: Here, the modulus of elasticity of the adhesive is used to calculate the moment of inertia for a hollow box. This approach can be chosen because the influence of the insulating material due to the low modulus (about 3.4 N/mm² for EPS as opposed of 6,500 N/mm² for the adhesive) is negligible. However, the calculation of the moment of inertia of the hollow body is both very complex and on the other hand a reduced value for the E-modulus has to be used for the adhesive due to the extremely small wall thicknesses. Since there is no suitable model for decay of the E-modulus, this approach was not further pursued.
2. Total cross-section method or n-digit procedure (Gesamtquerschnittsverfahren): In this approach, the whole body is broken down into parts of the same material and for each part of the body the area moments of inertia are calculated separately. For the total body, the elastic moduli and the area moments of inertia are summed weighted. The individual weighting factors are derived from the ratio of the modulus of the component to a fixed factor (usually the highest modulus of all components). These weighting factors are referred to as "n". Detailed information about this method can be found in [5].
3. Composite: In this method, the area moment of inertia of full section is used and the E-modulus is calculated from the E-moduli of the individual components. For this, the whole body is decomposed as with the total cross-section method. The moduli of elasticity of the parts are either added or their reciprocal values are added depending on whether they lie parallel or in series to the overall direction of the stress. Detailed information about this method can be found in [6].

Both methods give similar results for the expected deformation for the relevant loads (1,000 N/m²). For thinner elements with an insulation thickness of 120 mm, the total cross-section method gives about half as large values as the composite method. For thicker elements with an insulation thickness of approximately 200 mm arise in both methods the same values.

4. Testing

4.1 Deflection

Several prototypes were build and investigated to check if the computational models are suitable for predicting the deflection, which method produces better predictions, and to balance or derive the parameters for the models (material properties, geometric parameters, etc.) on the one hand and as a guide for deciding between different design variants on the other side.

Wind pressure tests were conducted on the test bed of Bauphysiklabors of the Graz University of Technology to gain information about the bending and fracture behavior of the elements. Here, pressure was applied the elements gradually up to a load of max. 4,000 N/m² while measuring the deflection

For these wind pressure tests 20 2,000 x 1,500 mm wide specimens were manufactured. These were designed concerning their inner structure just as they are to be used later. Here at the prototype three resp. four parameters have been varied. Each parameter can take one of two values, each representing an "extreme" value. The parameters are shown in more detail in the following.

- Adhesives: Two different adhesives were used for the bars and the top surfaces to get a feeling of the different behavior of a wide range of possible adhesives. On one hand, a pure cement adhesive, on the other hand a cement based adhesive with a high proportion of dispersion.
- Bars: In order to better assess the impact of the bars to the total static elements with and without bars have been tested. Elements without bars are composed of two EPS blocks with 750 mm in width and 2,000 mm in length joined together with a special EPS-adhesive to form a homogeneous block with the final dimensions. For elements with bars the standard EPS boards with 1,000 mm in length and 500 mm in width were used. In latter the bars are produced using the previously described adhesives.

- Insulation thickness: To examine the statics of the elements in a wide field of usage, the elements were implemented with two different insulation thicknesses. Firstly, working with 120 mm thick EPS boards to the other with 200 mm thick plates. This doubling corresponds to halving of the heat conductance value.
- Insulation material: In addition to the EPS based elements two elements have been produced with two types of mineral wool insulations (larger boards and smaller plates). Here, only the variants with bars and cement adhesive according to the combination 5 from the summary table were manufactured.

From these parameters, a total of eight variants result. In addition, derived from the combination with thinner insulation thickness, cement adhesive and with bars (variant 5) elements with mineral wool boards and mineral wool plates as insulation have been build. Two versions of each of the ten resulting specimens were manufactured. The following table represents all ten variations resulting from the above combinations.

Tab 1: List of types of elements for deflection testing

Variant	Adhesive	Bars	Thickness	Material
1	Dispersion	with bars	120 mm	EPS-board
2	Dispersion	without bars	120 mm	EPS- board
3	Dispersion	with bars	200 mm	EPS- board
4	Dispersion	without bars	200 mm	EPS- board
5	Cement	with bars	120 mm	EPS- board
5a	Cement	with bars	120 mm	MW- board
5b	Cement	with bars	120 mm	MW-plate
6	Cement	without bars	120 mm	EPS- board
7	Cement	with bars	200 mm	EPS- board
8	Cement	without bars	200 mm	EPS- board

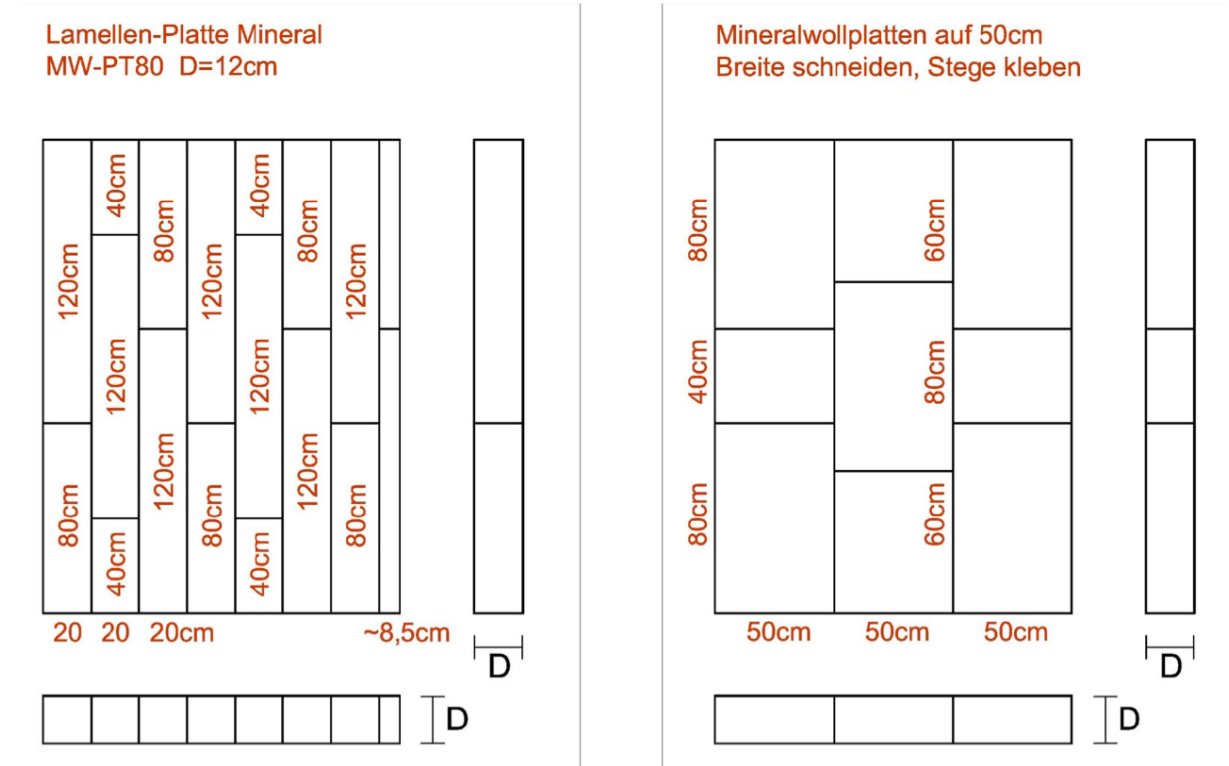

Fig. 4: Construction details of mineral wool elements. Left: plates. Right: boards.

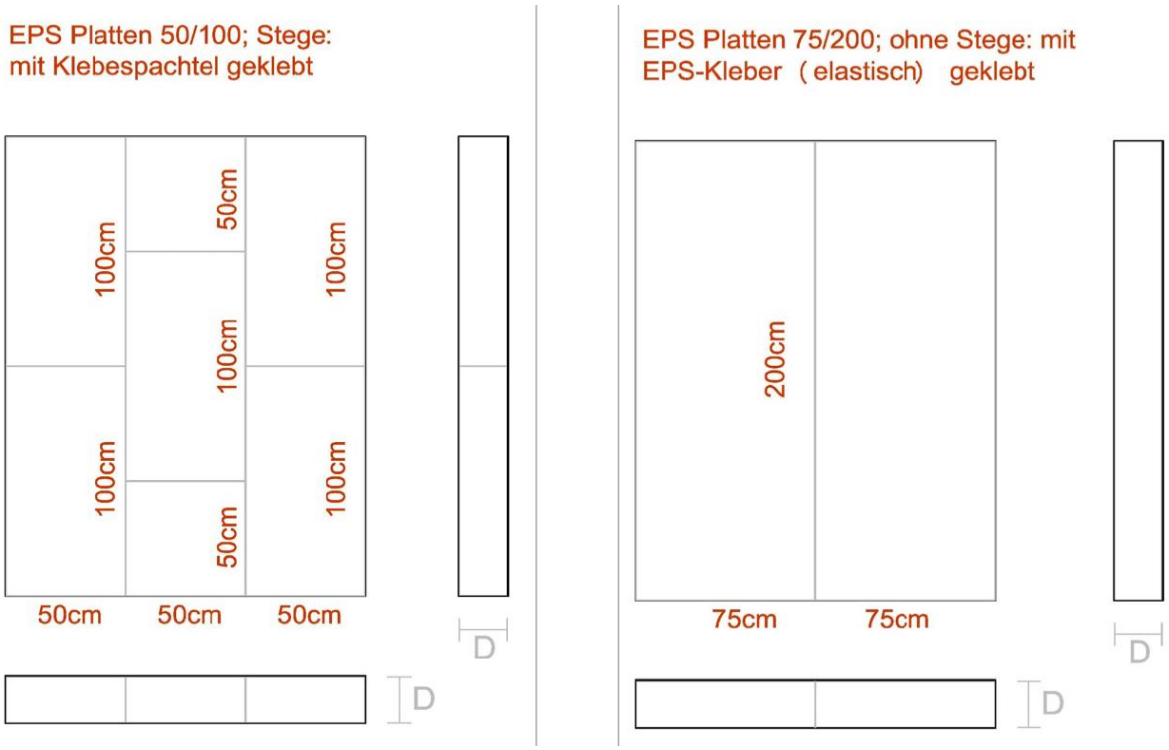

Fig. 5: Construction details of EPS elements. Left: with bars. Right: without bars.

4.2 Pull out tests

Based on the ETAG 017 32 specimens were made in total. In these test elements different variants of anchors (standard dowels, helical dowels, and threaded rods) were used. These were connected in different ways with the insulating body. On the one hand they have been directly applied through the insulating material; on the other hand they are nested into a bar between two halves of an insulation board. In addition, a part of the samples was performed with reinforcing mesh. The samples were clamped on a tensile testing machine and a force-distance curve was recorded. The specimens for the pull out test are 400 x 400 mm wide and have thickness of 160 mm. The following table gives an overview of the different variants.

Tab. 2: List of variants of specimens for pull out test

Nr.	Bezeichnung	Stück
1	Dowel in material	2
2	Dowel in bar	4
3	Dowel with reinforcement	2
4	Dowel in bar with reinforcement	2
5	Threaded rod	2
6	Threaded rod with reinforcement	2
7	Pre-test built 1	1
8	Pre-test built 2	1
9	Pre-test built 3	1
10	Pre-test built 4	1
11	Helical dowels in bar	2
12	Helical dowels in material	2
13	Threaded rod straight	2
14	Threaded rod straight with reinforcement	2
15	Threaded rod L-shaped	2

16	Threaded rod L-shaped with reinforcement	2
17	like 16 but with different adhesive	2

The experiments were performed in two different batches. The variants 7-10 were pre-test builts to test the procedure and the clamping of the specimen. In the first batch, the variants 1-10 were tested. In the second batch, the remaining variants were tested plus two specimens of variant 2 for comparison purposes. The test elements of the second batch were not fully cured due to the cold weather during the manufacturing.

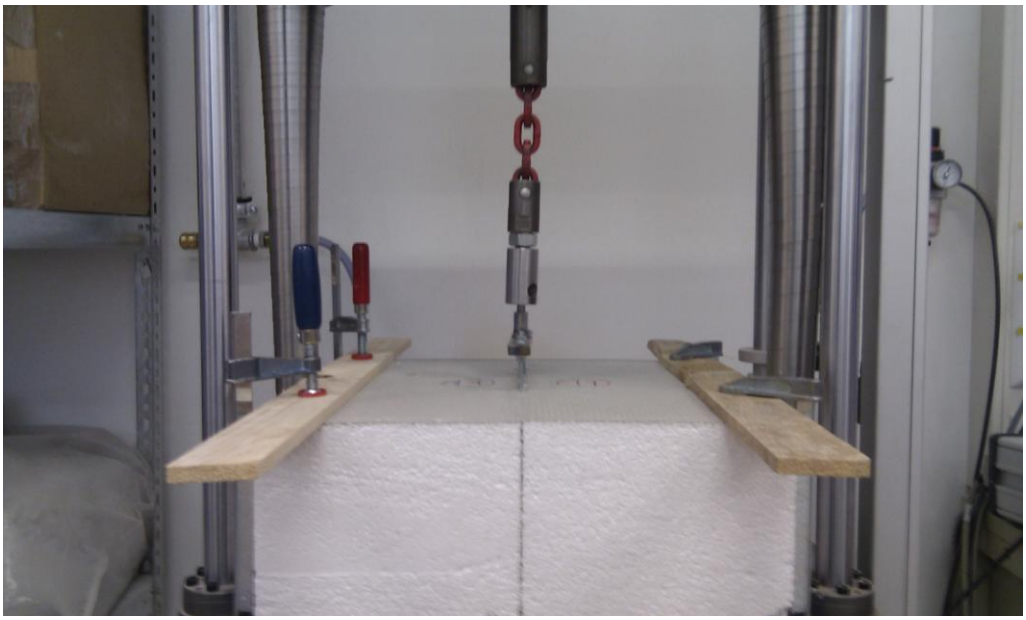

Fig. 6: Test set up pull out test.

5. Results of deflection

5.1 Failure Limits

The results obtained in the wind pressure tests have not only met but far exceeded the expectations. Although the computational models showed ex ante that the deflection should be within the permissible limits of a L/200, but it was not clear whether the items would handle the load at all or whether they would be damaged by the stress. The experiments have shown that the elements have less deflection than predicted by the models and beyond are also close to indestructible. Besides the measurement of the deflection it was tried to destroy all the elements by increasing the load to such an extent until there is a failure of the elements. Here, however, it was examined that the test bed could not keep up the pressure at a load between 3,500 N/m² and 4,000 N/m². Only one element (mineral wool board) broke at a load of about 3,800 N/m². All other elements have left the test bed intact. For comparison, this burden is equivalent to a heavy storm.

Tab. 3: Results of deflection tests (red values are lower than L/200)

5.2 Verification of mathematical models

Since the width of the part due to the mounting situation is not affecting the result in the experiments, the calculations were performed for components with a width of 1000 mm.

Tab. 4: Comparison of results of computational models and measurements

Type		Length [mm]	Width [mm]	Thick-ness [mm]	Area [m²]	Load Meas. [mm]	1000 GQS [mm]	[N/m²] VW [mm]	Load Meas [mm]	1500 GQS [mm]	[N/m²] VW [mm]	Load Meas [mm]	2000 GQS [mm]	[N/m²] VW [mm]

8	B	1,860	1,000	210	1.86	1.4			2.2			3.5		

The table shows, for four different specimens for three different strains (1,000 N/m²; 1,500 N/m²; 2,000 N/m²) in each case the measured deflection, the deflection of the total cross-section method (GQS), and of the composite method (VW). The values at GQS are in the thin components as mentioned about half the size of the values of VW. However, the measured values in these components at the higher loads showed larger values as predicted by GQS. Thus VW provides higher values for safeness for the dimensioning.

6. -Results of pull out tests

For each element, a force-distance curve was recorded and characteristic values were derived. On one hand, the maximum tolerable force was determined and the associated distance. On the other hand, for the distances of 1 mm, 5 mm and 10 mm the respectively there achieved forces were determined. The table provides an overview of these values represents the paths are given in millimeters and the forces in Newton.

Tab. 5: Results of pull out tests

17	A	13.8	336	43	121	248
17	B	15.4	339	30	137	246

The missing values in the variants 13-16 result in large part from the fact that the elements were not completely cured. Figure 4 shows the force-distance curves of the examples of variant 1. Almost the same maximum forces are reached, as in most variants. However, these are achieved in different distances.

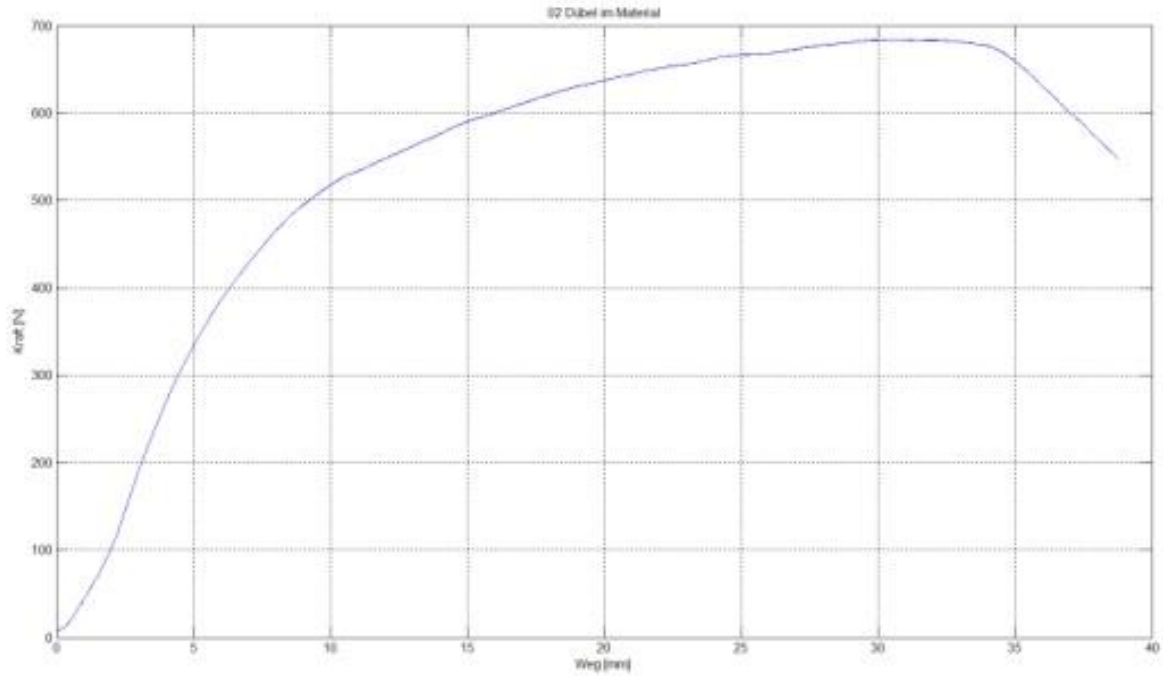

Fig. 7: Force-distance curve for variant 1B.

For Austria, as already described with the wind pressure tests, wind loads between 500 N/m² and 1,000 N/m² are expected in the normal case.

The dowels that are fixed only in the material (variant 1) reached in the experiments both a payload of about 600 N/m², but it was only after 30 mm resp. 50 mm distance. This would result due to plastically deformation of the EPS board in a degree of freedom for the dowels in the insulating material around this distance and after unloading the element could move freely along this distance. Thus, the facade would wobble.

However, as per m² more than one anchor is used - conventional EIFS, there are between four and eight dowels - which requires a load per dowel about 125 N/m². The dowels reach this capacity in both trials after 3 mm to 5 mm distance. These values are within the range, where the EPS may be deformed elastically. This means that on the one hand after the relief the elements are not free to move and second, this distance can be reduce by an initial load on the dowels during the mounting process, which was not done for the elements in the trials.

The pull out tests have shown that the extraction forces already can be coped with standard dowels directly mounted in the insulation material (variant 1), which are sufficient in areas with low wind load. For increased wind loads the dowels can be either combined with the bars or the number of dowel per square meter can be increased.

7. Discussion

The results of the static tests show that a minimum total thickness of the elements should be kept above: Tmin = 150(±10) mm = th.insulation 120 mm + adhesive 10 mm + plaster ~10 mm +mineral wool 30(±10) mm. This minimal overall thickness of the elements of 150 mm is also in terms of construction physics as well as from an economic perspective a sensible lower limit for conventional ETIC systems.

The static laboratory analyzes show that a maximum span of the elements of H max = 3,000 mm can be achieved. In further development this is the margin in order to produce storey high elements.

From the static tests with the production of the prototype and from the ongoing production of EIFS

elements for the first pilot project, the following potential for the optimization of construction, mounting and manufacturing process can be identified: The pull-out tests have shown that even with simple alternatives to the EIFS wall plugs better results can be achieved, especially when they are brought in bond with the adhesive layer. This approach promises to be purposeful for optimizing the development of the fastening system without dowels in combination with joints that operate with the two-stage sealing system and joint profiles. This brings advantages in terms of the stress of the sealing material and a greater security against the ingress of rain and it even allows drying out of the elements due to the intrusion of rain under absolute extreme weather conditions. This approach also simplifies the manufacturing process by eliminating a part of the substructure with plugs, screws and rails, while allowing the joint profiles to hold the cuboid of insulating material together during the curing of the adhesive.

8. Conclusion

The investigations carried out on EIFS elements have shown that insulating elements from components of the ETICS can be produced that have static properties that ensure the maintenance of functionality and usability even under extreme conditions. Thus EIFS elements can be prefabricated, which are suitable to be mounted as the exterior wall insulation for use in thermal renovation and new construction. Due to their possibility of disassembly they also meet the basic requirement for construction works No. 5, 6, and 7 of the Regulation (EU) No 305/2011 which now entered into force.

With this evidence, the foundation for the development of individualized industrial series production of EIFS cladding elements has been established. From use of these computer-based technologies can be expected, that the economic and ecological optimization of all areas in the entire production process of external wall insulation for buildings will finally begin.

Short Summary

A mobile sensor for measuring the U_g-value of window glazing was developed and tested. The sensor consists of two half-shells that are put onto the two sides of the glazing to be measured. One side of the glazing then could be heated up if necessary and the temperature signals on the two sides are measured. An analysis software transfers the transient temperature signals into the U_g-value of the glazing. The sensor allows short measurement times of about 10 minutes for double glazing and 20 minutes for triple glazing as well as a high accuracy of about ± 10% or ± 0.1 W/(m^2K), whichever is higher. The sensor covers the whole range of U_g-values between 0.5 W/(m^2K) and 4 W/(m^2K), which is typical for glazing found in the building stock. The sensor allows measurements on façade glazing as well as on inclined glazing, e.g. roof windows. Due to the option to actively heat up one side of the glazing, measurements can be made even if there is no temperature difference through the glazing. This is a big advantage compared to other measurement devices of this type, which can only be used in winter or when the environmental conditions are favourable.
A first prototype of the sensor was produced and successfully tested and validated in the laboratory as well as in field tests. A commercialization of the sensor is planned.

Keywords: U_g-value; measurement device; window glazing; energy-efficient buildings.

1. Introduction

Windows are an energy sensitive part of the building façade. However, after a window is incorporated into the façade, it is very difficult to determine the thermal insulation value of the glazing, especially if no product information about the glazing is available. There are some existing methods to measure the U_g-value of a glazing. These are devices based on temperature measurements like simple tools (e.g. [1]) that give more a rule of thumb than an exact value, or more sophisticated devices, like e.g. the U_g-meter of the company Helantec [2]. All these devices can only be used in winter or when a significant temperature difference between the inside and outside air exists. Precise measurements in the laboratory also can be used, but here the glazing has to be dismantled and transported to the measuring facility. A measurement device for the U_g-value that gives fast and accurate results independent of the temperature conditions and that can be used on-site is not state-of-the-art.

2. Sensor description

2.1 Measuring principle

Almost all commercial devices that measure the thermal insulation value of a glazing rely on stationary conditions, that is a constant temperature difference between the glazing surfaces. The U_g-value then is calculated from the measured temperatures of the glazing surfaces and the ambient (e.g. [1] or [2]) or from the temperature difference and the heat flux (e.g. guarded hot plate). These measurement principles all have some advantages and disadvantages:

- Measuring the temperature difference and the heat flux (typically in the laboratory) is very accurate, but the glazing has to be dismantled and transported to the measuring facility (no on-site measurements are possible).

- Measuring the temperatures on the glazing surface and the environment on-site can be a very fast method, but the accuracy is not so good. Even if high-quality sensors are used (e.g. [2]), there is no control of the outer and inner heat transfer coefficients during the measurement. Additionally, there has to be a significant temperature difference between the glazing surfaces which means, such measurements can only be performed during winter or similar conditions. And last not least, the glazing has to be in stationary condition which is very difficult to verify.

These considerations led us to a measuring principle that had to include the following points:

- The analysis must be transient to achieve short measuring times (independence of stationary conditions).
- The sensor must include components for active heating and it has to control the outer and inner heat transfer coefficients (independence of environmental conditions).
- The components must be of superior quality to achieve good accuracy.

This resulted in the measuring principle depicted in Figure 1.

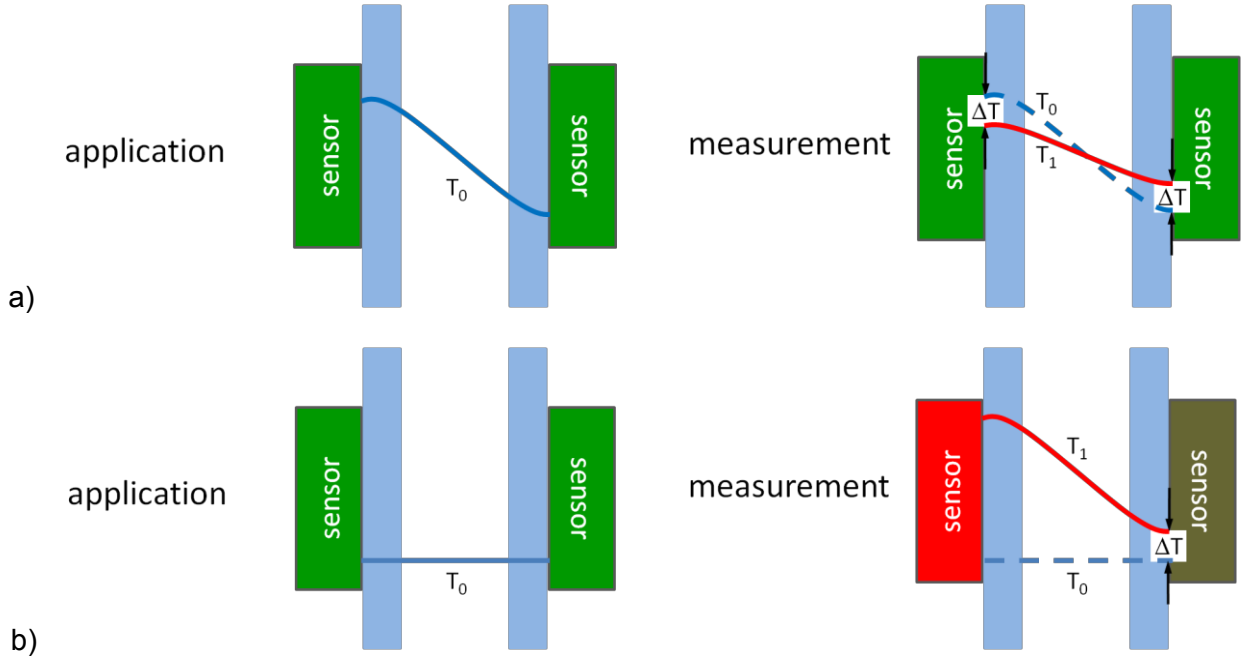

Figure 1: Measuring principle of the U_g-value sensor: If a temperature gradient exists (a) the passive temperature change is measured (no active heating); if no temperature gradient exists (b) one side will be heated up and the temperature rise on the other side is measured.

2.2 Sensor setup

The measuring principle was realized in a device consisting of two identical half-shells as depicted in Figure 2. A heating foil covers and protects the sensors for temperature and heat flux. Behind is the thermal insulation to eliminate environmental influences, which effectively sets the heat transfer coefficients to the ambient air to 0 W/(m^{2}K). A separator provides mechanical stability and allows the mounting of the backside equipment: the pump for the suction cups (not shown in Figure 2), the rechargeable battery, the transducer board for the measuring signals, and the WLAN transmitter. The data are received by the analysis software on a PC, where the measurements are controlled and the U_g-value is calculated.

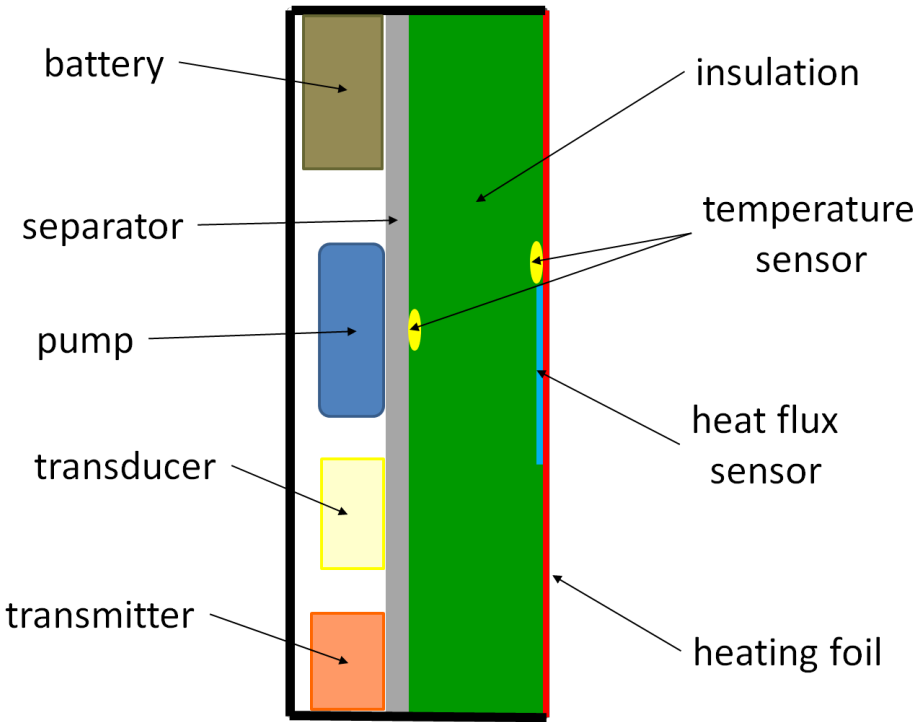

Figure 2: Cross-section of a half-shell of the U_g-value sensor (the glazing will be on the right). Both half-shells are identical.

Not shown in Figure 2 are the suction cups - placed in the four corners of the heating layer - that allow a quick and easy mounting of the half-shells.

2.3 Sensor control

The measurements can be controlled by the analysis and measurement software. At first, the thickness of the panes and the gap has to be determined with an accuracy of ± 0.1 mm. This can be done e.g. with the GlassBuddy® [3]. Afterwards, the sensor half-shells are put onto the glazing and the measurement is started. Dependent upon the glass surface temperatures, the passive mode (a) or the active mode (b) will be used. After an adequate measurement time (typically 10 minutes with double glazing and 20 minutes with triple glazing) the measurement is stopped and the analysis can be started. The software calculates the heat transmission coefficient of the glazing and gives a U_g-value of the glazing that is directly comparable to the DIN-value by adjusting the results to standardized conditions. This means, that a roof glazing with an U_g-value of 1.1 W/(m^{2}K) that has an effective U_g-value of 1.3 W/(m^{2}K) due to the inclination and the temperature conditions, will be measured as 1.1 W/(m^{2}K).

2.4 Sensor prototype

After successful laboratory tests with self-made sensors, a first prototype was built by the company Netzsch (see Figure 3). The prototype contains all the components that most probably will be used later on in the commercial product. With this prototype, a sensor that was very close to the intended commercial product could be tested.

Figure 3: First prototype of the U_g-value sensor.

3. Results

3.1 Validation measurements

First tests were carried out in the laboratory under defined conditions. The samples were double and triple glazing with variations in glass thickness, spacer distance, gas filling, and low-e-coating, but all had known U_g-values. They were measured with the prototype at room temperature and had no temperature difference, so the active mode (b) was used. Some of the samples were measured in an inclined position like in roof windows. A second set of tests followed with samples under temperature difference. These were varying kinds of double glazing that were installed in our institute building as windows and doors. Here, in addition to the active mode (b) the passive mode (a) was tested. Typical measurement times were 10 minutes for double and 20 minutes for triple glazing. The results of the measurements are depicted in Figure 4.

The measured data of the U_g-value correspond very well with the standardized values. The error bars in Figure 4 represent the measuring range in case of repetition measurements. As can be seen, almost all measurements lie within the project goal for the range of accuracy which is given by the green area (± 10% or ± 0.1 W/(m^{2}K), whichever is higher). The error bars show that the reproducibility also is very good.

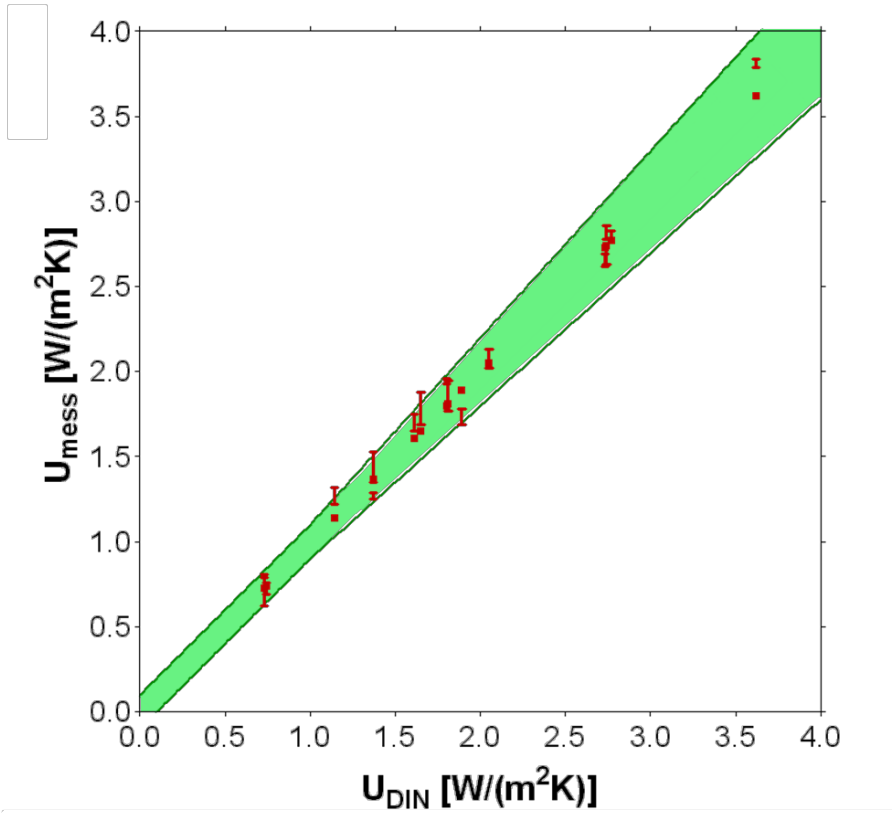

Figure 4: Comparison of U_g-values measured with the prototype compared to standardized values. The error bars represent the range of the measured values and the green area is the project goal for the range of accuracy.

3.2 Field test

After successful validation of the sensor with known samples, a field test with unknown glazing was performed. Here, only the assembly of the measured glazing was known, but not the actual U_g-value. In some cases, the U_g-value at the time of production given by the producer was available. Table 1 gives an overview of the measured glazing with their U_g-values calculated according to standards.

Table 1: assembly and properties of the glazing investigated during the field test.

no.	assembly	year of manufacture	inclination	$U_{g,DIN}$ [W/(m²K)]
1	6/10/4 (air)	1982	|	3,0
2	6/10/4 (air)	1982	|	3,0
3	4/14/*4 (argon, low-e)	2010	|	1,1
4	4/14/*4 (argon, low-e)	2010	|	1,1
5	*6*/14/6 (argon, low-e)	2010	|	1,2
6	6LSG/11/*6 (krypton, low-e)	2005	/	1,1
7	6LSG/11/*6 (krypton, low-e)	2005	/	1,1
8	4*/8/4/8/*4 (argon, low-e)	2011	/	0,8
9	4*/12/4/12/*4 (argon, low-e)	2011	|	0,7
10	4*/12/4/12/*4 (argon, low-e)	2011	|	0,7

The field test should give first feedback about the handling and convenience of the sensor as well as about its accuracy under “real conditions”. Therefore, all the measurements were performed in “real” buildings like the offices of the Project Management Jülich – the control center for this project on behalf of the German Federal Ministry – and some private apartments of our employees or their willing neighbours. The field test took place in late winter and early spring 2013 with corresponding weather conditions like moderate to cold outer air temperatures and sometimes direct solar radiation on the glazing to be measured (Figure 5). Both measuring principles, passive mode (a) and active mode (b) were used. The results are depicted in Figure 6.

Figure 5: Field test of the prototype with provisional anti-fall guard on façade glazing (left) and on roof glazing (right).

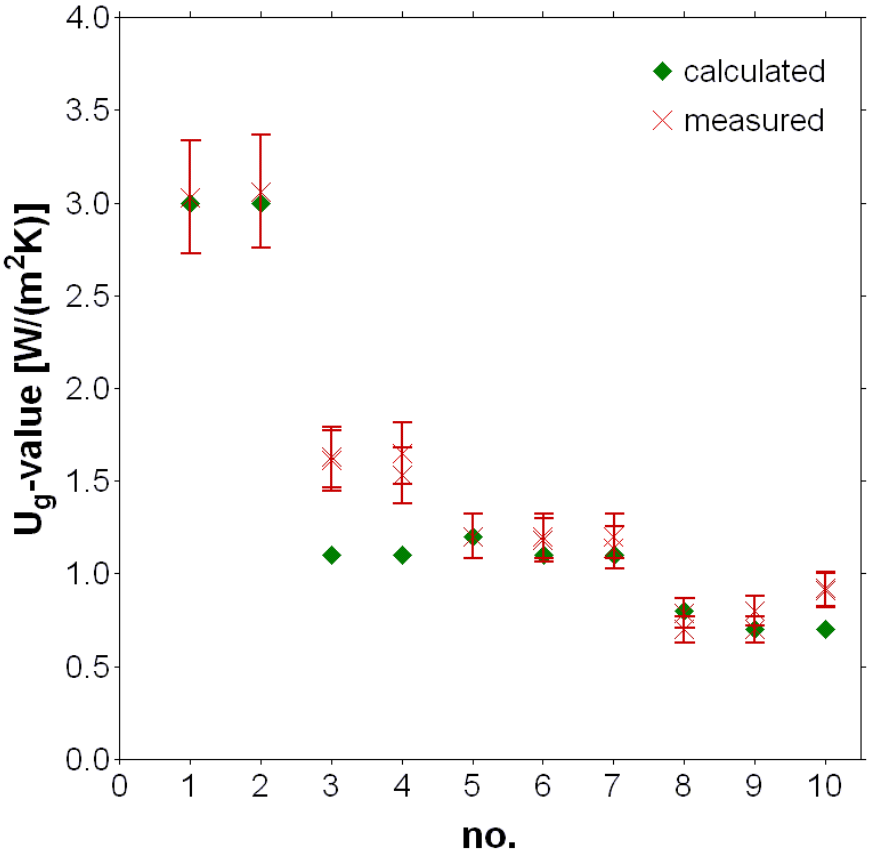

Figure 6: U_g-values of the field test glazing measured with the prototype and calculated according to standards. The error bars represent the accuracy of the prototype (± 10% or ± 0.1 W/(m^{2}K), whichever is higher) according to the validation measurements.

The results in Figure 6 show a very good agreement for the old glazing no. 1 and 2 (no low-e-coating and air filling) as well as for many of the newer glazing (with low-e-coating and argon or krypton filling). However, there are significant differences for glazing no. 3, 4, and 10. It must be noted, that all the measured values for glazing no. 3, 4, and 10 resulted in higher U_g-values than the calculated data, which is more plausible than lower values would be. In addition, the repetition measurements confirmed these higher U_g-values. Therefore, the measured values seem more reliable to us than the calculated values, even if this leads to the conclusion that the thermal performance of glazing no. 3, 4, and 10 deviates from the calculated value. There's a good chance, that the actual U_g-values of glazing no. 3 and 4 will be surveyed in the near future. If this happens, we will have the opportunity to compare our measurement results with reliable data.

4. Conclusions and Outlook

A new mobile sensor for measuring the U_g-value of glazing on-site was developed and a first prototype of the sensor was tested. The prototype allows short measuring times of about 10 minutes for double and 20 minutes for triple glazing. During validation measurements, we found an accuracy of about ± 10% or ± 0.1 W/(m^{2}K), whichever is higher. The sensor covers the whole range of U_g-values between 0.5 W/(m^{2}K) and 4 W/(m^{2}K), which is typical for glazing found in the building stock, and it is suitable for façade glazing as well as inclined glazing like in roof windows.

The sensor is an efficient tool to determine the thermal performance of unknown glazing on-site, e.g. when evaluating the energy savings potential of window refurbishment. It can also be used to check the current state of glazing, e.g. when there are doubts about the insulation value, and it gives a reliable indication if further measures should be initiated.

One open point is the influence of the weather conditions on the accuracy of the measurements. Even if the prototype worked very well in direct solar radiation during the field test, conditions that favour an inhomogeneous temperature distribution across the glazing like strong direct solar radiation especially in combination with partly shading of the glazing could be problematic. This will be investigated in further tests.

If the tests are successful, the sensor will be commercialized by the company Netzsch under the label $U_g$lass. The product should be available end of this year.

Summary

The assessment of environmental performances of buildings is now commonly based on a life cycle approach. The current studies highlight the problem related to the robustness and reliability of LCA. Calculation of building LCA conveys uncertainties due to: calculation model, data used into calculation and LCA user's level of practice. This study only concerns by the uncertainties related to the data used for calculation. The aim of this study is to identify the building materials and elements which have the highest influences on the environmental performance of single houses and those having the highest contribution to the uncertainties of the environmental performances of houses. A statistical method is used, it consists in two analyses: a sensitivity analysis and an uncertainty analysis. This methodology is applied to 16 single houses with different structure typologies and different location in France. Four different groups of building materials and elements are identified: materials with small sensitivity and small uncertainty; materials with small sensitivity but large uncertainty; materials with large sensitivity but small uncertainty and materials with large sensitivity and large uncertainty. This study can be useful for the stakeholders, on showing the key parameters on which they must pay attention during the designing phase of the in the project.

Keywords: Buildings life cycle assessment, sensitivity and uncertainty analyses

1. Introduction

Environmental harmful activities differ from one sector to another, but it is well known that one of the biggest contribution related to GHG emissions, ozone depletion, energy demand, destruction of natural habitats, etc., are due to the building sector [1]. Urgent changes are then required relating the energy saving, production and application of materials, use of renewable resources and to reuse, recycling of building materials and minimisation of GHG emissions [2]. However to be able to focus on the pertinent and most sensitive aspects of the building sector, it is fundamental to accurately quantify which part of the life cycle of which element has the main contribution to the environmental impacts. To do so, and since more than 30 years, scientific community have developed and validate life cycle assessment (LCA) methodology [3]. Considering ISO 14040, LCA methodology consists in four steps: goal and scope definition, creating the life-cycle inventory, assessing the environmental loads and interpretation of results [4]. The reliability of LCA in building sector as in the other industrial sectors is affected by the uncertainties and variability related to the data used for calculation, the methodology used and the user's knowledge. This study focuses only in the uncertainties and variability of the database used for calculation. The reliability and the robustness of results in building sector are more complex than the other industrial sectors, not only due to the complexity of buildings but also due to their very long service life which makes this sector unique in comparison to other complex products. This induces large difficulties on how to assess the whole life-cycle of building due to the facts that the energy during the use phase as well as its nature will drastically change during the 50 years of its use. Furthermore, the service life of building materials and elements can be lower than the building itself due to factors such as failure, dissatisfaction or change in consumer needs. Finally, a building project is a multi-stakeholders project which induces modifications all along the construction phase and uncertainties on the exact amount of materials used. Uncertainties in the environmental product declaration (EPD) are also controlled by the same type of uncertainties than for other industrial sectors: environmental database quality, technological variation between materials' production plant, distance of transportation, different methods used for the demolition of materials etc., [5]. Due to these uncertainties and variability of database the results of LCA in building sector are not robust and reliable.

Two main problems require urgent solutions: the minimisation of the environmental impacts of building sector and the minimisation of the uncertainties of the database used for the calculation of building performances. To do so, we need first to quantify the uncertainties and variability of data used for calculation and then identifying the biggest contributors in LCA results. The environmental performances of buildings are calculated by the decomposition of the project in building materials and elements. The elements such are the windows, solar water heater etc., were preferred to be treated as building element and not decomposed in materials as their lifetime is defined at that scale. This choice can also be justified by SETAC who recommend paying attention to reference flows and not necessarily distinguish every materials [6]. The key purpose of our study is the identification of key data and assumptions that have the highest influence on the result. The methodology used is based on a statistical method and includes both sensitivity and uncertainty analysis. Actually, a parameter which has a small uncertainty but large uncertainty may be just important as a parameter with larger sensitivity but smaller uncertainty.

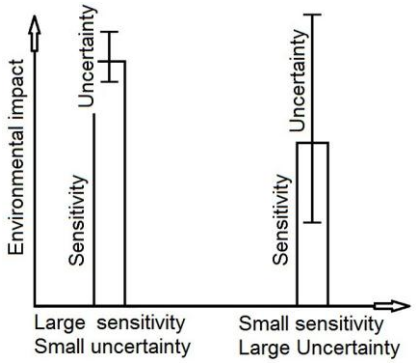

Fig1: The difference between an input with large sensitivity but small uncertainty and an input with small sensitivity but large uncertainty

Based on the relative contribution of the environmental impacts of materials to the environmental impacts of buildings (sensitivity analysis) and the relative contributions of the uncertainties of environmental impacts of materials to the uncertainties of the environmental impacts of buildings (uncertainty analysis) we have identified four different groups:

- Group 1: building materials and elements that have a small contribution to the environmental performances of buildings (small sensitivity) and a small contribution to the uncertainties of these performances (small uncertainty);
- Group 2: building materials and elements that have a small contribution to the environmental performances of buildings (small sensitivity) but a great contribution to the uncertainties of these performances (large uncertainty);
- Group 3: building materials and elements that have a great contribution to the environmental performances of buildings (large sensitivity) but a small contribution to the uncertainties of these performances (small uncertainty);
- Group 4: building materials and elements that have a great contribution to the environmental performances of buildings (large sensitivity) and a great contribution to the uncertainties of these performances (large uncertainty).

In fig. 2 we have summarize the four different groups of building materials and elements.

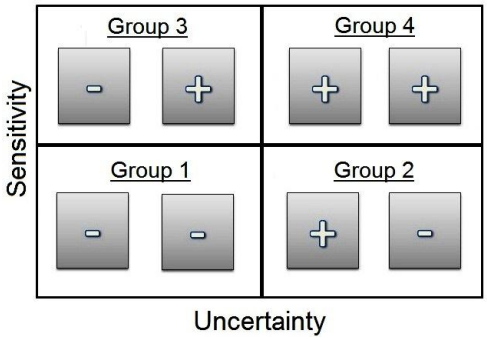

Fig 2: The four groups identified in function of sensitivity and uncertainty ("+" indicate 'large', and "–" indicate "small')

The description of the methodology is presented in the next section. Once the methodology is described it is applied in 16 single houses.

2. Methodology

2.1 Contribution analysis

A possible solution is the identification of materials which have the highest influence on the environmental performances of buildings as well as the identification of materials which have the highest influence on the uncertainties of the environmental performance buildings.
To do so we have to perform the contribution analysis. This consists in a combined sensitivity and uncertainty analysis. The sensitivity analysis is used for the identification of input variables that have large contribution on the output result. The uncertainty analysis is used for the identification of the inputs variables that most influence the uncertainties of the output.

2.1.1 Sensitivity analysis

The sensitivity can be used to simplify data collection and analysis without compromising the robustness of a result or to identify crucial data that must be thoroughly investigated. A possible definition of normalized sensitivity is the ratio of the relative change in output induced by a unit relative change in input. For an output variable *z* which depends on *n* inputs variables $x_1,x_2,\ldots,x_i,\ldots,x_n$ and their dependence which is expressed by a function *f* the normalised sensitivity of an inputs x_i is calculated:

$$S\left(x_i\right)=\left(\frac{\partial f}{\partial x_i}\right)_{X^0}\times\frac{x_i^0}{z^0} \quad (1)$$

Where: $X^0=(x_1^0, x_2^0,\ldots, x_i^0,\ldots, x_n^0)$ is the nominal scenario for which the values might be the mean the median or the mode. In our case we have used the mean values. And the z^0 is the nominal output calculated by the equation:

$$z^0=f\left(X^0\right) \quad (2)$$

In the special case where the output *z* is a sum of inputs x_i the equation of normalized sensitivity will have the form:

$$S\left(x_i\right)=\frac{x_i^0}{z^0} \quad (3)$$

2.1.2 Uncertainty analysis

Parallel to the sensitivity analysis we can perform an uncertainty analysis. For a random variable $X=(x_1;x_2;\ldots x_i,\ldots x_n)$, with a relation between the real value (in this study, we used the mean value), the input value that we have measured and its uncertainty can be written as: $x_i=x_{mean}\pm\varepsilon_{x_i}$. The degree of uncertainty is expressed by its standard deviation:

$$\sigma_{x_i}=\mathrm{var}\left(x_i\right)=\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}\left(x_i-x_{mean}\right)^2}=\sqrt{\frac{1}{n-1}\sum_{i=1}^{n}\left(\varepsilon_{x_i}\right)^2}=\sigma_{\varepsilon_{x_i}} \quad (4)$$

Standard deviation for a random variable measures the spread of the uncertainties in inputs variables [7]. Let consider an output *z* which depends on *n* inputs variables $x_1,x_2,\ldots,x_i,\ldots,x_n$ and their dependence which is expressed by a function *f*. After Hoxha *et al* [8] the relative contribution of uncertainties of each input variable to the uncertainty of output z can be expressed by the equation:

$$RC_{M2}=\frac{\Delta x_i}{\Delta z}\times 100 \quad (5)$$

where: $\Delta z=\sum_{i=1}^{n}\sigma_{x_i}\times\left|\left(\frac{\partial f}{\partial x_i}\right)_{X^0}\right|$, and $\Delta x=\sigma_{x_i}\times\left|\left(\frac{\partial f}{\partial x_i}\right)_{X^0}\right|$

2.2 Life cycle assessment of building

From the European Standard EN-15978 [9] the environmental performances of buildings are function of: energy and water used during the use phase of buildings and environmental performances of building materials and elements cotribution. In our study we will consider only the building materials and elements contributor. For a decomposition of the building in *c* building materials and elements the environmental performances of building I_f can be calculated as:

$$I_f=\sum_{i=1}^{c}I_{f,i} \quad (6)$$

The environmental performances of building materials $I_{f,i}$ are function of three key data which are: the environmental impact declaration (EPD), the number of use of material during the service life of the building and the quantity of material used during the construction. The equation proposed for the evaluation of $I_{f,i}$ is:

$$I_{f,i}=m_i\times k_{f,i}\times n_i \quad (7)$$

where: m_i is the mass of material *i* used during the service life of building;
$k_{f,i}$ is the environmental impact for the impact category *f* of life cycle of one unit mass of the building material *I*;
n_i is the number of time that the material I has to be used during the service life of the building.
From Aktas and Bilec [10], n_i is calculated by equation:

$$n_i = \frac{LB}{LM_i} \qquad \forall n_i \in R \tag{8}$$

LB is the service life of the building and LM_i is the service life of material.

2.3 Contribution analysis applied to building LCA

When contribution analysis is applied to the previous equation describing the environmental performances of buildings (equation 6), the partial derivative (simple sensitivity coefficients) of the different building material or element is equal to 1:

$$\frac{\partial I_f}{\partial I_{f,i}} = 1 \quad \forall i \in [1, c] \tag{9}$$

The equations of normalized sensitivity of materials have the form of:

$$S\left(I_{f,1}\right) = \frac{I^0_{f,1}}{I^0_f};\ \cdots\ S\left(I_{f,i}\right) = \frac{I^0_{f,i}}{I^0_f};\ \cdots\ S\left(I_{f,c}\right) = \frac{I^0_{f,c}}{I^0_f} \tag{10}$$

where:

$$I^0_{f,i} = m^0_i \times k^0_{f,i} \times n^0_i \tag{11}$$

is the nominal value of environmental performance of material *i* calculated by the nominal value of mass, impact coefficient and number of use of material during the service life of building. The nominal value are here considered as the mean values.

$$I^0_f = \sum\nolimits_{i=1}^{c} I^0_{f,i} \tag{12}$$

is the sum of nominal value of environmental performances of materials.

In our case the physical concept of the normalized sensitivity coefficients are that they measure the relative contribution of material impact to the building impact.

Also we have to perform the uncertainty analysis for a complete contribution analysis. The relative contributor coefficients after the equation (5) have the form:

$$RC_{M2}\left(I_{f,1}\right) = \frac{\sigma_{I_{f,1}}}{\Delta I_f};\ \cdots\ RC_{M2}\left(I_{f,i}\right) = \frac{\sigma_{I_{f,i}}}{\Delta I_f};\ \cdots\ RC_{M2}\left(I_{f,n}\right) = \frac{\sigma_{I_{f,n}}}{\Delta I_f} \tag{13}$$

Where:

$$\Delta I_f = \sum\nolimits_{i=1}^{c} \sigma_{I_{f,i}} \tag{14}$$

In the next section the methodology is applied in 16 houses.

3. Study

3.1 Presentation of houses case studies

In this study are modelled a sample of 16 French single houses. The surface are of these houses varies between 91 m^2 to 298 m^2, and they present more than 2400 m^2. They have different types of structure (reinforcing concrete structure, wood structure); different types of wall (block concrete, clay brick, cellular concrete block, wood, etc.,); different types of thermo insulation (rock wool, glass wool, wood wool, etc.,); different types of tiles (clay, concrete, slate); etc.

3.2 LCA data and uncertainties sources

The environmental impact of each building material is based on values from the French environmental products declaration (EPD) available in INIES database [11]. The variability due to these inputs variables comes from the fact that for the same material or elements there are different EPDs supplied by different producers. In the case where different EPDs were available, the mean

and standard deviation is calculated, and in the case where only one EPD was available, it isn't consider any types of variability.
The mean for the mass of material is considered that defined in the project and the standard deviation is calculated using a ratio for the coefficient of variation equal to 12% [12] that corresponds approximately ±30% of uncertainty about the mean value. The mean and standard deviation for the number of use of material during the service life of building are calculated using different references. In the table 1 we have presented the data used.

Table 1: Expected lifetime of materials. Mean value and standard deviation are calculated from a number of reference values for each material. Minimum and maximum values are also shown.

4. Results

In the fig 3 are shown the results obtained from the sensitivity analysis and uncertainty analysis of 16 houses. Classification of materials in four groups is done with a cut off of 10%. For the global warming potential indicator are identified four groups of materials in function of their contribution to sensitivity and uncertainty of results.

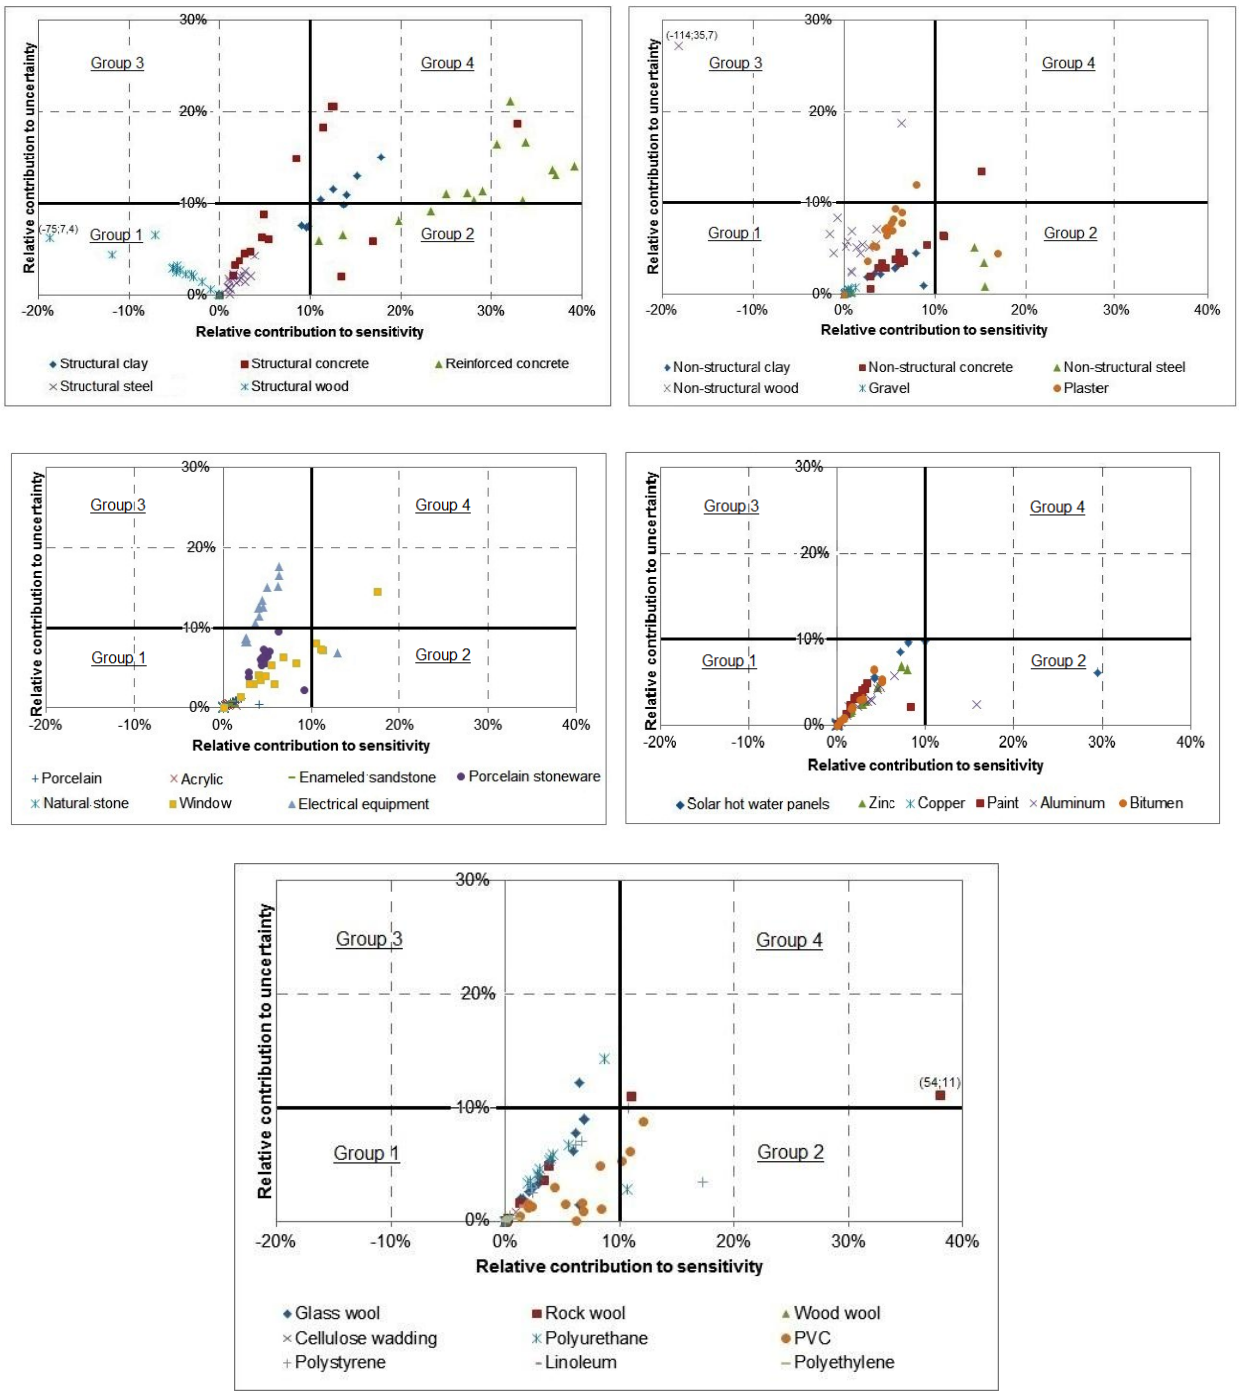

Fig 3: Results obtained of materials and elements for 16 houses

In the figure 4, we have summarize the forth groups of materials classified according the results calculated and presented in figure 3.

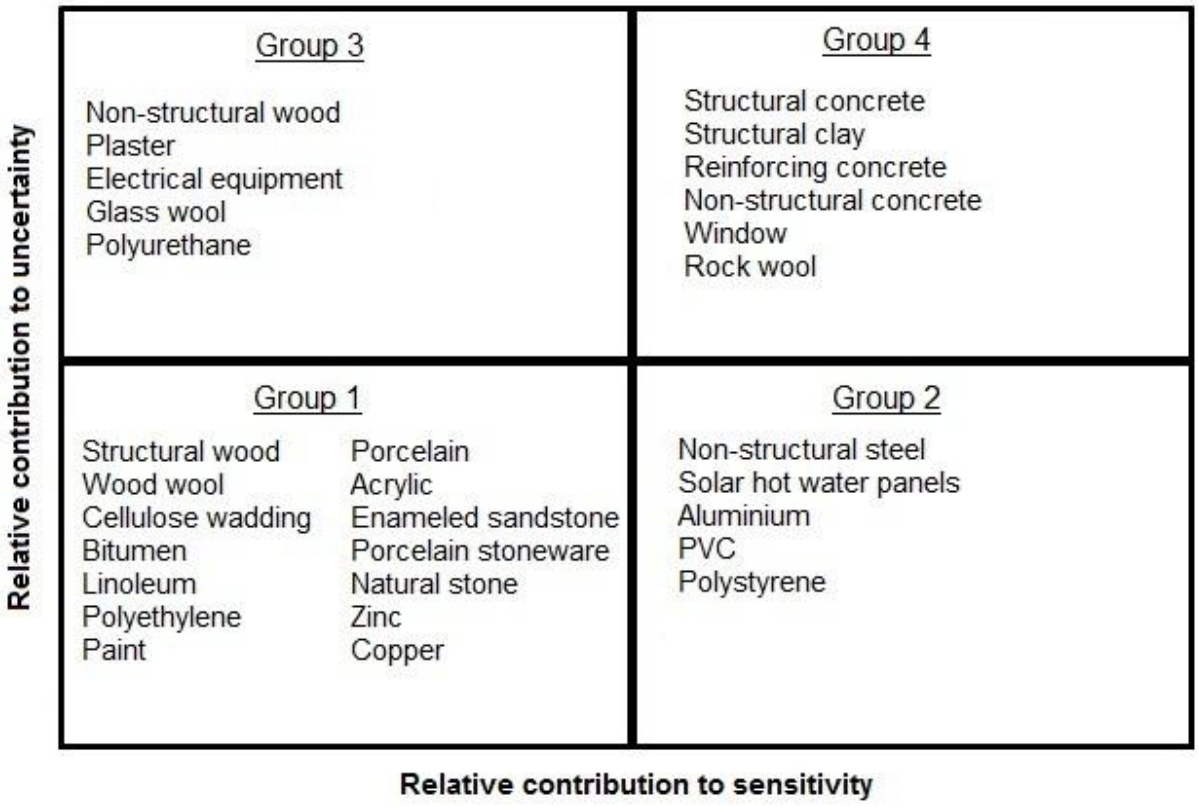

Fig 4: Building materials classified in four groups

5. Discussion

For the global warming potential indicator, the first group of materials with a small sensitivity and a small uncertainty are: non-structural steel, non-structural clay, gravel, linoleum, cellulose wadding, wood wool, polyethylene, porcelain, acrylic, enamelled sandstone, porcelain, stoneware, natural stone, paint. This is the group of materials for which the relative contribution to the impact of houses and its uncertainties can be considered as negligible. In the second group with large sensitivity and small uncertainty, the materials: non-structural steel, pvc, polystyrene, aluminium, solar hot water panels, plaster. These are the materials with a great contribution to the impact of houses, but their uncertainties can be considers as negligible. In the third group of building materials and elements with a small sensitivity but large uncertainties we identified the glass wool, non-structural wood and plaster. These materials have not the greatest contribution to the environmental performances of houses, but their uncertainties influence highly the uncertainties of the environmental performance of houses. Due to their uncertainties the environmental performances of houses aren't robust and reliable. And in the fourth group with large sensitivity and large uncertainty, we identified the materials such as: reinforcing concrete, structural clay, structural concrete, non-structural concrete and rock wool. This is the group where the materials have a great contribution to the environmental performance of houses as well as to the uncertainties on the environmental performance of houses. A special attention is recommended for the materials of the fourth group. We have accepted a largest possible cut off value of 10%. This can be a discussion point, due to the fact that the classification of materials will change for another value. Also this can be improved, but whatever the cut off value the result presented for the 16 houses will not change and the materials of fourth group will be classified always as the most critical data.

6. Conclusion and Perspectives

This paper is focused on the calculation of contribution of the building materials to the single

houses LCA, and the contribution of their uncertainties to the uncertainty of the single houses LCA. To do so, the methodology used is based on sensitivity and uncertainty analyses which identify the parameters having small contribution to the output and small contribution to the uncertainty of output, the parameters having small contribution to the output and large contribution to the uncertainty of output, the parameters having large contribution to the output and small contribution to the uncertainty of the output and the parameters having large contribution to the output and large contribution to the uncertainty. Previous studies have been working with Monte Carlo techniques that are relatively computationally heavy to conduct and time consuming. Our methodology is much simpler and when applied to 16 single houses, still allows the distinction of four groups of building. This study can be useful for stakeholders, on presenting the materials which affect the robustness of single houses LCA such as the plaster and material that have most negative impact to the environment such as the rock wool. In this study we have identified the four groups of materials, but further work is needed, in particular considering the cut off value.
A possible perspective of this study is the minimisation of the uncertainties of the materials in the third and fourth group. Another is the research of factors that minimize the environmental performances of materials of second and fourth group.

Short Summary

Three strategies are needed for the implementation of the ambitious 2000-Watt Society sustainability programme: efficiency, consistency and sufficiency. The 'SIA Energy Efficiency Path' [1] is an instrument that demonstrates that the set goals can be achieved by efficiency and the use of renewable energy sources. Standard values are assumed for space consumption and user behaviour. Fundamental information for sufficiency in the use of energy is still not available.
Sufficiency entails that demands be moderate and restrained. Although technical measures are the most important factors in the field of efficiency and consistency, man and his attitudes and actions are the central point for sufficiency. In this study, the fundamentals for quantifying the sufficiency potential of residential activities will be developed. In this case, we assume moderate sufficiency.

The most important parameters are living space, user behaviour (warm water consumption, electrical devices) and day-to-day mobility (distance, method of transport). The potential for sufficiency is surprisingly high: compared with today's typical behaviour, moderate sufficiency attitudes could almost halve both primary energy consumption and greenhouse gas emissions.

Keywords: sufficiency, eco-sufficiency, residential buildings, rebound effect, user behaviour, living space, 2000-Watt Society, SIA Energy Efficiency Path

1. Context

In Switzerland the energy demands of new buildings by square metre have fallen sharply owing to advanced standards and regulations, and even the renewal rate of existing buildings is increasing slowly. In parallel, however, in the field of buildings, a significant part of the gains in efficiency is offset by elevated consumption. The living space per person is rising continuously, which has a negative effect on total energy consumption and the emissions of greenhouse gases. This development is driven by the still growing prosperity in Switzerland. Starting from the assumption that this positive trend will continue in the future, it is at least questionable whether the turnaround in energy policy with new technologies and efficiency measures alone is possible.
The issue is that the goals are ambitious: The 2050 energy strategy of the federal state simultaneously pursues the phasing out of nuclear power and the reduction of greenhouse emissions. The city of Zurich decided in a referendum to implement the 2000-Watt Society, which entails ambitious reductions in non-renewable primary energy consumption and greenhouse gases.

Although the parameters and the influence of different measures are well known in the area of energy efficiency, the basics are still missing in the area of sufficiency.

2. Scope: The Potential of Sufficiency

The 'SIA Energy Efficiency Path' [1] is an instrument for implementing the stage targets of the ambitious sustainability programme of the 2000-Watt Society in the building sector. It focuses on the implementation of technical solutions by means of efficiency and consistency (use of renewable energies, renewable primary products and closed material cycles).
What remains hidden is user behaviour, which has a decisive influence on the achievement of the objectives.
The 'SIA Energy Efficiency Path' is based on a standardised square-metre consumption of living space per person and standardised user behaviour. Deviations from these standard assumptions have a very large impact on effective energy consumption and the personal targets of the 2000-Watt Society.

In this study, the potential for reducing primary energy and greenhouse gas emissions should be demonstrated; these can be determined by measures of sufficiency and which actors are responsible for them. New construction and refurbishment of residential buildings are considered.

3. Methods

The presented study clarifies and quantifies the potential of sufficiency in the areas of construction (embodied energy), operation and location-based day-to-day mobility.
The methodological basis is a total energy analysis, as elaborated on in the framework of the 'SIA Energy Efficiency Path', which also establishes the methodological link to the 2000-Watt Society.
The 'SIA Energy Efficiency Path' shows how the building and construction sector can reach the milestones of the 2000-Watt-Society programme by 2050. Crucial aspects form the primary energy consumption and greenhouse gas emissions that affect the climate. The difference between the energy values for 2005 (total energy according to official statistics) and the specified goal for 2050 produces a reduction factor of 0.55 for primary energy consumption and 0.34 for greenhouse gas emissions.

This study set up several case studies of different consumptions of living space per person, including variations in user behaviour during building operation and in mobility behaviour. The impact on primary energy consumption and greenhouse gas emissions was determined. Although this study’s title addresses sufficiency, the study also examines the potential of the opposite, namely wasteful behaviour.

In the area of construction, energy savings have been calculated with the methodology according to the SIA fact sheet 'Embodied Energy of Buildings' [2].
In the area of operation in particular, evaluation of the typical power consumption in different households leads to a differentiated picture of the potential, which can be assessed by user behaviour.
In the area of mobility, quantification is possible because of the methodology developed according to the SIA factsheet 'Mobility - Energy Demand depending on the Building Site' [3].

It was important to clarify which type of consumption needed to be calculated relative to the energy-related floor area and which type needed to be considered in relation to the people.

The calculations assume an efficient residential building (target values according to the 'SIA Energy Efficiency Path'), efficient equipment and efficient vehicles ('Fleet 2050' according to [3]).

4. Results

The potential for the reduction of primary energy consumption and greenhouse gas emissions by moderate sufficiency behaviour is considerable.

4.1 Living Space

The variation in living space per person—i.e., energy-related floor area per person—with a constant energy consumption per capita (a concept of the 2000-Watt Society programme) shows clearly that
less living space per person facilitates the achievement of the targets and more living space per person makes it more difficult. With a one-third reduction in the standard living space per person, primary energy and greenhouse gas emission savings of approximately 15% can be reached. This applies to new buildings and refurbishments.
As an additional option for savings in efficiency and consistency, this potential should not be underestimated.
Reducing the Swiss average energy-related floor area of 60 m2 per person can actually be managed by building owners and administrations such as those who manage non-profit residences (cooperatives, public residences) based on occupancy regulations.

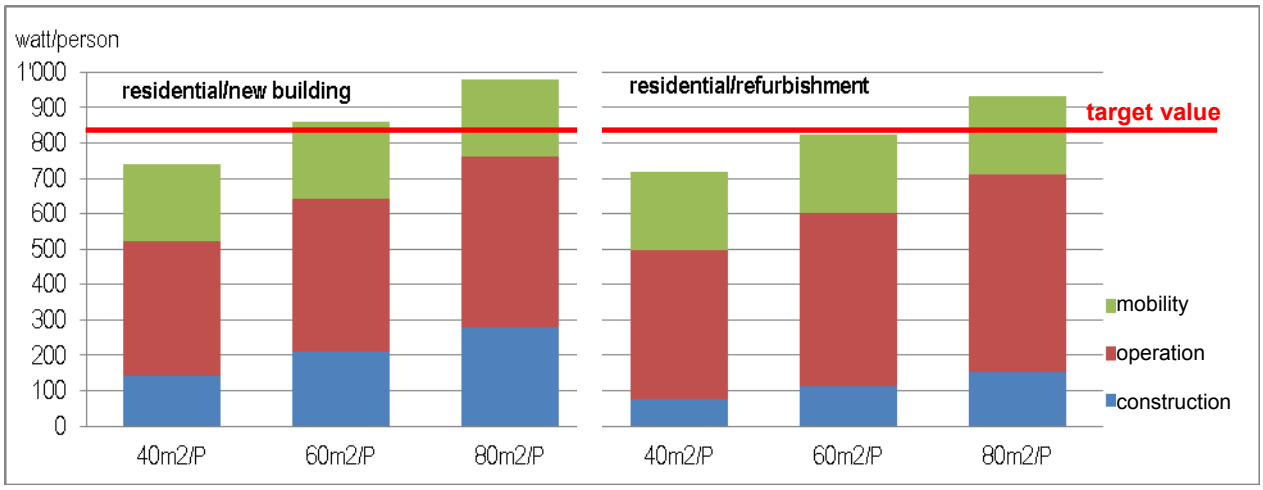

Fig. 1: Influence of variable living space per person on the average annual power consumption of primary non-renewable energy for efficient buildings (data in relation to the energy-related floor area per person), based on average user behaviour.

4.2 User behaviour in the operation of the building

Variable user behaviour during the building's operation changes both the personal and the space-related consumption. In operation, a great deal of potential can be tapped. Residents are challenged in their everyday behaviour and in the procurement of equipment and its use.
Efficiency assumes, then, that the focus of singular energy consumption shifts significantly towards the power-consuming operation of the facilities and lighting.
The greatest influence is that of users on household electricity consumption. The household electricity consumption of a typical two-person household compared with sufficient ones with either moderate or wasteful behaviour reveals an amazing range: the lavish household consumes roughly five times as much electricity as the sufficient one.
In addition, the influence of user behaviour on hot water consumption is substantial.

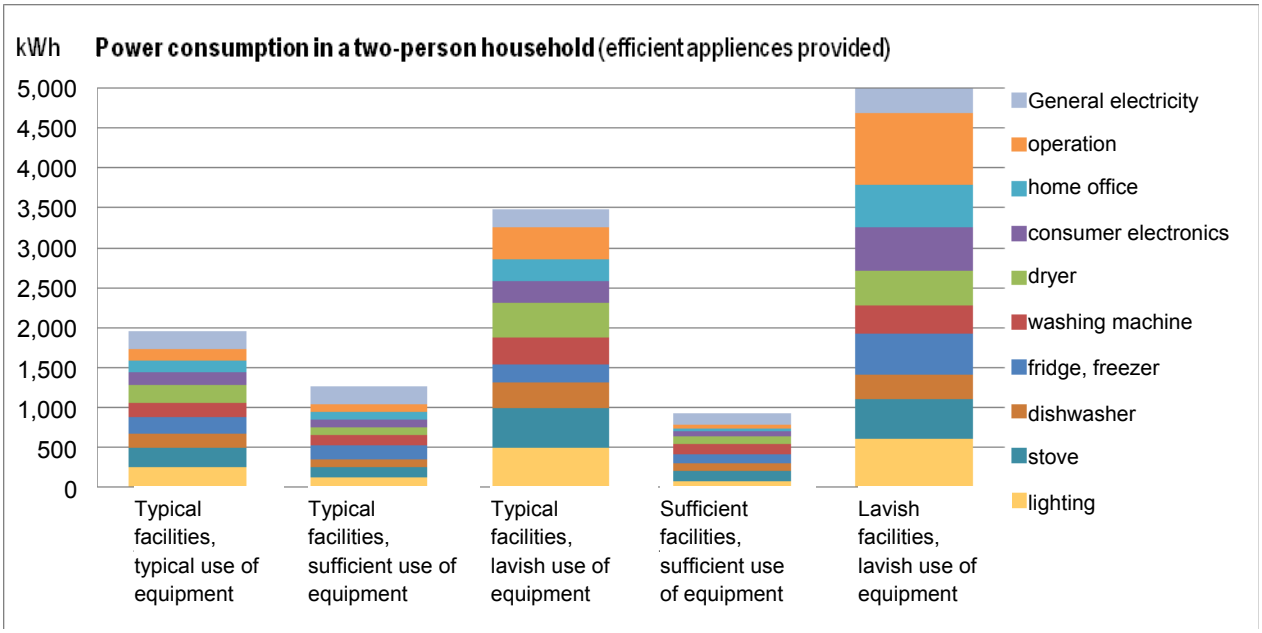

Fig. 2: Household consumption of electricity in a two-person household with 120 m2 energy-related floor area with variable user behaviour and variable facilities.

Two-person household	**typical**	**sufficient**	**lavish**
Examples Facilities			
Cooler / Freezer	Refrigerator (230 litres) with freezing compartment (25 litre)	Refrigerator (200 litres) with freezing compartment (17 litres)	Refrigerator (280 litres) with freezing compartment (24 litres), additional freezer
Home office	1 desktop PC, 1 laptop, 1 printer	1 desktop PC, 1 printer	1 desktop PC, 2 laptop, multifunctional device, laser printer
Use of equipment			
Dishwasher	150 wash cycles per year	80 wash cycles per year	250 wash cycles per year
Washing machine	220 washes per year	150 washes per year	nearly daily
Dryer	2/3 of laundry in dryer	1/3 of laundry in dryer	100% of laundry in dryer

Fig. 2a: Examples of different facilities' respective use of equipment scenarios in a typical, a sufficient and a lavish two-person household.

The potential of sufficiency, however, in almost all areas is smaller than the potential for increased consumption from lavish behaviour. This is partly related to the fact that the underlying values for standard uses are deliberately buried deep in the standards and regulations.
With a moderate attitude toward sufficiency, consumption of primary energy can be decreased in all three areas, construction, operation and mobility, by approximately 18% in new buildings and in refurbished buildings without a significant loss of comfort. The savings in greenhouse gas emis-

sions are smaller, at roughly 10% (this is owing to the relatively low greenhouse gas emissions from today's Swiss electricity mix).
Sufficient user behaviour cannot be prescribed, but incentives can be created. Building owners and governments can have only a very limited influence on user behaviour, such as limiting the initial equipment of the apartments to fewer and smaller devices. Two to four percent in primary energy savings and greenhouse gas emissions over the typical consumption of all three areas of construction, operation and mobility can be achieved through the apartment features provided by building owners and management.

4.3 User mobility behaviour

With variable user mobility behaviour, surprisingly great potential can be tapped. The acceptance of efficiency and sufficiency measures is very different in the field of mobility: what some value as a comfort benefit, such as living in a residential building with reduced parking spaces (with the possibility of travel by foot, by bicycle or by public transport for everyday mobility), for others constitutes an unacceptable sacrifice.
Sufficiency in everyday mobility, particularly in urban areas, is already happening today and is finding a growing number of voluntary followers. The reduced availability of cars, reduced distances in everyday leisure traffic and consistently use of public transport to and from work has halved primary energy consumption and greenhouse gas emissions compared with typical mobility behaviours.

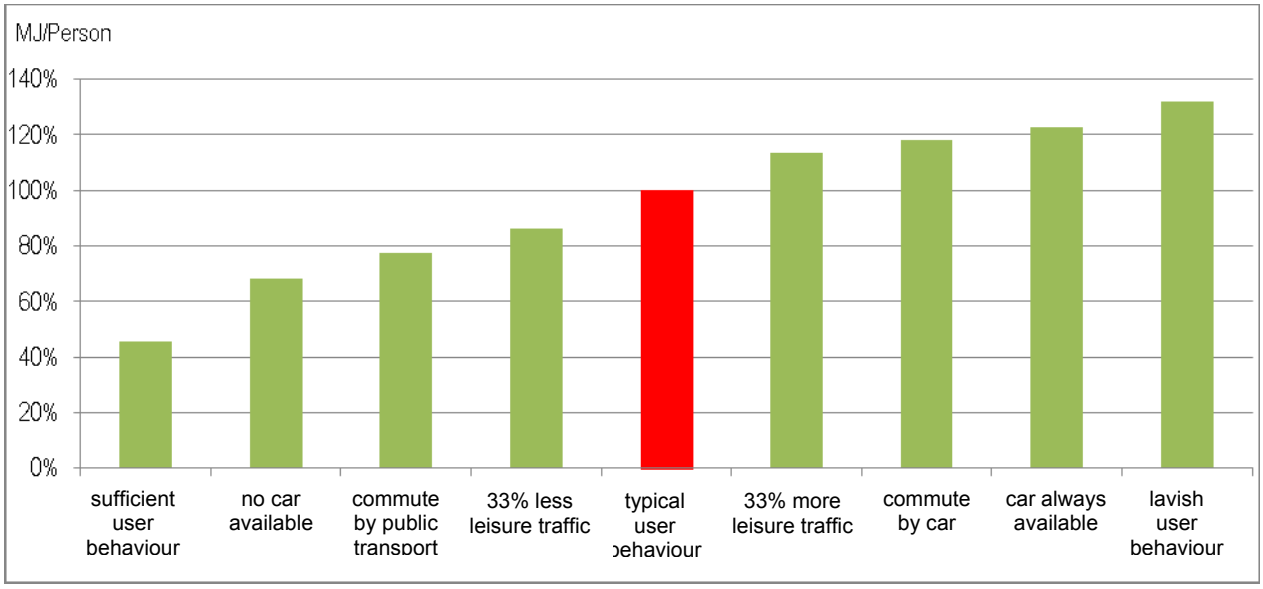

Fig. 3: Influence of sufficient and wasteful user behaviour on the primary consumption of non-renewable energy in everyday mobility in a residential building in the city centre with good public transport.

4.4 Superimposition of areas of influence

If the identified sufficiency areas—variable living space per person, variable user behaviour during operation and mobility—are superimposed, the result is a considerable sufficiency potential:
Even in an efficient building with equipment of the best efficiency rating and energy-efficient cars, moderate sufficiency can reduce primary energy consumption and greenhouse gas emissions by approximately 50%. The achievement of the 2000-Watt Society objective is quite easy to reach with the help of sufficiency. Achieving this goal requires the contribution of all stakeholders, includ-

ing the users of buildings. What is needed is not strong restrictions on the use of goods and services, which are connected to relevant energy consumption, but moderate restraint.

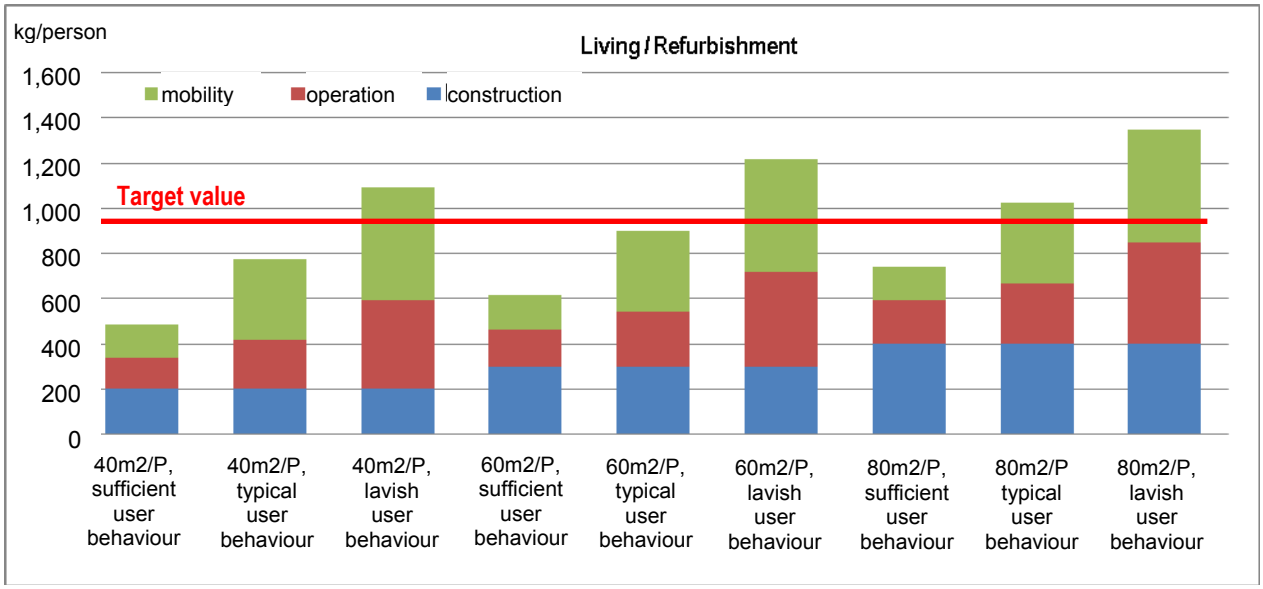

Fig. 4: Greenhouse gas emissions per person with variable living space per person and variable user behaviour in operation and mobility for a refurbished living space in the core of a city with good public transport access and an efficient building with efficient operating facilities, equipment and vehicle fleet.

Whether sufficiency is realised or not lies clearly in the hands of the users. The influence of building owners and authorities is significantly smaller but not insignificant.

Savings from moderate sufficiency by actors (energy efficiency provided) **Initial state according to SIA-Efficiency Path Energy** 100% = target value	 **Living space per person**	 **Heating and warm water, ventilation, light, household appliances ICT+ small appliances**	 **Mobility**
Initial installation building owners	Savings by reducing the standard living space per person by one-third: 15%	Savings from equipment: 2–4%	Savings from equipment: 2–4%
Operation administration			
User (tenant) behaviour		Savings from equipment and user behaviour: 10–18%	Savings from equipment and user behaviour: 12–20%

Fig. 5: Saving potentials for actors engaged in moderate sufficiency. The % figures relate to savings in comparison to typical behaviour and are based on the sum of primary energy and greenhouse gas emissions from the construction, operation and mobility of an efficient building and efficient equipment, operating facilities and vehicle fleet (new construction and renovation).

5. Discussion

Technical measures, as the main focus of efficiency, can be made obligatory by legal specifications, regulatory restrictions on the marketing approval of equipment or the definition of requirements for granting construction projects. They are typically accepted because they do not entail waivers but, on the contrary, a gain in comfort through which the necessary investment can be justified. Sufficiency measures, on the other hand, are usually perceived as a loss of comfort and address the everyday and individual behaviour of residents. Here, legal regulations would have to compete with much larger acceptance problems. Sufficiency can be promoted, for example by occupancy requirements for single housing estates, by economical equipment in dwellings, by waiving parking spaces in single housing estates, by taxes and of course through comprehensive, constantly repeated information.
Implementation measures and motivation are not the focus of this study (see study [5]). When the great potential of sufficiency is to be actually realised, new approaches will be needed in this area (see e.g., [6]).

What this study can offer, however, is a quantification of the potential of moderate sufficiency behaviour, differentiated by actors and differentiated according to individual measures. There are already several examples of how these measures are being implemented voluntarily: The cooperatives in Zurich are currently building car-free housing developments in which the consumption of land per person is clearly reduced compared with the national average. The residential estates that belong the City of Zurich have an average living space per person that is well below what is designated as moderate sufficiency in this study.
Nearly half of all households in the city of Zurich have no car, and even 62% of work trips are made in Zurich by public transport, by bicycle or on foot. This study shows how important the contribution of moderate sufficiency behaviour is for meeting the goals of the 2000-Watt Society concept.

As a digression from this study, the effects of measures of sufficiency in an inefficient building were examined: compared with an efficient building, there is similarly great potential for percentage reduction in inefficient buildings (download of the final report in German [8] www.stadt-zuerich.ch/nachhaltiges-bauen > Fachinformationen).

6. Perspectives

This study has been able to describe moderate sufficiency behaviour for residential buildings and to quantify the different reduction potentials between primary energy and greenhouse gas emissions. This represents an important step towards an objectification of the discussion about sufficiency and its necessary extent. It also allows for an appreciation of the already planned and implemented steps building owners and administrations are taking towards sufficiency. Finally, the study allows users to compare their own behaviour with that of a typical household, a moderately sufficient household and a lavish household.

Crucial for achieving the large reduction potential of sufficiency will be social developments. Sufficiency will establish itself as a desirable and voluntary action only through the personal behaviour of people who are accepted as role models. How such a development can be promoted must be the focus of future work in the broad field of sufficiency.

Short Summary

Is it possible to entirely abolish energy-consuming air conditioning systems and simultaneously maintain a high living quality, a comfortable atmosphere and sufficient natural light in a high density living environment? To find answers to this question, the paper will use the completed case study “The MET” in Bangkok designed by WOHA Architects Singapore. The possibilities of abolishing a/c, will appear in building analyses, interviews with experts and conclusions from detected (measured) acoustic decibel, temperature and wind speed. The substantial questions are: Which existing knowledge and which architectural strategies must be combined and modified to create the optimal system in respect to building energy consumption and low carbon sustainability? What is their impact in terms of architectural design? How will these conditions influence the building typologies, floor plans and detailed openings in housing construction?
The paper will clarify the challenges in the design processes to realize those typologies, façade structures and windows details in tropical conditions.
This paper is part of the dissertation by this author and focuses as its central theme, how the design of a building and façade structures can affect good living quality and interior climate in tropical and subtropical regions without the use of a/c.

Keywords: Low Energy, Residential High Rises, Air-Conditioning, Living Comfort, Energy-Consumption, The MET WOHA Architects, Opening Requirements, Cross Ventilation, Floor Plan Configuration, Façade Structures, Building Typologies.

1. Introduction

This field survey investigates whether a pleasant living comfort with natural ventilation and without usage of air conditioning is possible. The hottest climatic period (April) was selected as research period, in order to determine the worst case or the most extreme and serious condition. There is air conditioning for each residential unit. However, one can assume that when utilizing the building concept the air conditioning might not be necessary. The appropriation of air conditioning meets the comfort requirements of the clients, the wealthy residents, and accounts for the standardization of air conditioning for every apartment in tropical regions. It is the purpose of this proposal to identify whether a comfortable living environment can actually be facilitated without the use of air conditioning.

2. Residential High Rise Project The MET

The MET is a pilot project, not because of its height amounting to 266 meters and thus constituting the tallest residential high rise in Thailand, but because it represents a completely new high rise type. The Singapore architects WOHA have developed a specific solution for a dense construction with natural ventilation in the tropics. “Most tropical high-rise housing in developing countries replicate cold-climate models, with sealed facades and total reliance on air-conditioning and mechani-

cal Ventilation. However, in the tropics light winds, year-round balmy weather, constant temperatures and high humidity make outdoor living desirable. In addition, the environmental conditions high-up in dense and populated Asian cities are preferable to those near the ground – there is more privacy, better views, lower humidity, stronger breezes, better security, less noise and less dust."[1] The project has won numerous awards and prizes. At last it was nominated in May 2013 for the Aga Khan Award for Architecture. The porous structure of the building enables the natural ventilation of the 370 residential units. The building consists of three residential towers, the interspaces are open and therefore, a good ventilation of the overall structure is possible (fig. 1). These basic structures are merely connected via bridges and walkways which facilitate the building with half-public communication zones and private recreational areas with green surfaces (fig. 3).
Moreover, the exposure is optimized. None of the rooms requires artificial lighting throughout the day. Only the kitchen in its closed version (e.g. floor type 29 in the middle part of the house) requires artificial exposure. However, the partitions are not supporting and can therefore be removed upon request.
Vertical cultivation and high-rise gardens provide additional conditioning of fresh air (fig. 2).

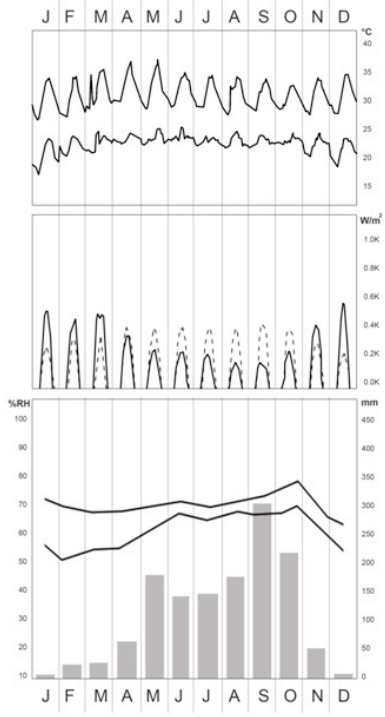
3.0 Climate Conditions Bangkok

The climate in Bangkok is warm and has a relatively high humidity. On principle, the climate can be distinguished according to three seasons. Summer, winter and the rains. The latter is triggered by the monsoon climate. The urban island-heat-effect causes a temperature increase and prevents excessive cooling during the night. Within these night hours the temperature in Bangkok therefore declines by 5 - 10 degrees Celsius. The prevailing climate urges people to use air conditioning throughout the whole year. The Bangkok residents actuate these aerations particularly during the summer months (March to July) (fig. 4)



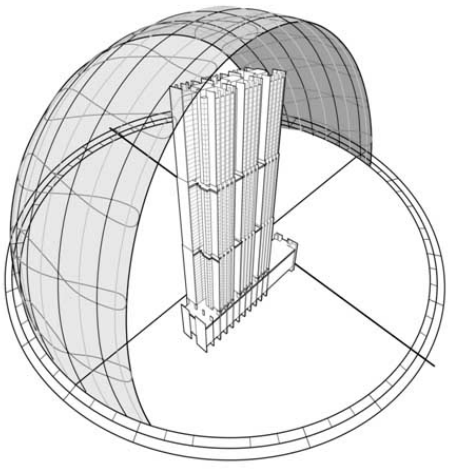


Fig. 3. Integration of Community Decks, Fig.4. Weather Bangkok © Dr. Nirmal Kishnani (1,2)

3.1 Wind direction and solar altitude

At this location the major wind direction is predominantly oriented from north. The building is transverse to this wind direction and can therefore ideally absorb the wind within its porous structure and openings (fig. 6).
The static basic structure of the building is based upon a supporting construction, which is arranged in north-south direction. Thus, these protruding features function not only as essential architectural design elements but principally serve as shields for window openings, because the building was situated parallel to the course of the sun (east-west) (fig. 5).

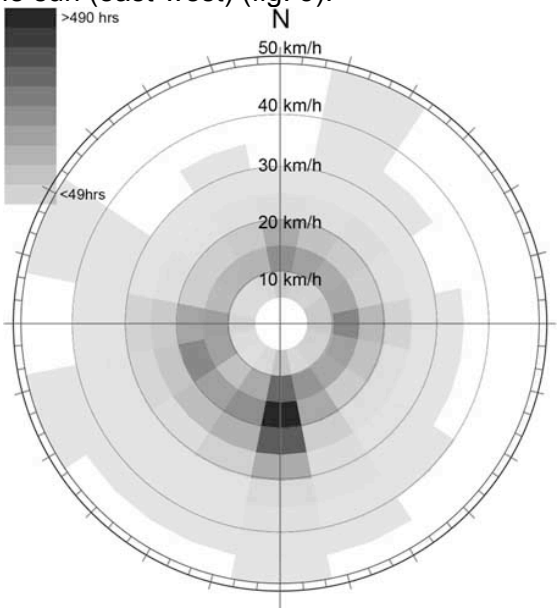

Fig. 5. Sun Course over the MET, Fig. 6. Wind Direction and Wind Speed © Nirmal Kishnani (3,4)

3.2 Wind currents

Wind currents exist in vertical and horizontal direction. The horizontal weather winds produce wind pressure and suction. They collide with vertical wind currents and their intensity is therefore mitigated. Thus, both wind currents provide for a variety of air movements and the wind can ideally infiltrate the apartments. The vertical wind currents originate from temperature and pressure differences and take place within the building structure and between the residential towers (fig. 7 and 8). This uplift that triggers various air circulations is utilized by swallows that can continuously be watched around the building. With their enclosed basic structures and flat building facade surfaces other high rise buildings cause undesired one-sided and strong air currents. These lead to extreme wind blows that are uncomfortable for pedestrians and that are also avoided by gliders at a greater height.

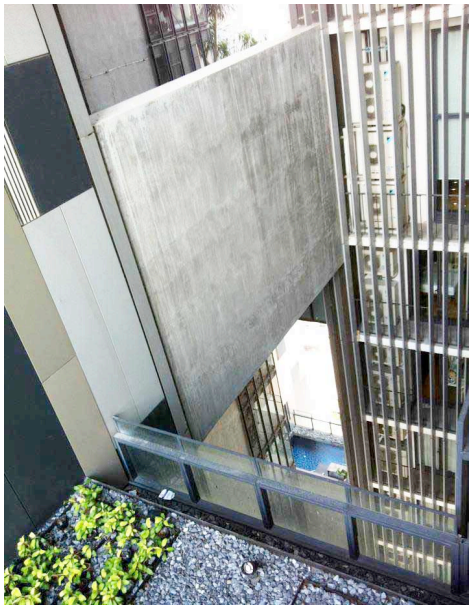

Fig. 7. and 8. Building Structure the MET ; © Ferdinand Oswald; Photo: Ferdinand Oswald

3.3 Wind speeds

Due to Bangkok‘s vicinity to the sea a sufficient wind strength within the city can be expected throughout the whole year (fig. 6). At increasing altitude the wind speed increases steadily. At the street level, the wind speed is almost zero. Measurements at the Sathorn Road displayed a wind speed of only 0.52 meters per second (m/s). This air flow cannot even be noticed as a slight breeze (wind strength 0-1)[2].
Nevertheless, 65 meters further, along the ground floor entrance area leading up to the MET, there is a very high air circulation of 6.13 m/s. The measurements on spot correspond to the wind strength 4, a moderate breeze (fig. 9). Even at the ground floor the building structure creates wind currents. This appoints to the efficiency upon which the building structure directs the wind downwards.

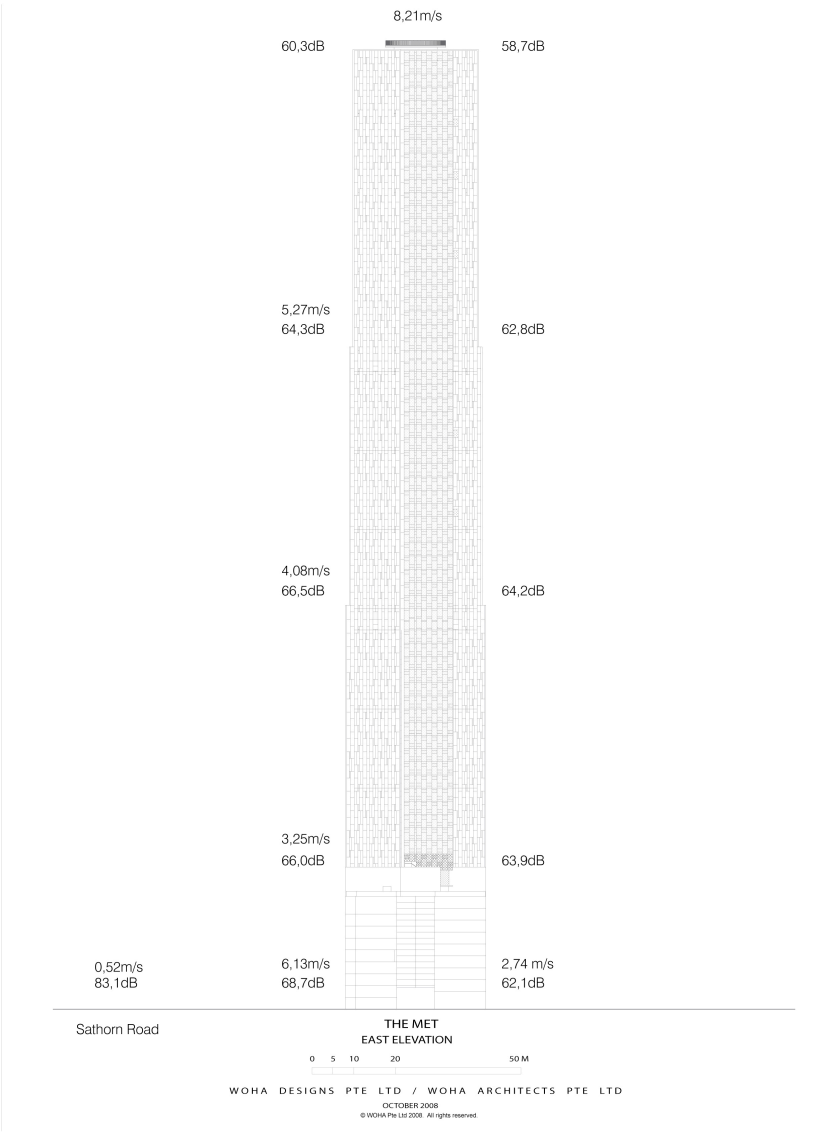

Fig.9. Results Wind Speed and Decibel; © Ferdinand Oswald, WOHA (5)

Due to the higher wind speed at increasing altitude there are less cultivations at higher storeys. In the upper third of the building there are hardly any balconies with trees and cultivations (fig. 10). The WOHA architects are widely experienced at transposing cultivations upon residential high rises. It is probable that the strong winds up to a height of 260 meters adversely affect the plants. In consideration of the strong wind strengths the stability of the trees must be ensured. Moreover, the evaporation at the surface of the leaves as implicit result of the wind presents a danger. Due to the lesser contact surface of the winds and the possible prevention from leave separation, small-leaved plant species are more suitable for an environment that is exposed to wind [3].
Nevertheless, the higher residential units (top third) are in particular demand. (Despite the higher costs of top-storey residential units in comparison to the lower two-thirds of the building, these vacant top-apartments are seldom. Status: April 2013.) They provide better views, facilitate a better ventilation (stronger wind speed) and a better air quality. The top wind speed has been measured at the roof top of the building. The wind speed accounts for 8.21 m/s and therefore corresponds to the wind strength 5 (Beaufort) that is identified as fresh breeze. The measured vertical wind current at the top storey reaches a similar wind strength. It is caused by the uplift and the channel-shaped interspaces of the residential towers reinforce this chimney effect.

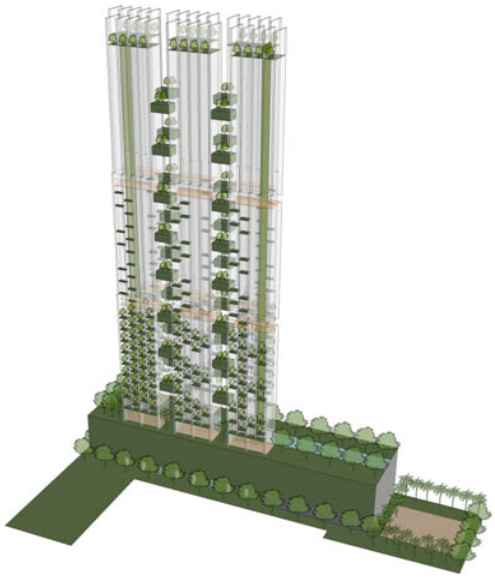

Fig.10. Integration of Greening, © Dr. Nirmal Kishnani (6)

3.4 Impact of water areas on comfort

Water areas are located in the common areas and some of the apartments are allocated with private pools. The air as it is cooled off by water circulates within the building structure and can eventually flow into the residential units. In the entrance area the pleasant breeze, the shade, and the influence of the numerous bodies of water establish a comfortable place to linger. In this area air measurements accounted for a temperature of 32.3 degrees Celsius. Simultaneously, the temperature at Sathorn Road was 4.2 degrees Celsius higher (36.5 degrees Celsius) (fig.11).

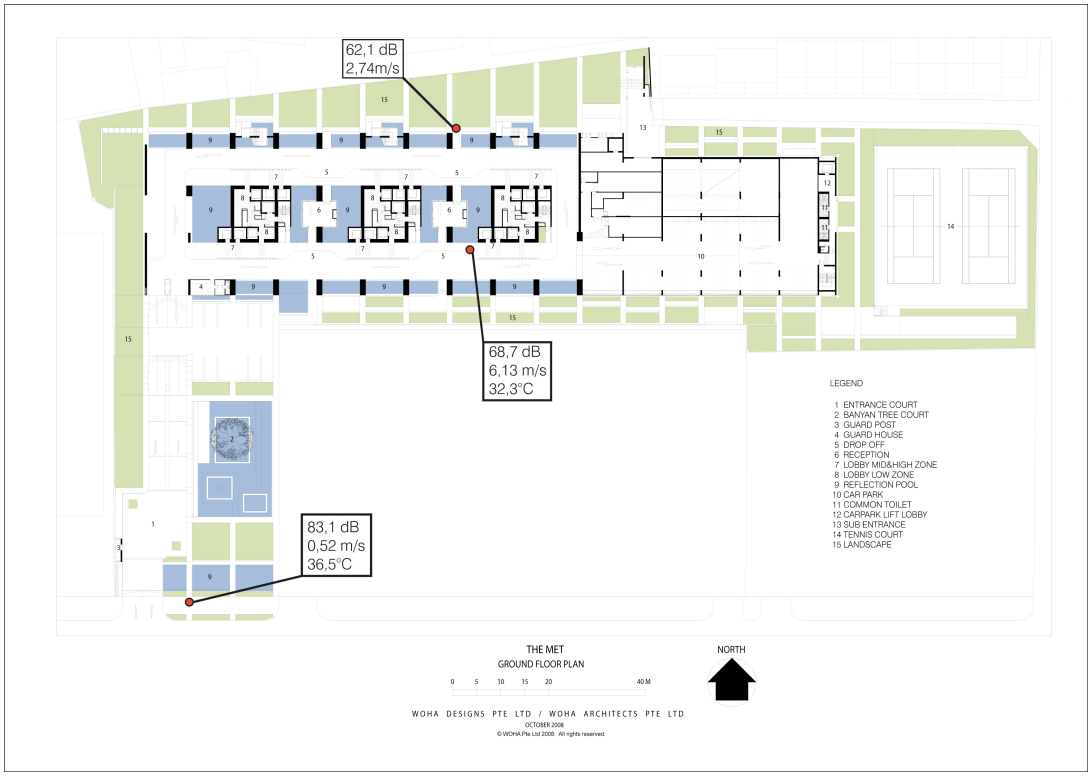

Fig.11. Ground floor the MET - Wind Speed, Decibel and Temperature
© Ferdinand Oswald, WOHA (7)

4.0 NATURAL VENTILATION

Natural ventilation enables a renunciation of air conditioning. This requires a closer investigation of the following three levels of the building:

1. The porous structure of the building as it is already described above.
2. The floor plan configuration which must facilitate cross ventilation.
3. The openings must meet numerous requirements and comply with external influences.

These will be elaborated according to the following points:

4.1 Floor plans

The three residential towers each contain a core development with two residential units. One unit is oriented towards north, the second unit faces south; both are staggered in reverse order. This enables an air entrance from the rear of the residential units and a very efficient cross-ventilation (fig. 12). Numerous windows can be opened from north and south in order to provide thorough ventilation. However, the hallway between several rooms must be partially ventilated (dependant on the floor plan type). According to the standard floor plan of the middle units (storeys 29th to 46th) there are two bedrooms with integrated bathrooms that are located at the facade side. Cross ventilation of the bedrooms is only provided when the doors are open. This leads to privacy restrictions. The opening of the balcony door and the tilting-window in the bathroom allow for an one-sided ventilation. However, due to the absence of the cross ventilation its efficiency during the hot climate period is disputable (fig. 13). A solution to the problem in terms of this floor plan type is difficult. The room layout of the large bedroom in combination with the bathroom facilitates continuous cross ventilation. The cross ventilation can also be implemented in the living room and kitchen without any restrictions. If the small bedrooms were connected to both facade sides they would be conceptualized as through rooms without a hallway.

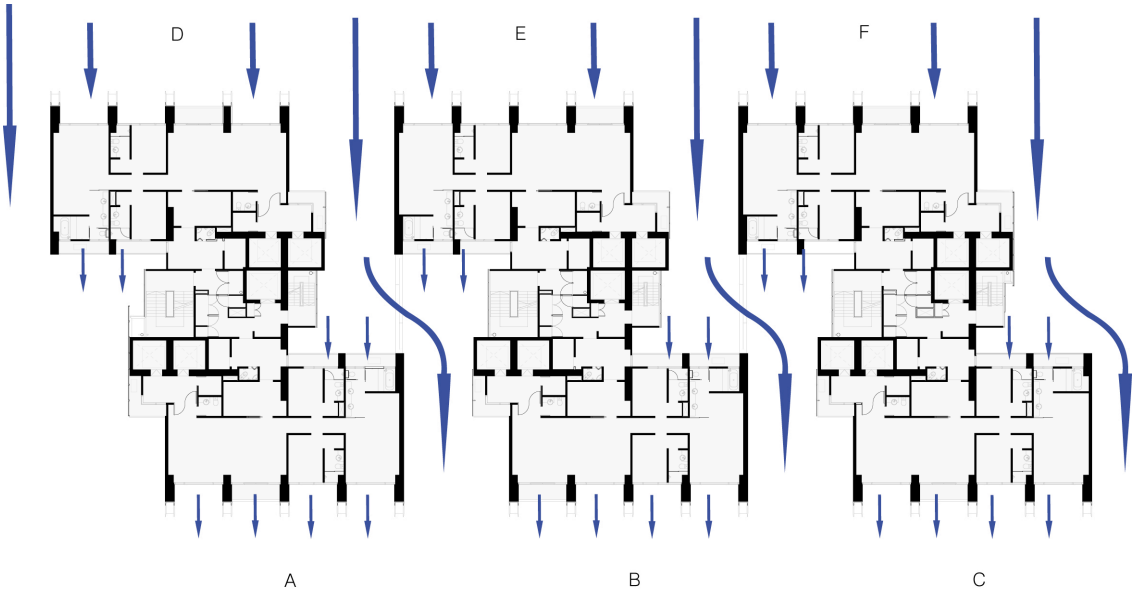

Fig.12. 29th Floor Plan the MET with Wind Circulation; © Ferdinand Oswald, WOHA (8)

4.2 Openings

Altogether there are 14 doors and window flaps that can be opened for the purpose of cross ventilation within one residential unit (Exemplified according to unit 29C, middle area, storeys 29-45 there are 9 window flaps, 4 doors to the canopied area, and one sliding door to the balcony). Although there are only 3 doors and 2 window flaps along the back facade side, there is sufficient air current throughout the residential units. Theoretically, there are 196 different ventilation combinations that result from these 14 openings (fig. 13).

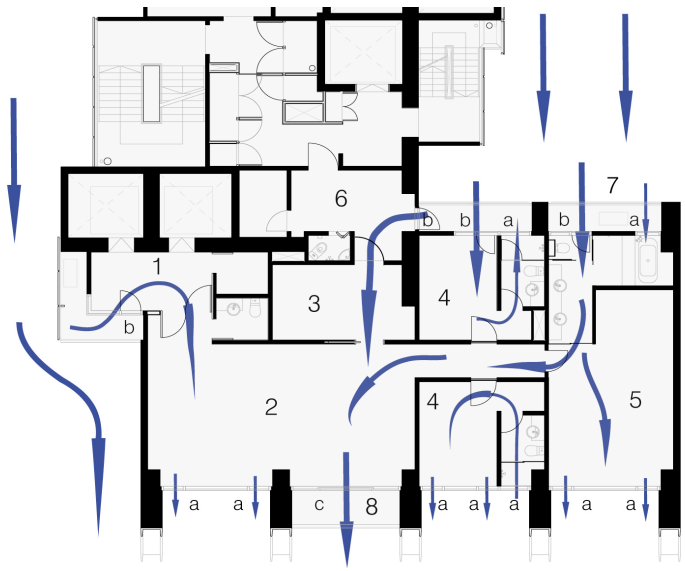

Fig.13. 29th Unit C Floor Plan the MET with Openings Categorization
© Ferdinand Oswald, WOHA (9)

Moreover, an air current in longitudinal direction can be actualised, for instance from the northern bedroom through the living room. The apartment entrance door was designed to be air-permeable and therefore allows for a continuous air current. It is made of vertical wooden staves and exhibits the necessary permeability for the air current to circulate onto the openings in the living room (fig. 14a). The window flaps can be folded out from beneath. This tilting mechanism anticipates the penetration of rain. In terms of the intense monsoon-rains in the rainy season this mechanism is an indispensable attribute for windows located at the outer facade. A suitable dosage of the air current via the ideal opening cross section is problematic. The loggia doors and window flaps allow only for a thorough opening or closing (fig. 14c). Merely the balcony sliding door enables a fine adjustment of the opening cross section. Thus, the air current volume and – intensity cannot be perfectly controlled. A needlessly high air change might be created. This excessive air speed triggers for instance a situation in which loose papers get blown away. One solution could be the development of window openings that allow for a decided control of the opening cross section. An example here could be the traditional wooden struts window of the old Tulous of the Fujian region in China (fig. 14 d and e). These can be regulated manually and with minimal movement of the element. However, the disadvantage here is that the shut-off struts no longer ensure light transmittance. Throughout the research project Structure and Facade, the IAT - Institute of Architecture Technology, Graz University of Technology is currently developing opening systems that meet these requirements. It is yet to be identified which cross sectional opening shape and size may represent the ideal opening for natural ventilation (fig. 15 c).In contrast to the overhead window flaps, the loggia doors have no locking function. Therefore, problems alluding to excessive draft are triggered. The loggia doors thunk shut with a loud bang. One way to solve this problem would be the appropriation of different adjustable opening angles in order to fix the doors.

4.3 Noise exposure road traffic

The noise exposure caused by road traffic at one of the most frequented roads in Bangkok accounts for 66.6 decibels (dB) at the middle part of the building and is therefore relatively high. The attempt of closing the window in order to create comfort did not improve the situation in terms of noise exposure. The windows are provided with single glazing and do therefore not contribute to soundproofing. Furthermore, the decentrally assembled cooling units are directly attached to the window. Even when the windows are shut the actuated air conditioning creates tremendous noise within the residential unit.
Noise measurements at the southern facade averting the street displayed only a slight noise reduction. This is justified by the fact that the adjacent building situated further south reflects the traffic noise back to the MET.
On average the noise exposure is only 2 dB lower than on the facade facing the street. At increased building altitude the noise exposure declines. On top of the building the decibels are least, at the middle part of the building they are very high. The higher acoustic measurements at the middle part of the building are justified by the fact that the adjacent building on the opposite side reflects the sound back (fig. 9).
The Hong Kong Housing Authority has used the so-called Noise Reducing Window (fig. 15 a). The window is constructed using two glass plates behind each other. Thus, the wind must pursue a labyrinth-like way and the acoustic waves cannot penetrate the interior of the room. Moreover, the perforated acoustic absorber is attached to the window reveals in order to transmit the noise. ."[4]
When taking into account the diversion of the wind flow the question is raised whether there is still sufficient wind speed inside the apartments. The wind pressure must reach a specific strength in order to facilitate efficient cross ventilation. A further development and investigation of this issue is perfectly reasonable, because the noise exposure of road traffic within Asian cities is usually very high. Unfortunately, it is likely that Bangkok's road traffic might increase within the next years, as the Thai government has started subsidizing the registrations for cars. Thus, it can be assumed that the noise exposure caused by vehicles in road traffic is on the rise.

4.4 Air pollution

"The motor vehicle traffic is one of the main causes of air pollution. Particularly in urban areas, the exhaust gases cause serious adverse effects on people and the environment."[5] However, air pollution caused by road traffic at the MET does not present a problem. Although the building is located at one of the most frequented thorough fares of Bangkok, the air quality is very good.
This is justified according to the following, "In the 90s Bangkok grew so fast that the air quality dropped to a miserable level. The government has enacted emission regulations, ensured the widespread introduction of unleaded petrol, and issued a regulation that allowed cars with catalytic converters only. In addition, simple but effective measures were carried out, for example, paved roads in order to stir less dust. The air quality in Bangkok is now better than American standards stipulate."[6]
The Thai government subsidizes gas-powered cars. "Although today conventionally powered vehicles emit fewer pollutants than a few years ago, the emission of exhaust gas components such as benzene and soot particles continues to present significant environmental impacts. Especially the pollutant emissions of diesel engines earn much criticism."[7] Thus, gas-powered vehicles are less harmful to the air than gasoline-powered vehicles. Unfortunately, the production of gas-powered cars will now be abolished in Thailand. In terms of the air pollution problem in other Asian cities the appropriation of air filters should be considered. However, the use of such air filters would possibly diminish the air current to a degree that might be no longer sufficient. At the same time an exposure through window openings should be facilitated. A material specification that meets the requirements of translucency, weathering, and air cleaning should be deployed (fig. 15 b).

5 CONCLUSION

Due to the existent floor plan structure natural ventilation and the simultaneous renunciation of electronic air conditioning is enabled within the residential units of the MET. The measurements and the evaluation demonstrates that, even within Bangkok's hot season, natural ventilation and air currents do allow for a pleasant living comfort. The problematizing standards of the openings (fig. 15) can be added up to within one window. However, this requires openings that meet all these needs simultaneously.
The requirements of noise, air filtering, opening cross-section, as well as sun and rain protection must therefore be equally achieved upon this single opening.
Upon enquiring [8] the employees of the MET about the use of air conditioning, the survey led to the following results:
The experience of the staff revealed that most residents of the MET actually renounce the use of air conditioning. This thesis is based on the numbers taken from power consumption measurements within the individual units. The investigations of Dr. Nirmal Kishnani [9] confirm these numbers. "45% of the residents say, that they have low to moderate dependence and reliance on air-conditioning." The idea of returning to the passive natural air conditioning is currently difficult to implement among tropical cities. The electricity prices are low, facilitating a relatively affordable operation of the refrigeration systems. Air conditionings are easy to get and easy to install. Mostly these are assembled already in advance by the client or operator of the building, since this adds up to the expectations of the patronage.
Mistakenly, the air conditioning seems to present the only assumable answer to the external factors of heat, humidity, noise, and air pollution. The air conditioning is a deeply-rooted standard that meets the need of comfort in a self-evident and simple manner. Surprisingly, the floor plan conceptualizations and openings of older residential properties in Bangkok contain functioning cross ventilations without air conditioning. The invention of the decentralised air conditioning has changed the types of housing in the last 50 years thoroughly. We need to focus on and prove the assumption that the adaptation and reinterpretation of traditional housing typologies for new residential buildings aspires to a realization of the living comfort in a sustainable way. The MET proposal has become a pioneer project in its own right, representing architectural innovation in tropical regions.

Short Summary

The Recast of the Directive on the Energy Performance of Buildings (the EPB Directive) came into force on 9 June 2010. EU member states should until 9 June 2012, publish the relevant laws and administrative regulations necessary to implement its provisions. European regulatory efforts towards increasing energy efficiency of buildings are focusing on a comparative methodology framework for calculating cost-optimal levels of minimum energy performance requirements for buildings and building elements. Such requirements should be the first step into low or zero energy buildings.

In this paper the consideration on different indicators for requirements of low energy and nearly zero energy buildings are presented. The scope of the paper is to show that none of the buildings system (like hybrid or natural ventilation) can be excluded from using in such buildings. This conclusion is crucial for integrated energy design process as designer should not be limited to specific number of systems solutions.

In the paper the calculation of three systems are presented (natural ventilation, DCV ventilation and mechanical ventilation with heat recovery). It was shown that, the choice of indicator for requirements should include not only the useful energy (heat), but also electricity (heater) and other non-energy operating costs (filters). The correct ratio is multi-dimensional, and its range depends on the used assumptions.

The given consideration shows that the estimation of energy requirement cannot be done using only one indicator eg.: useful, final or primary energy. Such approach may leads to excluding some systems that can be other than recommended.

Keywords:Low energy buildings; energy criteria; LCC

1. Introduction

Directive 31/2010/EU [1] requires the introduction of nearly zero-energy buildings but does not specify a minimum or maximum harmonized requirements and detailed guidance framework procedure for calculating the energy performance of building. Member states have to define what that means exactly for them. Taking into account the local conditions in the definition does not preclude the adoption of a uniform methodology in all Member States.

The Directive defines a nearly zero-energy building as a high energy performance building and requires the determination of the ratio of primary energy. Very low or almost zero energy demand

of the building should be covered from renewable energy sources or renewable sources produced on-site.

Based on the definition given in the directive, the nearly zero-energy building is technically *net zero energy* building that is consuming 0 kWh/(m^2a) energy (however it is not clarified what kind of energy should be taken into account: final, primary, supplied). According to the rule of optimal costs laid down in Directive almost net zero net energy building is defined as a building determined using the rules of the national methodology of optimal costs, consuming more than 0 kWh/(m^2a) energy. In order to clarify the general definition it was necessary to specify which energy flows should be included in the evaluation of energy performance and how the primary energy factors should be used to calculate the ratio of primary energy of building. To standardize the methodology the overall definition of the balance border with the inclusion of active solar systems and wind power, as well as technical clarification of the term "near" contained in the Directive becomes an essential element.

Methodology of the cost optimal and requirements defined of its use indicates use as an indicator a final or delivered energy, as they are associated with costs. Primary energy can be defined as an additional indicator, as used for its determination the primary energy factors include biased (not related to the quality of the building) political aspect. However, many Member States selected as requirement a primary energy supplemented by other requirements. The requirements have technical and economical quality which means that they must refer to existing technologies and be set as economically viable. This cost-effective level by the European Commission may be determined by the cost optimal methodology described in Regulation EC 244/2012 [2].

In this paper the consideration on different indicators for requirements of low energy and nearly zero energy buildings are presented. The scope of the paper is to show that none of the buildings system can be excluded from using in such buildings. This conclusion is crucial for integrated energy design process as designer should not be limited to specific number of systems solutions.

2. Energy in requirements

Genesis of formulating energy requirements is derived from the early twentieth century. With the development of technology and the decreasing availability of raw materials it began to formulate the energy requirements for buildings. At the beginning heat loss was the main issue, so a maximum heat transfer coefficient for a single partition or the entire building were given. Since 1995, Poland has introduced requirements for the maximum permissible value of useful energy for residential buildings in kWh/m^2a, which coincided with the publication of the method for calculating this value. From the point of view of energy performance of buildings it was the only requirement, although by then some first calculations of final energy and thus costs were given. For other types of buildings maintained the requirements for building components such as heat transfer coefficients and the surface area of the glass partitions. In accordance with the adoption of the climate package, published directives on buildings, measures to reduce energy consumption have become systematically harmonized. In connection with the implementation of Directive 91/2002 on the Energy Performance of Buildings Member States were obliged to publish the so-called. minimum requirements. A summary of these activities is provided in online accessible publication titled Implementation of the Energy Performance of Buildings Directive (EPBD), Country Reports 2008, Brussels, 2008, ISBN 2-930471-29-8, EAN 9782930471297) [3]. During the implementation of the EPBD some research aimed at comparing the requirements from the various Member States were carried out. Examples of such works are Intelligent Energy for Europe projects called TABULA and ASIEPI. In comparison the rules adopted in Poland in 2008 are the least demanding of all member countries.

The requirements for nearly zero energy building consist of several specific requirements. These include primary energy and useful energy, as well as the tightness of the building and in the case of non-residential buildings useful energy for cooling.

An expressing requirements in units of primary energy is burdened with charges of adjusting object location (same building with electric power for heating has to be three times better than a building

supplied with district heating networks). If we assume, that the requirements should be independent of the location then the variables that affect the energy consumption of the building are the quality of envelopes and windows of the building, the efficiency of installations, climate and standard usage. Determination of whether the building have good or bad energy performance will be easy to define, regardless of its location. In this case, the requirements can be formulated in units of final and useful energy. Otherwise, if the distinction is primary energy it will not be able to conclude what is the energy performance of the building itself.

In conclusion, each indicator adopted for the requirements has its advantages and disadvantages, which should be know when deciding to choice it. Poland in the proposal of the new requirements for buildings plans to introduce partial requirements and primary energy requirements.

3. Traps of useful and final energy

In guidelines of Passivhaus Institut in Germany, the Austrian standards, definitions used in countries such as Sweden, Denmark, Norway and Finland requirements are always formulated with regard to the rate of useful energy demand for heating and ventilation rather than rate of final energy demand. So it is defined by the passive house standard according to Passivhaus Institut in Germany. Building achieved the passive standard if:

- usable energy demand for heating and ventilation does not exceed 15 kWh/m^{2}a,
- primary energy demand for heating, ventilation, hot water, auxiliary equipment, lighting, all the building equipment, household appliances and electronics, cooking, etc. does not exceed 120 kWh/m^{2}a.

Requirements for low energy standards should also be related to the rate of useful energy demand for heating. The indicators should not be taken into account additional energy consumption by auxiliaries.

Statement of requirements as indicators of final energy demand is a big mistake and can lead to increased energy consumption in buildings. For example, in buildings where the ground heat pump is the heat source the total efficiency of heating system will be about 3.0. With this performance achievement of final energy demand equivalent to 15 kWh/m^{2}a occurs with a usable energy demand for heating and ventilation equal to 45 kWh/m^{2}a. The achievement of final energy demand equal to 75 kWh/m^{2}a occurs with a usable energy demand for heating and ventilation equal to 225 kWh/m^{2}a. This means that when heat pump system with heating efficiency of an average 3.0 is used the buildings which should have passive standard are only low energy buildings, and low energy buildings are much worse than currently build.

The problem of final energy can be solved using the method cost optimal methodology. The calculation of the global cost is performed according to the methodology given in the comparative Commission Delegated Regulation 244/2012 (EU), using the method of financial calculations, from the formula:

$$C_g(\tau) = C_I + \sum_j \left[\sum_{i=1}^{\tau} \left(C_{a,i}(j) \times R_d(i) \right) - V_{f,\tau}(j) \right] \quad (1)$$

where:

- τ means the calculation period (30 years for residential and public buildings and 20 years for non-residential buildings),
- $C_g(\tau)$ means global cost (referred to starting year τ_0) over the calculation period,
- C_I means initial investment costs for measure or set of measures j,
- $C_{a,i}(j)$ means annual cost during year i for measure or set of measures j,
- $V_{f,\tau}(j)$ means residual value of measure or set of measures j at the end of the calculation period (discounted to the starting year τ_0),

$R_d(i)$ means discount factor for year i based on discount rate r to be calculated according to (2)

$$R_d(p) = \left(\frac{1}{1+r/100} \right)^p \tag{2}$$

where p means the number of years from the starting period and r means the real discount rate.

Calcutalion of global cost is performed on the basis of knowledge (estimation) of the final energy. Therefore, the determination of the requirements should be done using LCC methodology. It follows that the requirements laid down by the LCC will be different for different power systems.

4. The paradox of useful energy ratio - case study

In order to show the paradox of using in the requirements the useful energy the calculation of the energy demand for ventilation in the single family house were provided. It was assumed that the heat loses through external envelopes are constant and only ventilation system was taken into account.

According to Polish standard the hygienic air flow rates for single family house with two bathrooms and kitchen with gas cooker are: 2x50 + 70 = 170 m^3/s. It was assumed that ventilated volume of the building is 300 m^3, and ratio of n_{50}=3 air change per hour (for natural ventilation system). The total outside air flow is then:

$$V_{ve} = V_0 + V_{\inf} = \frac{170}{3600} + \frac{0.05 \cdot 3 \cdot 300}{3600} = 0.047 + 0.013 = 0.06 \quad m^3/s \tag{3}$$

The heat transfer coefficient for heat loses for natural ventilation is equal:

$$H_{ve} = \rho_a \cdot c_a \cdot \sum_k \left(b_{ve,k} \cdot V_{ve,k,mn} \right) = 1200 \cdot \left[1 \cdot V_0 + 1 \cdot V_{\inf} \right] = 1200 \cdot \left[1 \cdot 0.047 + 1 \cdot 0.013 \right] = 72 \quad W/K \tag{4}$$

The heat transfer coefficient for heat loses for mechanical ventilation with heat recovery of 85% is equal:

$$\begin{aligned} H_{ve} &= \rho_a \cdot c_a \cdot \sum_k \left(b_{ve,k} \cdot V_{ve,k,mn} \right) = 1200 \cdot \left[(1-\eta_{HR}) \cdot V_f + 1 \cdot V_x \right] = \\ &= 1200 \cdot \left[0.15 \cdot 0.047 + 1 \cdot 0.00875 \right] = 18.96 \quad W/K \end{aligned} \tag{5}$$

Where V_x:

$$V_x = \frac{V \frac{n_{50}}{3600} e}{1 + \frac{e}{f} \left(\frac{V_{su} - V_{ex}}{V \frac{n_{50}}{3600}} \right)^2} = \frac{300 \frac{1.5}{3600} 0.07}{1 + \frac{0.07}{15} \left(\frac{170 - 170}{300 \frac{1.5}{3600}} \right)^2} = 0.00875 \quad m^3/s \tag{6}$$

For the mechanical ventilation n_{50}=1.5 1/h and the *e* and *f* coefficient were taken from standard EN 13790.

In Table 1 the summary of heat transfer coefficient for natural and mechanical ventilation is given.

Table 1: Heat transfer coefficient for ventilation

Ventilation	Heat transfer coefficient [W/K]
Natural	72.00
Mechanical	18.96

On the basis of the calculated values of heat transfer coefficient for ventilation the heat demand for whole year can be estimated. The calculation was done using Warsaw climate data and using monthly calculation method. In Table 2 the results of the calculation are presented.

Table 2: Heat demand for ventilation

Ventilation	Heat demand [kWh/a]
Natural	7031
Mechanical	1852

It can be noticed that heat demand in case of the mechanical ventilation is about 3.8 times less than for the natural ventilation. However in the mechanical ventilation additional energy for fans is required. Using the national regulation [4] it was assumed that in the mechanical ventilation two fans (each of 80 W) are installed and the ventilation is working whole year. For such data the energy demand for electricity was calculated.

$$E_{el} = 160 \cdot 8760 = 1387 \quad kWh/a \tag{7}$$

Taking into account the energy consumption of fans the mechanical ventilation system needs 1852 kWh of thermal energy and 1387.2 kWh of electrical energy. For the determination of the useful energy for heating only thermal energy needed to heat the ventilation air taken into account, while omitted larger and more expensive part associated with the electricity. A more complete assessment of the two systems is when referring them to the primary energy or costs. In the case of natural ventilation system thermal energy of 7031 kWh/a, is about 3.8 times higher than for the mechanical ventilation with heat recovery 1153 kWh/a. If we take into account the primary energy or costs, the mechanical ventilation system with heat recovery needs 1852 kWh/a + 3*1387 kWh/a = 6015 kWh/a primary energy to 7031 kWh for natural ventilation system, so that the difference is significantly reduced.

The first conclusion that must be drawn here is that the eligibility criterion in units of useful energy (heat) eliminate from the analysis a components necessary for the operation of technical systems including ventilation.

The second conclusion from the analysis is 3.8 times higher thermal energy consumption by natural ventilation system. Assessing qualifications or eliminations from the list of recommended technology, based on just the heat demand can lead to false results. After taking electricity consumption, it appears that natural ventilation is not much worse than mechanical. This means that at least should be allowed to be used along with mandatory recommendation.

The third conclusion is that eligibility criteria of useful energy should be supplemented by other forms of energy necessary for the operation of technical systems.

Natural ventilation is unpredictable and in many situations is not working. Demand controlled ventilation (DCV) eliminates the disadvantages of natural ventilation, making it works regardless of

weather conditions, and also by the ability to control ventilation can adjust the air flow in each room to the needs of users. In practice, the possibility of reducing the air flow is used in the absence of people or at night. Most of the central mechanical ventilation units has three levels of performance. Selection of these units is made in such a way as to meet the hygienic performance requirements for middle level of ventilation unit performance. Installed in the units programmers allow individual time programming of the air flows. Inhabitants reduce airflow during their absence, and increase it in the summer in order to disperse of the heat gains. Sometimes they turn down mechanical ventilation and open windows (which from the point of view of the Polish regulations is not allowed).

In the case of demand-controlled ventilation it is possible to individually adjust the air flow to the ventilation needs in each room. The degree of this adjustment depends on the technical sophistication of the system. Below, the estimation of the ventilation air flow reduction in accordance with the technical capabilities of both ventilation systems and the impact of the reduction on the heat and electricity consumption are presented.

4.1 Mechanical ventilation with heat recovery

Mechanical ventilation should work whole year, for 8760 hours. In presented case study the calculated hygienic air flow is equal 170 m^3/h. The second step (II) in the mechanical ventilation unit provide 200 m^3/h (first step (I) gives 100 and third (III) 400 m^3/h). It was assumed that in the winter ventilation unit on II step only during the presence of all inhabitants for example during 12 hours a day, at other times is running at I step. In the summer, during the day (approximately 10 hours) in order to disperse heat from the solar gains a ventilation unit is operating at III step and at the rest of the day at II step. This assumption is justified if we assume that the priority of people is the most out of the ventilation system. In practice, in the summer ventilation system is used to set hygienic air flow requirements and the heat gains are being removed by opening of the windows. In accordance with Polish ventilation regulation a ventilation air flow for the calculation can be reduced by 40%.

Average hourly flow of ventilation air supplied during the heating season by the air handling unit is (5840 * 170 + 0.6 * 170 * 2920) / 8760 = 147 m^3/h, and in the summer is 170 m^3/h, therefore to calculate the electricity consumption of the fans we can assume that the ventilation unit operates all year round on the second step providing 200 m^3 of air per hour. From this assumption the heat transfer coefficient for mechanical ventilation with 85% of the heat recovery is equal:

$$H_{ve} = \rho_a \cdot c_a \cdot \sum_k \left(b_{ve,k} \cdot V_{ve,k,mn} \right) = 1200 \cdot \left[\left(1 - \eta_{HR} \right) \cdot 0.6 \cdot V_f + 1 \cdot V_x \right] = \\ = 1200 \cdot \left[0.15 \cdot 0.6 \cdot 0.047 + 1 \cdot 0.00875 \right] = 16.55 \quad W/K \tag{8}$$

The heat demand for this case is equal to 1616 kWh/a.

Calculation of electrical energy consumption should be made on the basis of the technical specifications of the selected ventilation unit. After analyzing of several air handlings units it can be assumed that on the second step the fan power is equal to 150 W (see Table 3).

Table 3: Fan power at given air flow rate of selected air handling unit

Step of working	Air flow [m^3/h]	Fan power [W]
I	100	38
II	200	150
III	400	600

For such data the energy demand for electricity was calculated.

$$E_{el} = 150 \cdot 8760 = 1314 \quad kWh/a \tag{9}$$

Taking into account the energy consumption of fans the mechanical ventilation system with 85% heat recovery needs 1616 kWh/a of thermal energy and 1314 kWh/a of electrical energy.

Assuming primary energy factors (gas primary energy factor = 1.1 and electricity 3.0) and energy cost (0.54 PLN/kWh for electricity and 0.20 PLN/kWh for gas, 1 euro = 4 PLN) the total primary energy demand and total operating costs can be calculated. The results are presented in Table 4.

Table 4: The primary energy and total operation cost of mechanical ventilation with heat recovery

Parameter	Heat	Electricity	Total
Primary energy [kWh/a]	1.1*1616	3*1314	5720
Cost [PLN/a]	1616*0.20	1314*0.54	1032.76

4.2 Demand Control Ventilation (DCV)

Ventilation DCV is a type of mechanical exhaust ventilation in which the area of the inlet openings are regulated and the buoyancy force is supported when needed (at times when the temperature difference is too small to produce adequate buoyancy). The buoyancy force is supported by low-speed exhaust fan mounted on the outlet duct. The power of such fun for the single family building is about 6-10 W. In the heating period the number of hours in which a temperature is above 12℃ is about 1000. In the summer, the building is ventilated by opening the windows.

The heat transfer coefficient for DCV ventilation can be calculated from following formula:

$$H_{ve} = \rho_a \cdot c_a \cdot \sum_k \left(b_{ve,k} \cdot V_{ve,k,mn}\right) = 1200 \cdot \left[1 \cdot V_0 + 1 \cdot V_x\right] = \\ = 1200 \cdot \left[0.7 \cdot 170/3600 + 1 \cdot 0.00875\right] = 50.2 \quad W/K \tag{10}$$

According to the Regulation on the scope and form of the energy audit using automatically regulated diffusers the ventilation air flow can be reduce by a factor of 0.7.

The heat demand for this case is equal to 4902 kWh/a.

For such data the energy demand for electricity was calculated.

$$E_{el} = 10 \cdot 8760 = 88 \quad kWh/a \tag{11}$$

Taking into account the energy consumption of fans the DVC ventilation system needs 4902 kWh/a of thermal energy and 88 kWh/a of electrical energy.

Assuming primary energy factors (gas primary energy factor = 1.1 and electricity 3.0) and energy cost (0.54 PLN/kWh for electricity and 0.20 PLN/kWh for gas) the total primary energy demand and total operating costs can be calculated. The results are presented in Table 5.

Table 5: The primary energy and total operation cost of DCV ventilation

Parameter	Heat	Electricity	Total
Primary energy [kWh/a]	1.1*4902	3*88	5655
Cost [PLN/a]	4902*0.20	88*0.54	1027.92

The presented analysis of energy demand of three systems: natural ventilation, mechanical

ventilation with heat recovery and DCV ventilation, done on the basis of existing legislation and the given assumptions indicates a significant disadvantage for determining energy standard of buildings in units of useful energy. Forcing investors to use mechanical ventilation leads to some savings during heating period, but that decision has consequences related to the consumption of electricity during whole year. As shown in Table 5 it can lead to higher operating costs of the mechanical ventilation system than DCV. The estimation of the operation cost of mechanical ventilation does not include: the cost of filters replacement and electricity consumption of the heater to defrost the heat exchanger or to heat the inlet air. This is important in the case of high-performance heat exchangers (eg 85% such as that above). Detailed calculation of energy demand for these ventilation systems can be performed using the simulation method. These considerations were carried out using standard balance methods just to address the problem.

5. Conclusions

On the basis of the considerations, the choice of indicator for requirements should include not only the useful energy (heat), but also electricity (heater) and other non-energy operating costs (filters). The correct ratio is multi-dimensional, and its range depends on the used assumptions.

As it was presented in the analysis the total primary energy demand can be higher for systems with lower energy demand for heating (DCV ventilation vs. mechanical ventilation with heat recovery). In some cases the additional energy demand for electricity for fan can provide higher primary energy demand for whole building. Also the operational cost are higher in the case of mechanical ventilation with heat recovery. It must be stated that in the cost calculation only energy cost were taken into account.

The given consideration shows that the estimation of energy requirement can not be done using only one indicator eg.: useful, final or primary energy. Such approch may leads to excluding some systems that can be other than recomended.

The paper was focused on requirements for heating period. It should be noticed that requirements only for heat demand decreasing can lead to very good standards in the heating and overheating in the summer. For example, nearly zero-energy buildings in Denmark and Belgium are checked for possibility of overheating. Using Polish methodology of energy demand calculation such indicators are not calculated.

Short Summary

A set of four buildings with different types of construction was analysed using a Life Cycle Assessment (LCA) in order to identify the main contributors to overall embodied carbon emissions. The results are presented by virtually “cutting” the buildings in two different ways, focusing not only on the building as a whole, incorporating all its various materials, but also on the individual impact of each building element (floor, ceilings, external walls, etc.) on the one hand, and on the impact of a predefined standard enclosed floor space (e.g. basement space, typical floor space, roof space) on the other. The aim of this approach is to clarify what the interrelations of the different individual parts of the buildings are within their overall functional context while at the same time allowing for a meaningful representation and interpretation of their respective impacts with regard to embodied carbon emissions. As a result, different perspectives and levels of detail are covered in the critical impact evaluation of each building, giving a thorough and comprehensible answer to the question of where the embodied CO_2 of the buildings is primarily located. The allocation of carbon emissions to the floor space of each storey, instead of to the floor space of the whole building, demonstrably produces relatively homogeneous results, which facilitate the comparison of the buildings from the sample and their diverse characteristics.

Keywords: buildings; carbon emissions; different types of construction; different perspectives

1. Introduction

Life Cycle Assessment (LCA) has been established as an effective method for evaluating the environmental impact of products and services over their lifecycle. The general LCA procedure is described in the ISO regulations 14040 [1] and 14044 [2]. For LCAs of buildings, the DIN EN regulation 15978 [3] gives a more detailed description of the aspects that require particular consideration in the context of a building. Despite many efforts in recent years to simplify the rather complicated LCA procedure for buildings, in order to make it more easily applicable to the needs of architects and planners, there are still various challenges to be met. An essential one of these is the presentation of LCA results in a way that clearly provides valuable information for the architect regarding which building elements contribute most to the overall environmental impact of a building. As architects characteristically have a strong visual perception of the built environment, it is crucial to provide them with more than just a numerical analysis of a building’s environmental impact in order to help them advance their building designs. A thorough and comprehensible answer to the question of where the embodied CO_2 of the buildings is primarily located requires a critical impact evaluation of a building that incorporates different perspectives and different levels of detail. The key to addressing this challenge and to facilitating LCAs of buildings could be the definition of the functional unit in a more intuitive way than is usually applied in existing studies.

The functional unit is the unit to which all inputs (resources, energy) and outputs (waste, emissions), as well as the environmental impact results of an LCA refer. In this paper, the authors utilize two different functional units: one is a functional unit commonly applied in many existing LCA studies of buildings (1 m² of general floor space per 1 year of the building's lifetime); the other is a functional unit that corresponds to 1 m² of a specific floor space (basement, ground floor, upper floor or loft) per 1 year of the building's lifetime. A building sample of four individual apartment buildings is analysed in a comparative LCA and the results for the embodied carbon emissions of each building element are displayed for both functional units. Two different virtual cutting approaches for the buildings are required in order to properly determine the emission results of the two functional units. A schematic view of the second cutting approach helps visualize the different concepts. In chapter 2, the characteristics of the four buildings from the sample are introduced, followed in chapter 3 by the LCA modelling specifications, which were applied for the calculation of carbon emissions. In chapter 4, the two different approaches to virtually cutting the building are described and in chapter 5, the carbon emission results for both functional units are presented, followed by the conclusion and discussion in chapter 6.

2. Characteristics of the building sample

The building sample consists of four apartment buildings with diverse characteristics.

- **Building 01** is the largest of the four buildings. It contains 111 accommodation units and is a massive construction, mainly of reinforced concrete (floor, ceilings, external and internal walls, roof) and concrete block (internal walls). Insulation materials are the following: recycled glass foam fill, expanded polystyrene, polyurethane foam, mineral wool, and extruded polystyrene. There are five floors above ground and one basement floor (including underground parking spaces). The building has a flat roof planted with vegetation. The energy reference area of this buildings is 12 430 m^2.

- **Building 02** is a medium-weight construction and contains two accommodation units. The construction is mainly of reinforced concrete (floor, ceilings, external and internal walls), timber (ceilings, external and internal walls, roof), and sand-lime brick (internal walls). Insulation materials are the following: mineral wool, recycled glass foam fill, extruded as well as expanded polystyrene, and polyurethane foam. The building has three floors above ground and one basement floor. It has a pitched roof clad in fibre cement. The energy reference area of this building is 350 m^2.

- **Building 03** is a lightweight construction containing three accommodation units. The construction materials are timber (ceilings, external and internal walls, roof) and reinforced concrete (floor, ceilings, external and internal walls). Insulation materials are the following: mineral wool, recycled glass foam fill, foam glass and cellulose fibres. There are three floors above ground but no basement. The building has a flat roof planted with vegetation. The energy reference area of this building is 374 m^2.

- **Building 04** contains four accommodation units and is a massive construction. The materials used for the main construction are reinforced concrete (floor, ceilings, roof) and masonry (external and internal walls). Insulation materials are the following: expanded polystyrene and polyurethane foam. There are two floors above ground and one basement floor. The building has a pitched roof clad in galvanized sheet steel. The energy reference area of this building is 622 m^2.

Details of the building characteristics can be found in the descriptions of mfh01, mfh02, mfh03 and mfh04 in the dissertation by V. John [4].

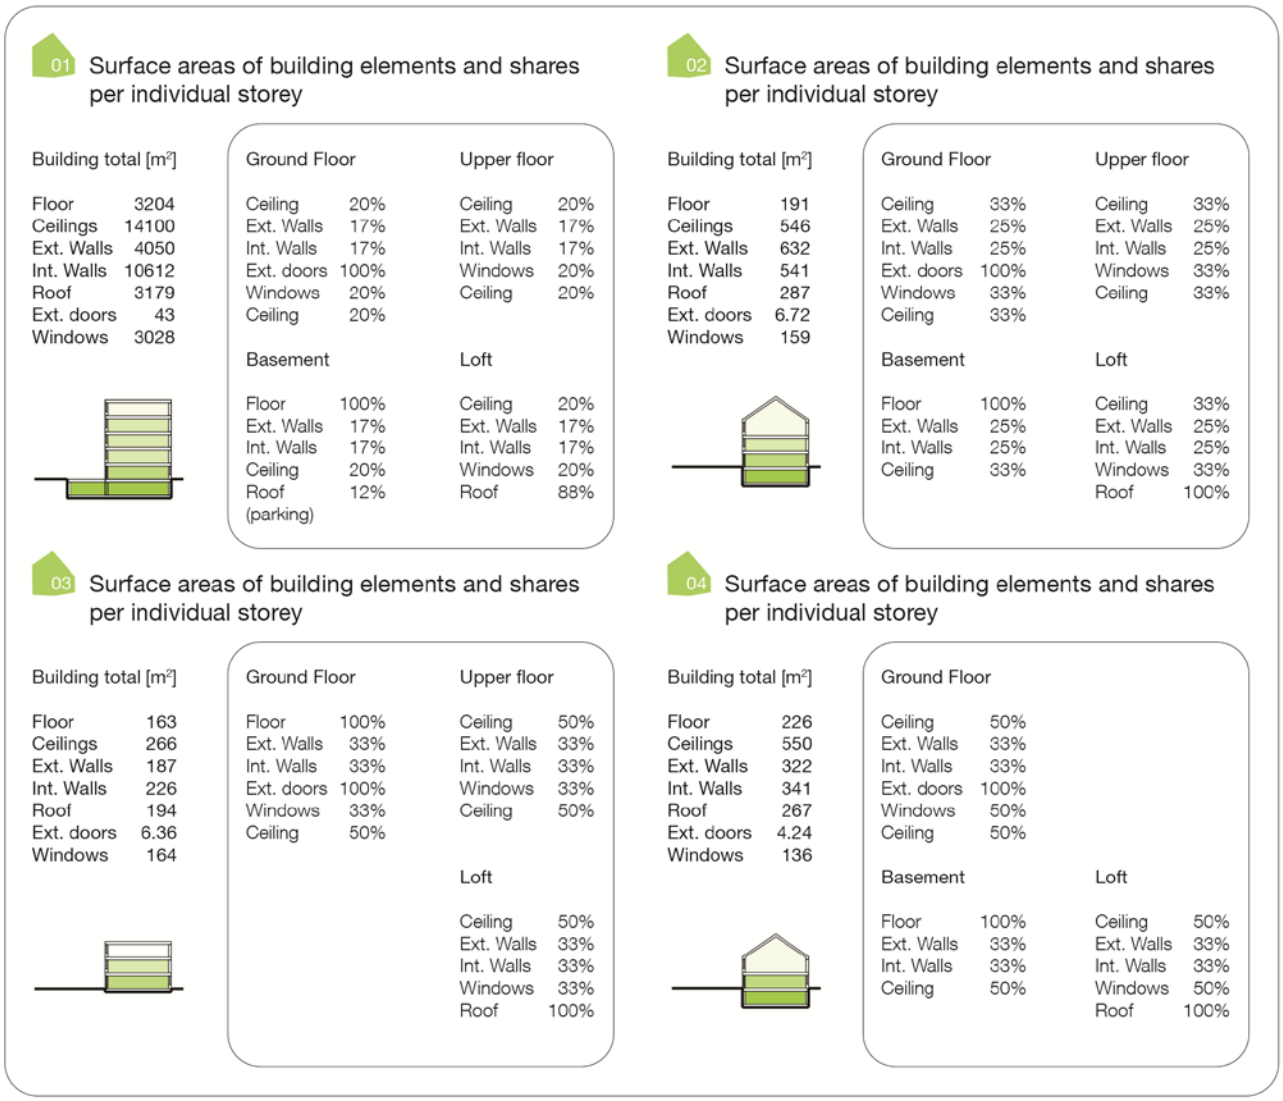

Fig. 1 Surface areas of the building elements and their shares per individual storey

3. LCA modelling specifications

The carbon emission results were calculated using the professional LCA Software SimaPro [5] (version 7.3.0) with the implemented LCI database Ecoinvent [6] (version 2.2). The values indicate the Global Warming Potential GWP 100a (IPCC 2007 GWP 100a V1.02 [7], referring to a time horizon of 100 years for emissions). Included in the calculations are all materials required for the construction, replacement and deconstruction of the building elements (floor, ceilings, external and internal walls, roof, external doors, and windows) over the building's lifetime of 60 years. It is assumed that the main construction materials have a service life of 60 years, while all other materials need replacement after 30 years (with some minor exceptions). All LCA modelling specifications for the buildings can be found in the appendix of the dissertation of V. John [4].

4. Approach: virtual cutting of the buildings

For the presentation of carbon emission results for the four apartment buildings, two different virtual cutting approaches have been chosen for comparison.

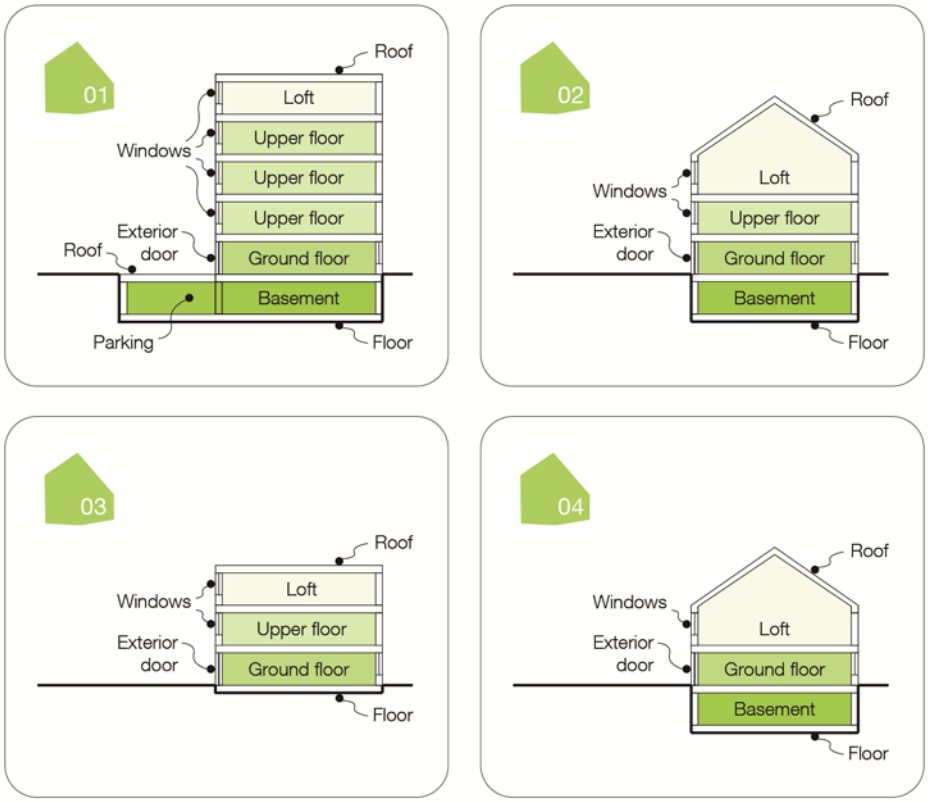

Fig. 2 Schematic view of the floor space characterisations for the virtual cutting approach 2

4.1 Virtual cutting approach 1

The first approach aims at breaking down the total kg CO_2 eq of each building to the functional unit of 1 m² of general floor space (in this case the energy reference area) for 1 year of the building's lifetime. This approach is commonly utilized for LCAs of buildings and facilitates a general comparison of the four buildings by levelling out the huge differences in building sizes. It is, however, not the best way of showing clearly where exactly the main contributors to the final result are situated within the building. When looking at a building from an architect's point of view, there is no such thing as a general 1 m^2 of floor space to which the overall building emission results could be meaningfully allocated. Instead, each storey has its individual contributors to the final result. The floor element, for instance, only contributes to the lowest building storey, while the roof element normally only covers the top storey. Furthermore, the exterior door is usually on ground floor level, while external and internal walls are found on all storeys.

4.2 Virtual cutting approach 2

Consequently, the second approach to virtually cutting the buildings aims at systematically defining four typical storeys within a building according to their specific, typical characteristics. The carbon emissions are then calculated for 1 m² of this specific floor space for 1 year of the building's lifetime. The characterisation of the storeys follows some simple rules defined by the authors:

- **Loft**
  The top storey of the building, defined as consisting of the elements roof, ceiling (at the bottom of the space), windows, and external and internal walls.

- **Upper floor**
  The storey(s) between ground floor and loft, defined as consisting of the elements ceiling (at both the bottom and top of the space), windows, and external and internal walls.

- **Ground floor**
  The first storey above ground, defined as consisting of the elements ceiling (at both the bottom and top of the space), external doors, windows, and external and internal walls.

- **Basement**
  The storey below ground, defined as consisting of the elements floor, ceiling, and external and internal walls.

Within the building sample, two exceptions from these rules were found in the buildings 01 (where, due to the underground parking space, the roof element had to be partly allocated to the basement) and building 03 (where the basement is missing, so that the floor element is allocated to the ground floor instead).

To enable easy and consistent calculation of the individual shares of each building element per storey, the total surface area of each element was divided by the number of events in which it occurs in the building. For instance, in building 01, there are five ceilings within the whole building, as can be seen in the schematic vertical sections in Fig. 1 and Fig. 2. This means that for each event the share of the ceiling is 20%. When computing the values for the ground floor storey, this leads to a total contribution of 40% of the total ceiling surface area, as there is a ceiling element on top as well as on the bottom of this storey. It is worth mentioning that the splitting of the buildings into the four aforementioned storey types leads to the ceilings being counted twice, so that, in the end, the sum of the results for all the storeys of one building is higher than the original total result for that same building. However, this is unproblematic, as this approach aims at comparing the characteristics and embodied emissions of each individual storey rather than those of the whole building. The total surface areas, as well as the shares of all element contributions for each storey, are shown in Fig. 1. Fig. 2 illustrates the main characteristics of each of the buildings from the sample.

5. Carbon emission results for the two different cutting approaches

5.1 Results for virtual cutting approach 1

Fig. 3 shows the results of the embodied carbon emissions analysis for each building element of each building, using the unit kg CO_2 equivalents per 1 m^2 of energy reference area for 1 year. The graph shows clearly that with this virtual cutting method there is much variation in the distribution and relevance of the results for the different elements. While in buildings 01 and 04 the ceilings and the roof contribute the most to the overall environmental impact of the building, for building 02 the external walls and ceilings are most influential and for building 03 it is the roof, windows, floor and ceilings that affect the result most significantly. These graphs reflect the high degree of originality of each building, emphasising its individual characteristics in comparison with the others.

5.2 Results for virtual cutting approach 2

The graphs in Fig. 4 show the results of the second cutting approach and allow a clearer understanding of where exactly the most significant carbon emissions are located within the building. In the graph at the top left-hand corner of Fig. 4, the results for the annual embodied emissions are shown for each of the buildings per 1 m^2 of individual storey floor space of the basement, ground floor, upper floor and loft respectively. Viewing the building elements in this way, the four buildings display fewer individual differences and a more consistent distribution of the carbon emission results than was observed in Fig. 3 using the first cutting method. Of the four buildings, building 01 has the highest carbon emissions for each storey. The percentage values displayed below this graph indicate the differences in environmental impact of the other three buildings from the sample in comparison with building 01. For the basement, the differences in the results of the four buildings vary by a maximum of 27%, the results of the ground floor by 33%, the

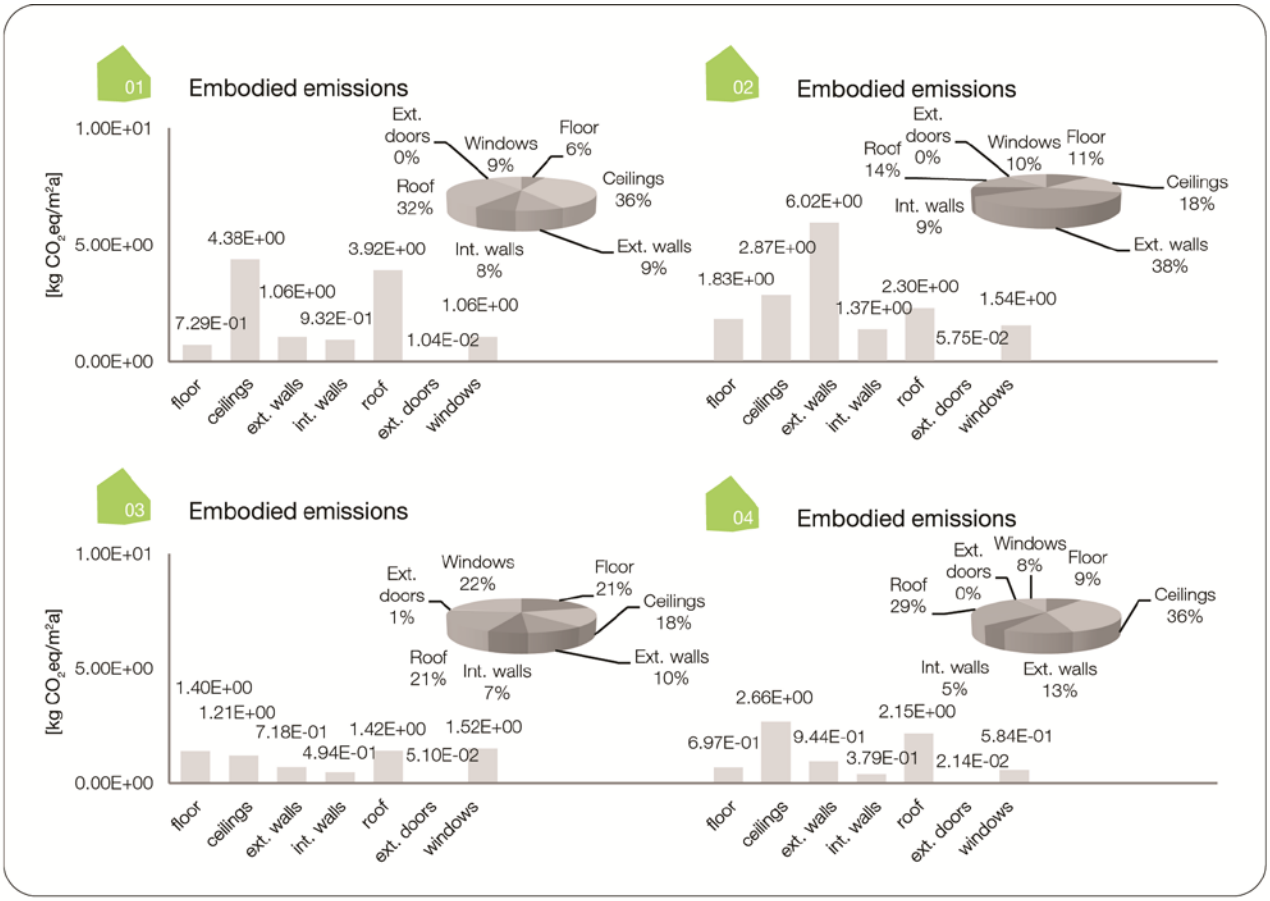

Fig. 3 Embodied carbon emission results (virtual cutting approach 1)

upper floor results by 41%, and the loft results by a maximum of 56%. The individual contributions of the building elements per storey are shown in the graphs at the bottom of Fig. 4. The generally high influence of the ceiling and roof elements for the buildings 01 and 04, the dominant influence of the external walls and ceilings in building 02, as well as the influence of the roof, windows, floor and ceilings in building 03, are also apparent with this second cutting approach. Nevertheless, the buildings resemble each other much more closely when comparing the pie charts of each of their storeys individually than when comparing the buildings as single units. It can be observed by comparison of Fig. 3 and Fig. 4 that by cutting the building into different storeys a more detailed depiction of the embodied carbon emissions for each individual building is obtained, while at the same time a higher degree of similarity within the building sample is perceptible. This enables the determination of the embodied emissions for an average square metre of a basement, ground floor, upper floor and loft. It can be stated, that for this particular building sample a typical square metre of basement contributes 8.07 kg CO_2eq/m^{2}a (±16% deviation) on average, while for the ground floor it is 8.48 kg CO_2eq/m^{2}a (±20% deviation). The upper floor accounts for a mean of 8.04 kg CO_2eq/m^{2}a (±26% deviation) and the loft contributes 14.86 kg CO_2eq/m^{2}a (±45% deviation). Apparently, the basements, ground floors and upper floors of the four buildings have nearly the same environmental impact on average, while the lofts exhibit the largest deviation in their results.

The four graphs at the top right-hand corner of Fig. 4 show the amounts of embodied emissions per 1 m^2 of individual storey floor space for 1 year (y-axis) and the total size of the storey floor space (x-axis) for all four buildings together. For this particular building sample, there appears to be a linear trend, indicating that an increase in total storey floor space leads to an increase in the annual embodied emissions per 1 m^2 of individual storey floor space. However, in order to verify this trend, it would be essential to analyse more buildings, preferably with an energy reference area of ≥ 1000 m^2, as there is a huge gap in the divergence of the sizes of the buildings 02, 03 and 04 on the one hand, and building 01 on the other.

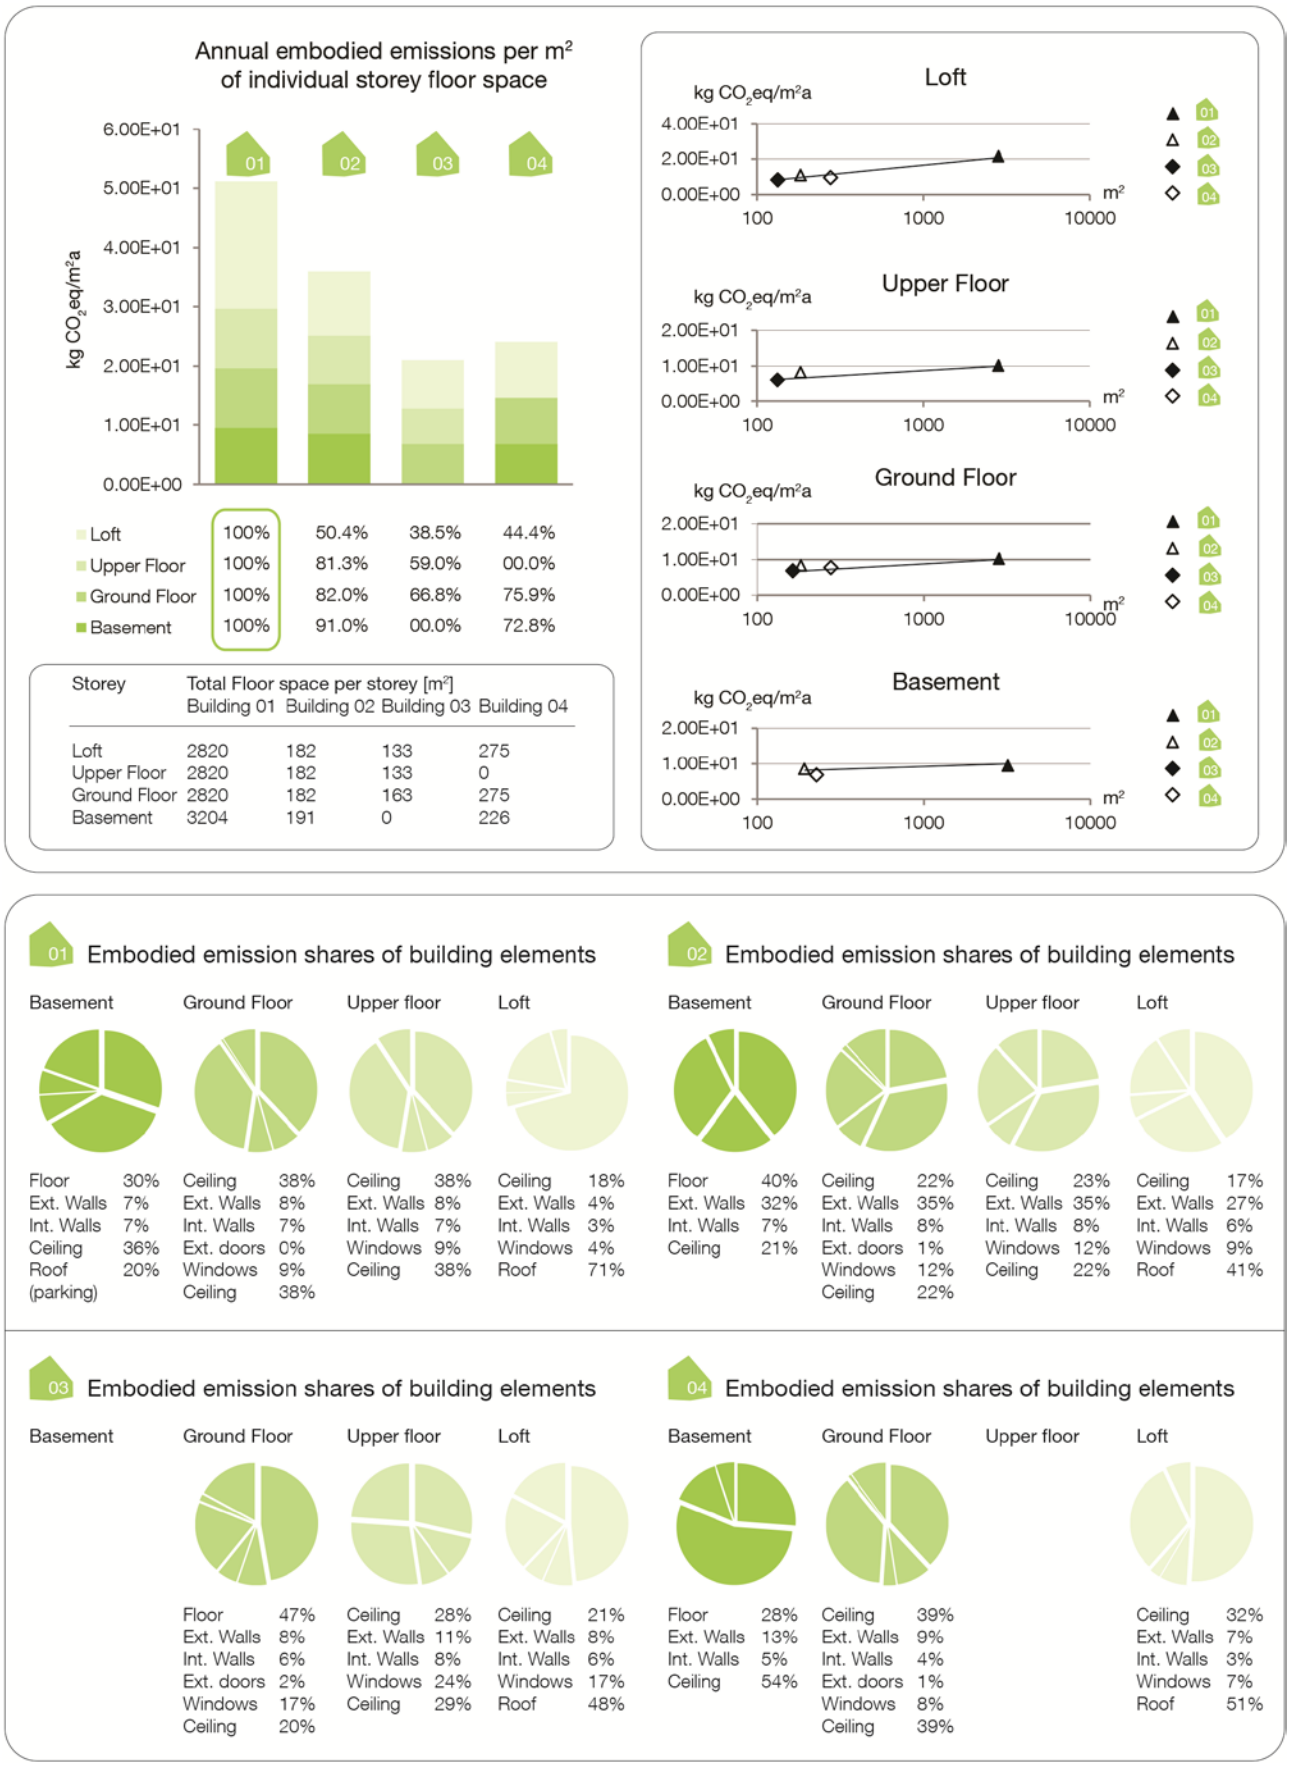

Fig. 4 Embodied carbon emission results (virtual cutting approach 2)

6. Conclusion and discussion

The presented approach of virtually cutting the buildings from the sample in two distinct ways helps to clarify the interrelations of the different individual parts of the buildings within their overall functional context. While the first functional unit can be utilized in order to get a broad view of the embodied carbon emissions of the various building elements of the whole building, the second functional unit enables a more sophisticated allocation of the results, with regard to the anticipated location of the most relevant elements per storey. In their combination, the two approaches allow a meaningful presentation and interpretation of the impact of each of the building elements by showing them from different perspectives and with different levels of detail. It can be observed that the second virtual cutting approach shows fewer individual differences and a more generic distribution of the carbon emission results of the four buildings compared with the results of the first cutting approach. This second approach thus helps to derive a comprehensive and intelligible answer to the question of where the embodied CO_2 of the buildings is mainly located, and, beyond that, helps determine the embodied emissions of an average square metre of basement, ground floor, upper floor and loft with a minimum and maximum deviation from the mean value. As the buildings within the depicted set exhibit a high level of variety with regard to their construction types and the embodied carbon emissions of their individual building elements, the rather high degree of homogeneity of the results as displayed by the second virtual cutting approach is especially remarkable. It was demonstrated that by schematically cutting the buildings on the basis of only a few simple conceptual assumptions about the specifications of each storey, a consistent comparison of a set of diverse buildings is feasible, and that quite similar results can be generated from the direct comparison of the same storey of the various buildings. It was shown, that the carbon emissions results per specific storey floor space of the basements, ground floors and upper floors of the four buildings are nearly the same on average (around 8 kg CO_2eq/m^2a), while the loft exhibits a significantly larger variation in the results than the other storeys. This finding might help in roughly estimating the impact of a standard storey of a building. Determining the impact of a standard storey of basement, ground floor, upper floor and loft can help architects and planners to quickly evaluate the performance of their building design using these values as benchmarks, enabling them to localize which storey and which building elements bear the highest optimization potential for their specific project.

Short Summary

Zero Carbon in the building industry is a goal that can be reached by focusing on energy- and resource-efficient solutions and by utilising renewable resources both for building materials and energy supply. By this, buildings and settlements can become CO_2 neutral and independent from fossil energy resources. The project *Zero Carbon Village* has developed solutions in three strands and is planning to implement them in a residential settlement:

1. Efficient modular prefabrication, consisting of a technical part (industrialised prefabrication of building and service modules) and an organisational part (*virtual factory*)
2. Highly energy-efficient and sustainable building materials (straw bales as insulation materials in prefabricated wooden frames)
3. Energy self-sufficiency: Buildings shall be supplied mainly with renewable thermal energy

In the strand of *modular prefabrication*, industrialised mass production of ecological passive houses and modules and the development of a *virtual factory* lead to an improved competitiveness, higher quality, and higher flexibility. Modular building elements can more easily be disconnected and upgraded with respect to changing user expectations (*re-use system*). In the concept of the *virtual factory* existing SMEs (small and medium enterprises) produce building parts in a decentralised way while a central umbrella organisation takes care of logistics and marketing. This concept takes into account the requirements and resources of small companies.

Not only building elements, but also construction materials can be re-used and recycled. Disposal of materials should always be the last option (*cascades principle*). The development of *highly energy-efficient and sustainable building materials* based on renewable resources is an important step towards the reduction of “grey energy”. Straw bales as certified building material play an important role: they have been adapted for pre-fabrication and modular construction, based on results of previous projects (certification of straw bales). Logistics and production processes were optimised as well in order to reach high quality of the building material.

Energy self-sufficiency of the buildings in the settlement is based on the utilisation of thermal energy, which is gained from solar energy and biomass. The *Zero CO_2 Cooler*, a refrigerator running on hot water, is also being developed to be integrated in this system.

Keywords: Renewable building materials; renewable energy; life cycle analysis; life cycle design; sustainable systems for buildings

1. Introduction

A relatively large percentage of energy and resource consumption occurs in the building sector [1]. This concerns the production of building materials, the construction of buildings and also the energy consumption during the use phase caused by the users. Energy for space heating and increasingly for space cooling is needed especially for buildings of low energetic standards. Furthermore, energy for domestic hot water and appliances (like cooking stove, washing machine, light and other electrical devices) is required. Along the life cycle of buildings additional energy and resource consumption results from demolition and disposal of buildings or building parts at the end of their lifetime.

Huge amounts of construction waste are a further consequence of demolition or remodelling of buildings as well as waste at the construction site (packaging, plastic pipes, clippings of insulation materials etc.), which is difficult to recycle or dispose of.

1.1 Project aim

With its high consumption of energy and thus mostly fossil fuels for the majority of processes, the building sector is also one of the biggest perpetrators of CO_2 emissions. But buildings and settlements can become CO_2 neutral and independent from fossil energy resources. To reach this goal, different solutions have been developed to be implemented in a settlement in Lower Austria, containing residential buildings, a community center and an innovative energy supply system.

1.2 Methods

The concept of Zero Carbon Village is based on energy-efficient building solutions (passive house components, improved household appliances, thermal insulation etc.) and on the utilisation of renewable resources for building materials to reach a lower energy demand for production as well as shorter transport distances. In addition to this, deconstruction is considered from the planning process on to promote recycling and composting after the use period. For a further reduction of the carbon footprint it is also necessary to have an energy system using locally available renewable resources.

2. Modular Prefabrication

One of the approaches to reach the aim of resource and energy-efficiency is the standardised prefabrication of components combined with an efficient coordination of the participating companies. With this strategy, waste will be reduced to a minimum as well as unnecessary material consumption through design and installation errors [2].

2.1 Advantages of prefabricated building parts

In the field of industrial prefabrication, manufacturing processes of building components and modules are standardised so that the finished parts are aligned to each other. Therefore the construction time on the building site can be shortened, material waste reduced and assembly faults avoided.

Prefabrication is already possible for large elements, such as complete bathrooms units or rooms with integrated kitchens [3]. Continuation of modularisation should encompass the manufacturing of compatible elements for the building envelope, housing technology as well as appliances. This requires inter alia a well-planned cabling concept for all components of the energy system (supply and demand side). The system of wires and pipes should be kept short and without crossing so that the elements are easy and fast to connect on the construction site. The cabling has to be taken into account already in the planning phase. The design of the floor plan types is important in this context as well if the modules and the housing technology should be combined in an efficient

way while still allowing flexibility.

Beside an efficient connection of the building envelope and housing technology in a high quality, the modular building elements have the advantage of being easily assembled, disassembled and upgraded after their useful life or when user demands change (*re-use system*) (see fig.1) [4].

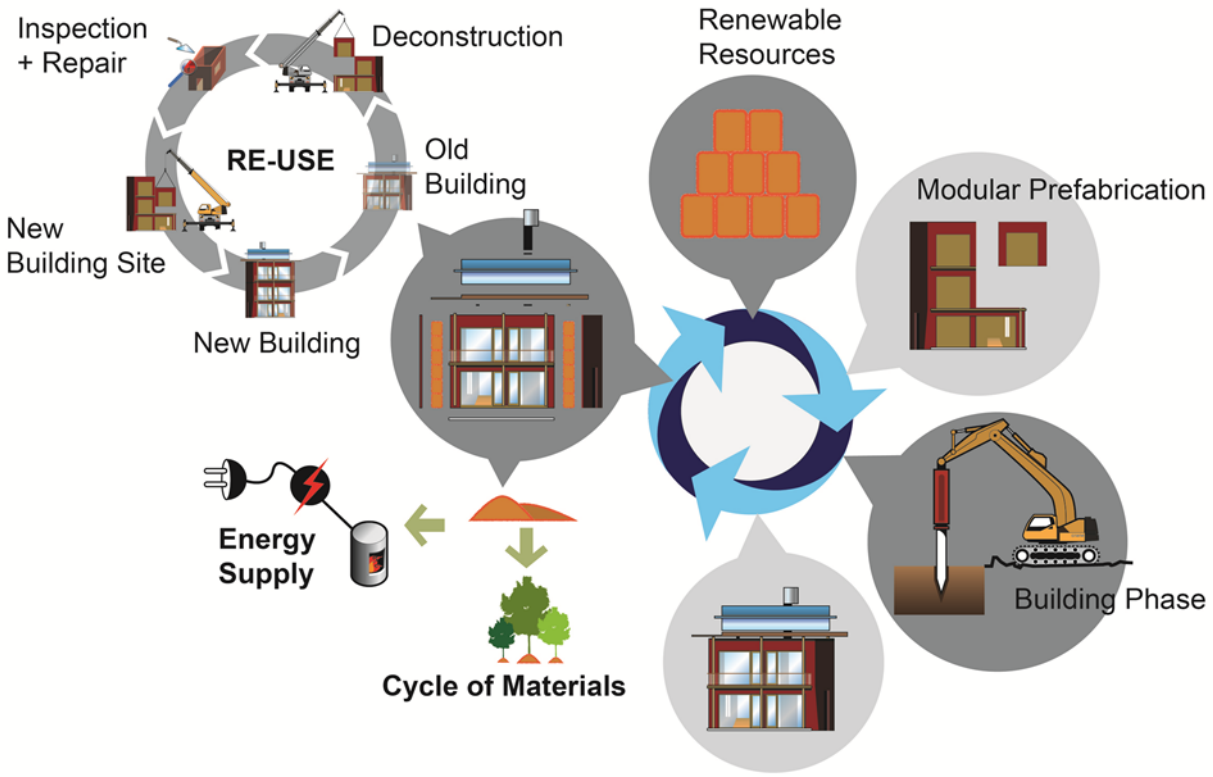

Fig. 1: Life cycle of building materials and components [4]

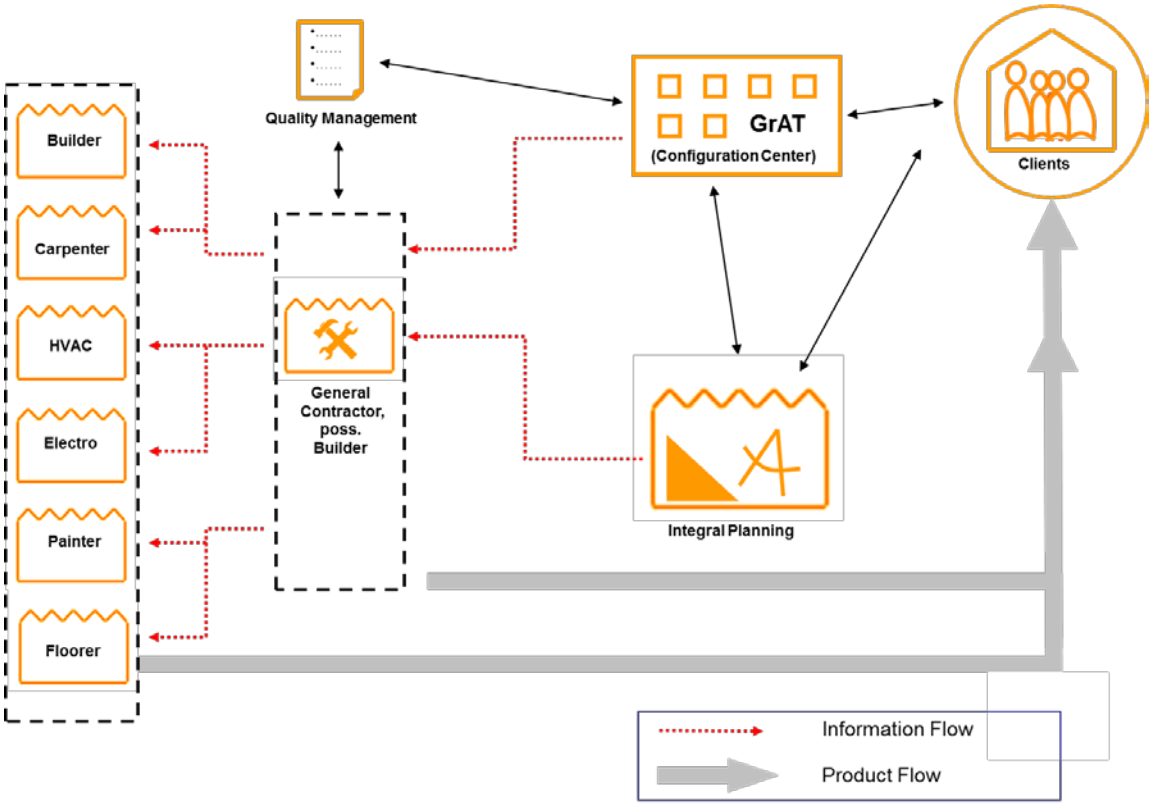
Waste as well as time and energy can be saved during the building phase through prefabrication of elements and modules. This is not only beneficial for building owners, but also for manufacturers because of a more economic production with higher quality.

2.2 Virtual factory

The production of prefabricated modules can take place according to the concept of the *virtual factory*. In this concept single elements or building parts can be produced in a decentralised way by a network of SMEs (small and medium enterprises) around the key trades builder/carpenter. Logistics and marketing on the other hand are performed by a central umbrella organisation to increase efficiency and competitiveness. The whole process is carried out through integral planning in which also the clients are involved from the beginning. In the virtual factory individual enterprises can continue to work in their own domain and region, but realise major projects together with the other partners.

This organisational concept combined with modular prefabrication is an efficient way of reaching high quality of the manufacturing of buildings and is also perfectly suitable for the use of regional construction materials to contribute to the overall objective, the increase of the regional added value (see fig. 2). [4;5]



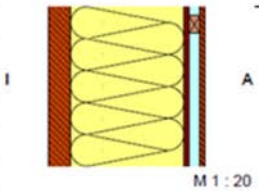


Fig. 2: Virtual factory [5]

3. Sustainable Building Materials

Not only whole building parts and modules, but also individual construction materials can be re-used, recycled or used for energy production, as shown in fig. 1. The degree of recyclability depends on the properties of the used materials as well as their assembly within the construction.

Highly energy-efficient and sustainable building materials based on renewable resources, such as straw bales, have been proven to be functional, and show a very low primary energy demand (PEI) and positive effect for the CO_2 balance of the building [6;7;8]. With the Austrian Technical Approval (ÖTZ) in 2010, the functionality of straw bales as an insulation material has been certified [9]. Because of the simple production process (the raw material straw only needs to be pressed and tied up) the production energy of the straw bales is by a factor of 100 lower in comparison to conventional insulation materials such as EPS, comparing wall constructions with the same U-value. There are several variants for wall construction using wood and straw, one of which is pictured in fig. 3.

AW straw-wood

	U =	**0,081**	-96,49	390,16	

Fig. 3: Wall construction of renewable and local materials [10]

A first variant consists of whole modules which have been prefabricated and filled with insulation material in the factory. A second option is to prefabricate individual elements and then let SMEs of the virtual factory assemble them on the construction site.

For the second variant, as shown in fig. 3, it is possible to prefabricate the elements made of CLT (cross laminated timber) accurately with a CNC shaper as well as the wooden components for the façade, which then are supplemented on site with the materials straw and clay, which were taken from immediate vicinity. All materials used in this construction can be disassembled and therefore re-used or recycled (see cascade principle in fig. 4).

Disposal of materials, renewable or non-renewable, should always be the last option. A lot of cascade potential however is wasted because of material composites which are no longer separable. Therefore it is necessary to use detachable connections and fittings, which can already be foreseen in the factory. Concerning the re-use and recycle possibilities it is hence important to examine not only single materials but to evaluate the entire construction [10].

Wood-straw wall construction	Useful life	Composting	Product recycling	Material recycling	Thermal utilization	Disposal	Additives	Regional
CLT-wood	100	no	re-use	further use -> e.g. chipboards	yes - 18 MJ/kg	possible after thermal pre-treatment	very small proportion of binder materials (PUR adhesive)	yes
straw bales	50	yes (after opening)	re-use (if necessary cutting/tying -> insulation material)	further use (opening, if necessary baling) -> straw bales, fertilizer, bedding	yes - 17,5 MJ/kg	possible after thermal pre-treatment	thread (hemp, sisal, PP)	yes
clay plaster	100	yes (if only natural additives)	re-use (moistening with water, cleaning -> clay plaster)	further use (moistening with water) -> new clay products	not possible	disposal category 3 possible (but usually composting)	hemp, flax etc. possible	yes
wooden laths (timber, planed, tech. dried)	60	yes	re-use	further use -> e.g. chipboards	yes - 18 MJ/kg	possible after thermal pre-treatment	-	yes
wooden fasade (timber, rough, air dry)	60	yes	re-use	further use -> e.g. chipboards	yes -18 MJ/kg	possible after thermal pre-treatment	-	yes

Fig. 4: Cascades principle [10]

4. Energy self-sufficiency

Demand for electricity keeps rising in private households of EU-27 countries, despite increasingly energy-efficient devices. From 1999 to 2009 demand has risen by 18.5 % [11]. This situation asks for a resource-efficient energy concept that foresees renewable energy sources, such as the one which is planned to be installed in the Zero Carbon Village.

In conventional energy systems in households, most appliances are operated by electricity although they actually provide thermal energy services. In contrast to this, the *energy self-sufficiency* of the buildings in the Zero Carbon Village is based on the maximum utilisation of thermal energy gained from solar energy and biomass. All thermal appliances such as washing mashine or dishwasher are operated by thermal energy. Also the *Zero CO_2 Cooler,* a refrigerator running on hot water, is being developed to be integrated in this system [12], while cooking is provided by biogas.

Through a consequent consideration of the required form of energy and the use of the most appropiate technologies, it should be possible, based on the energy balance (input/output), to reduce the consumption of electrical energy by up to 80% compared to the median consumption of Austrian households [13] (see table 1).

Table 1: energy consumption and saving potential in Austrian households through ZCV energy concept [4;5]

electric loads in households	median	electricity ZCV	electricity reduction to	thermal energy ZCV (excl. heating)
	kWh/a	kWh/a	%	kWh/a
hot water heating	1612	0	0%	1612
recirculation pump	347	347	100%	0
freezer	329	0	0%	189

** calculated energy demand for heating of the S-House [8]

The settlement Zero Carbon Village is foreseen to contain 80 living units distributed into different multi-storey buildings (two and three floors) as well as terraced houses with an average size of 85 m^2. Thus electrical energy demand for the entire village is about 54 MWh/a and thermal energy demand is about 198 MWh/a (without heating).

Because of measured solar radiation for the chosen location in Lower Austria (global radiation 1559 kWh/m^{2}a, direct radiation 710 kWh/m^{2}a, diffuse radiation 848 kWh/m^{2}a) [14] a theoretical demand for 250 m^2 of photovoltaic panels as well as 767 m^2 of solar collectors has been calculated for the provision of all 80 living units. However, due to imbalanced radiation over the year, especially in winter, a biomass back-up system is necessary to cover the thermal energy demand, using e.g. logs or wood pellets. Technologies for the production of both thermal and electrical energy, such as micro-CHP, are an optimal supplement for solar collectors and photovoltaic systems in winter seasons. For provision of the cooking devices 28 m^3/d of biogas are needed, which can be produced in a local biogas plant close by [5].

5. Results, discussion and conclusion

To reach the project goal, a carbon neutral settlement with an innovative energy supply system, it is necessary to combine the three strands: modular prefabrication, sustainable building materials, and energy self-sufficiency, each of which shows great effects for reducing primary energy demand. For implementation and further replication on a larger scale, they have to be combined while taking into account urban development aspects, since building compounds bring in additional resource-saving options as compared to individual buildings: Building density, number of stories, A/V (surface area/volume) ratio and building orientation are factors that influence the heating energy demand and which are relevant for integration into the urban environment. High density housing thus shows advantages compared to one-family houses [15].

The emphasis on material and energy decisions is seen in a broader scope of different requirements: The dense typologies are complemented by services to target an efficient overall concept, such as collective waste management or mobility concepts (support of public transportation, car sharing programs, charging stations for e-cars, individual parking places exclusively situated at the boundary of the area). The outdoor area can be designed using

environmentally materials for pathways [16] and green areas as well as common kitchen gardens can be provided.

In order to reach sustainable development of the settlement, it is necessary to provide different options for housing and usage so as to attract diverse demographic target groups (varying in age, income, family status, etc.).

Taking into account these planning aspects on a larger scale and combining them with energy and resource-efficient solutions on a technical level thus brings about carbon neutral solutions which can also be up-scaled to urban development.

Keywords: Sustainability, carbon efficient constructions, Life Cycle Assessment (LCA), carbon footprint, wooden buildings

1. Introduction

This paper is based on the findings of the European €CO2 project and its Austrian part EcoTimber. Both projects focus on defining the carbon footprint and primary energy balances of wooden houses during their full life cycle. The project consortium consists of 20 research organisations and companies from Finland, Sweden, Germany, Italy and Austria. The €CO2 project stared in November 2010 and ended in March 2013, while EcoTimber will finish in September 2013 [1].

“Wood is an environmentally friendly material. Wood houses are carbon storages.” These claims have been heard countless times, but often lack scientific proof. Fundamental understanding of how carbon footprint and primary energy balances accumulate during the full life cycle of a building is often missing. Tracking greenhouse gas stocks and flows of wood-based construction materials from cradle to grave is a complicated task, and many methodological questions are still subject to discussions amongst experts. Within the €CO2 and EcoTimber project the aim was to contribute information on this topics and cover the knowledge gap by (1) creating holistic understanding of carbon efficiency in the full life-cycle of a building, (2) by defining technical potential and obstacles for the use of wood in carbon efficient constructions, (3) by developing practical solutions for calculating and optimising the carbon footprint of different wood construction systems and (4) by disseminating results to relevant stakeholders, including construction industry.

The first part of this paper focuses on the methodological considerations of the project team. It will briefly summarise the standards that where applied and give an overview on methodological discussions among the European research partners on topics beyond standards. The consequences of the LCA methods chosen on the Austrian datasets will also be described in brief. The second and major part of the paper is dedicated to the LCAs of wood products and three wooden residential buildings that have been carried out by the authors. Several variations on the buildings and HVAC concepts have been taken into account, some of which will be discussed in detail. The evidence of the results of these building LCAs on the discussion on carbon efficient buildings as well as further research questions will be discussed at the end of the paper.

2. Methodological considerations

Within the €CO2 project assessment concentrated on three environmental impact categories, namely green house gas (GHG) emissions, carbon storage and primary energy (PE non-renewable, PE renewable process and PE renewable feedstock). Standards for Life Cycle Assessment (LCA), the calculation of carbon footprint and environmental product declaration (EPD) were taken into account when deciding on a common calculation method. Life cycle phases were defined and represented according to EN 15804. An overview on relevant standards is given in figure 1. According to the standards, LCA of construction works can be carried out on two levels: product level and building level. As the project covered LCAs for wood products and buildings, methodological issues always had to be discussed on both levels.

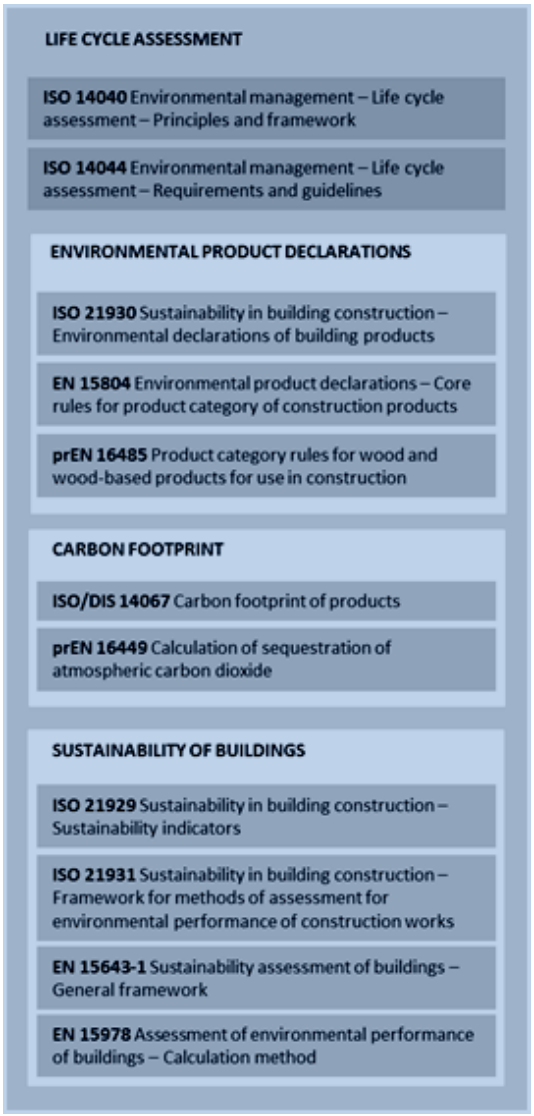

Figure 1: Overview on relevant standards (source: €CO2)

2.1 Databases

The environmental assessment of products and buildings requires a lot of input information, for example on the quality and quantity of materials and elements needed, the impact for their extraction and treatment, the energy demand and supply of the building, maintenance work and end-of-life scenarios. Such information can be taken from assessment tools and databases or be compiled for the specific case. The latter option enables much more precise results but is often too time-consuming. Generic information taken from databases such as ELCD (European reference Life Cycle Database, facilitated by the JRC of the European Commission) [2], GEMIS database [3], the German GaBi [4] or the Swiss Ecoinvent databases [5] is much easier available but may not always represent the materials and processes of a specific product or building. Within the €CO2 project generic and specific data have been compared for certain cases (e.g. data on the wood harvest process in Austria have been compared with Ecoinvent data, see figure 2). For the building case study databases have been combined with specifically imposed data (e.g. in Austria Ecoinvent data and more specific data from the IBO software EcoSoft have been used).

2.2 Special LCA topics

The comparability of case study results, even if based on the same standards is limited, because of the use of different input data but also because of methodological decisions beyond standards. Discussion within the project aimed at the definition of functional units, allocation, service life of products, building elements and whole buildings, system boundaries, energy supply, carbon storage in building elements and consideration of substitution and end-of-life scenarios. A book published on the results of the projects provides detailed information on each of these issues[1].

[1] The book was not published at the time this paper was facilitated. Information on this publication will be available from the project website and directly from the authors.

The use of physical or economic allocation methods to split up input and output flows on two or more co-products was controversially discussed amongst the experts of the project. The topic was especially important to the project as the wood working industry often produces multiple products. On building level, allocation is important for the construction stage (phase A5) for allocating energy to different processes on the construction site. EN ISO 14044 states that allocation must be avoided wherever possible (e.g. through dividing of processes in two or more sub-processes or expanding the product system and including additional functions related to co-products) [6]. If this is not possible EN 15804 foresees the following allocation rules: Use of physical properties such as mass or volume if the difference in the revenue generated by the co-products is low (a difference below 25 % is regarded as low). For higher differences economic allocation, based on market prices or price-relations, should be used [7]. However, this 25 % rule sets an arbitrary boundary that may be problematic for some wood based products.

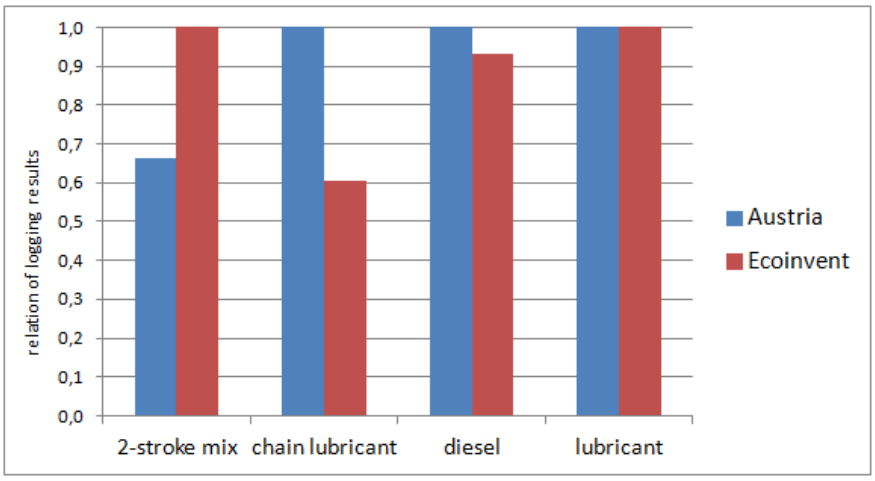

Figure 2: Harvesting Austria compared with Ecoinvent. Data in litre per bank meter from 100 % (own analysis [11])

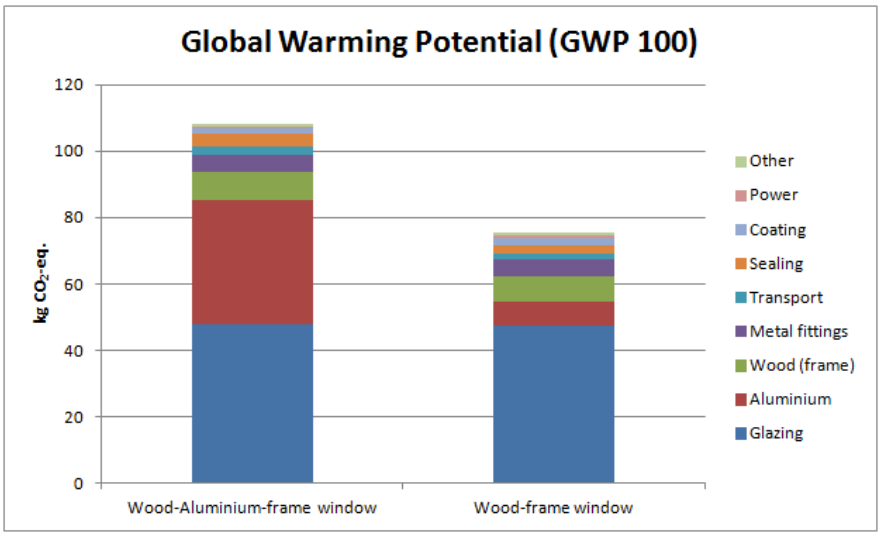
When analysing the whole life cycle of a building, service life becomes an important parameter for calculation. International and national standards and guidelines recommend different life spans that are often inconsistent. Within the €CO2 project service life of building elements has been determined according to a scientific literature-based background document facilitated by Takano [8]. On building level a service life of 50 years has been decided for common analysis. Although different standards state much longer service lives for wood buildings [9] and products [10], many buildings are reconstructed much earlier for socio-economic reasons.

Other controversial topics are the handling of carbon storage in building elements during the service life of the building and scenarios for the end-of-life phase. When a tree is harvested, the carbon accumulated during its life time is transferred into other pools such as building elements, where it is temporarily stored during the lifespan of the building. In the meantime, assuming sustainable forest management, another tree is panted and accumulates carbon while growing. On a landscape level the carbon stock in living biomass therefore tends to be stable or even rising over time, as harvested trees are compensated by new trees growing [12].



Over the life cycle of a building, there is no change in the carbon stock in the building itself [13]. In the LCA, stored carbon can be indicated by the negative values for carbon feedstock in phases A (production) and B (maintenance), if service life of the product is more than 10 years [14]. At the end of the service life, wood can either be reused (in that case no carbon is released to the atmosphere), decomposed or combusted. In the latter cases the carbon stock is oxidised and re-enters the atmosphere as CO_2. These emissions add to the total GHG emissions in phase C of the LCA. If the burned demolition material is used to replace fossil fuels, a reduction in CO_2-emissions depending on the energy content of the material can be accounted for in phase D (substitution) [15, 7]. This is considered to be one benefit of using wood constructions; however the quantification of these GHG benefits is discussed controversially, because of e.g. varying carbon intensity of the fossil fuel replaced, leakage, soil carbon reduction and uncertainties about how wood will be han-

dled by future waste management systems [15]. According to global total primary energy consumption predictions by the European Environment Agency (EEA), coal will increase its share dramatically until 2030 [16]. Considering this fact replaced fossil fuel should be coal. In present calculations natural gas, which seems to be the domestic marginal energy type, is the replaced fossil fuel according to the agreement in the LCA paper of EPD platform Austria [17]. The benefit of temporal storage of carbon during the service life of the building is more difficult to assess and therefore not displayed in the LCA. A carbon sequestration effect occurs, when the total stock of wood buildings is increasing and lasts until the amount of wood entering the building stock is equal to the amount of wood released when demolishing buildings [18].

2.3 Method and database used for the Austrian case studies

Although many methodological issues have been harmonised for use within the €CO2 project, national case studies are still based on country-specific information and assumptions. For Austria the life cycle of three buildings has been assessed. The assessment is based on a mass balance according to the construction details and a generic data set. Basic data for standard processes like energy and transport systems, basic materials, forestry, disposal processes and packaging materials are obtained from ecoinvent data v2.1. Some additional generic data for raw materials and intermediate products have been established by IBO in the course of product assessments and research projects [21]. All data use the UCTE mix from ecoinvent data v2.1 as electricity source, independent of the factual electricity source (UCTE = Union for the Coordination of Transmission of Electricity). The global warming potential (GWP) is calculated according to IPCC 2007 [19], all other LCIA-indicators (not published here) according to CML 2001 v1.05 [20]. The software EcoSoft (v3.4.2) was used to carry out the calculations [23].
The assessment of the buildings is divided into the life cycle phases A to D according to EN 15978 [22]. Data for construction materials are aggregated from cradle to gate (phase A1-3). Transport from factory gate to site (phase A4) is based on average transport distances of building products in Austria. For the construction process of the building on site (phase A5) only digging, evacuation of excavation material and refilling with gravel were considered. The amount of material losses was calculated according to Takano (2011) [8]. Energy demand for heating and warm water use in the use phase (phase B6) was calculated according to the Austrian energy performance certificate for buildings. Replacement of building products (phase B4) was considered, all other B phases (maintenance, repair and refurbishment) were disregarded. Deconstruction and transport from site to waste treatment (phase C) is taken into account and depends on the material. For module D a typical scenario for the Austrian situation of waste wood treatment is applied. More details on the assessment methods can be found in IBO (2009) [21].

3. Life cycle analysis on product level

For the following products life cycle inventory data was collected: Cross laminated timber (CLT), windows, doors, internal doors, glued laminated timber (GLULAM), wooden floors, solid wood boards and cellulose fibre.

Figure 3: Share of components of GWP100 without considering carbon storage for wood frame and wood-aluminium frame windows. One standard sized (1230 x 1480 mm), triple glazed window (own analysis)

Data for the production of these products was collected directly from manufacturers. Questionnaires have been sent to the companies, covering the following topics: raw material, ancillary input, output, packaging material, production energy, emissions, production waste, wastewater and additional questions to the entire life cycle: delivery, mounting, use phase and end of life. Additionally each plant has been visited at least once to verify the data collected. The LCA calculations were carried out using Simapro LCA software with Ecoinvent database.
Since assessment results can't be published directly, mean values for the share of components of GWP100 without carbon storage for wood frame and wood-aluminium frame triple glazed windows are shown in figure 3 as an example, representative for the different examined products. Considering that a wide range of manufacturers participated in this project, results can be seen as quite representative for Austrian wooden products.

4. Life cycle analysis of three wooden residential buildings

Within the €CO2 project, case studies on building LCAs where carried out in all participating countries. While the production phase A1-3 with an observation period of 50 years was considered by all partners, further emphasis of the research was decided individually for each partner. The aim of the Austrian case studies was to analyse primary energy input and CO_2-emissions over the life cycle of very energy efficient residential buildings (Passive Houses and Nearly Zero Energy Buildings – NZEB). Three existing buildings, one multi-storey building (MSB), one row house (RH) and one single family house (SFH), which represent typical residential buildings according to the Austrian building typology (developed within the EU-project TABULA [24]) have been chosen for this analysis. However, the wood construction systems they incorporate are quite innovative and not yet common (for these building types) in Austria. The external walls of the MSB and SFH are massive wood constructions (CLT panels) with an insulation of mineral wool. The RH consists of post and beam external walls with glass wool in the cavities and a polystyrene external insulation. The roof and ceilings (except for the basement ceiling) of all three buildings are made of CLT as well. All buildings feature a high degree of prefabrication.

Table 1: Overview on three case study buildings (reference cases)

	Multi-storey building (MSB) Mühlweg	**Row house (RH) Steinbrechergasse**	**Single family house (SFH) Schönkirchen**
			
Gross floor area	2.052 m²	668 m²	210 m²
Living area	1.565 m²	531 m²	161 m²
Number of flats	18	5	1
Construction system	massive wood construction, concrete basement	wooden post and beam construction, concrete basement	massive wood construction, brick garage
Heating demand	8,3 kWh/m²a	14,1 kWh/m²a	11 kWh/m²a
Operative energy use	86.875 kWh/a 42,3 kWh/m²a	40.240 kWh/a 60,3 kWh/m²a	2.923 kWh/m²a 13,9 kWh/m²a
Heat generation	combined gas and solar thermal system	pellet boilers	heat pump
Heat distribution	ventilation system, radiators	ventilation system, radiators	ventilation system
Electricity generation	-	PV (151 m² solar panels)	-

The MSB and the SFH have been built according to the Passive House standard (heating demand of less than 15 kWh/m²a according to PHPP calculation software) while the row house was originally designed as a Low Energy House with an average heating demand according to Austrian building regulations. Within the project the row house has been virtually changed into a Nearly

Zero Energy Building by use of PV-cells, mechanical ventilation and additional insulation. The buildings are supplied by different heating systems but are all equipped with mechanical ventilation with heat recovery. Table 1 provides an overview on the three case study buildings.

For all three buildings different parameters have been modified to analyse the effect on the LCA results. Variations include different construction systems (wood, brick and concrete construction for the MSB and SFH; higher and lower insulation standards for the RH), energy supply systems (variation in the heating system for the MSB, additional PV system for the RH), building concepts (with garage or basement for the SFH) and service life (50 and 100 years for all reference cases). Additionally several detailed analysis have been carried out, e.g. focusing on the dominance of building elements and materials. Some of the results will be discussed more in detail on the following pages.

For the RH a dominance analysis on the building elements was carried out to study the contributions of building elements on the overall results for the production phase (phase A1-3). The results are shown in figure 4. The PV system (consisting of 151 m² collector, inverter, electric installations and fastening system for the roof) contributes most to the emissions (almost 30 %), however it also reduces GHG emissions significantly due to the electricity production, as will be explained later in figures 6 and 7. The concrete elements of the basement also have a large impact on the GHG emissions, followed by the roof, floorings and exterior walls. However, energy input for the basement is almost entirely non-renewable while the other elements store significant amounts of carbon and include a higher share of bonded energy which can be recovered at the end of the life cycle (phases C and D). This can be considered as the advantage of wood as a construction material. The results are also valid for the other two case study buildings.

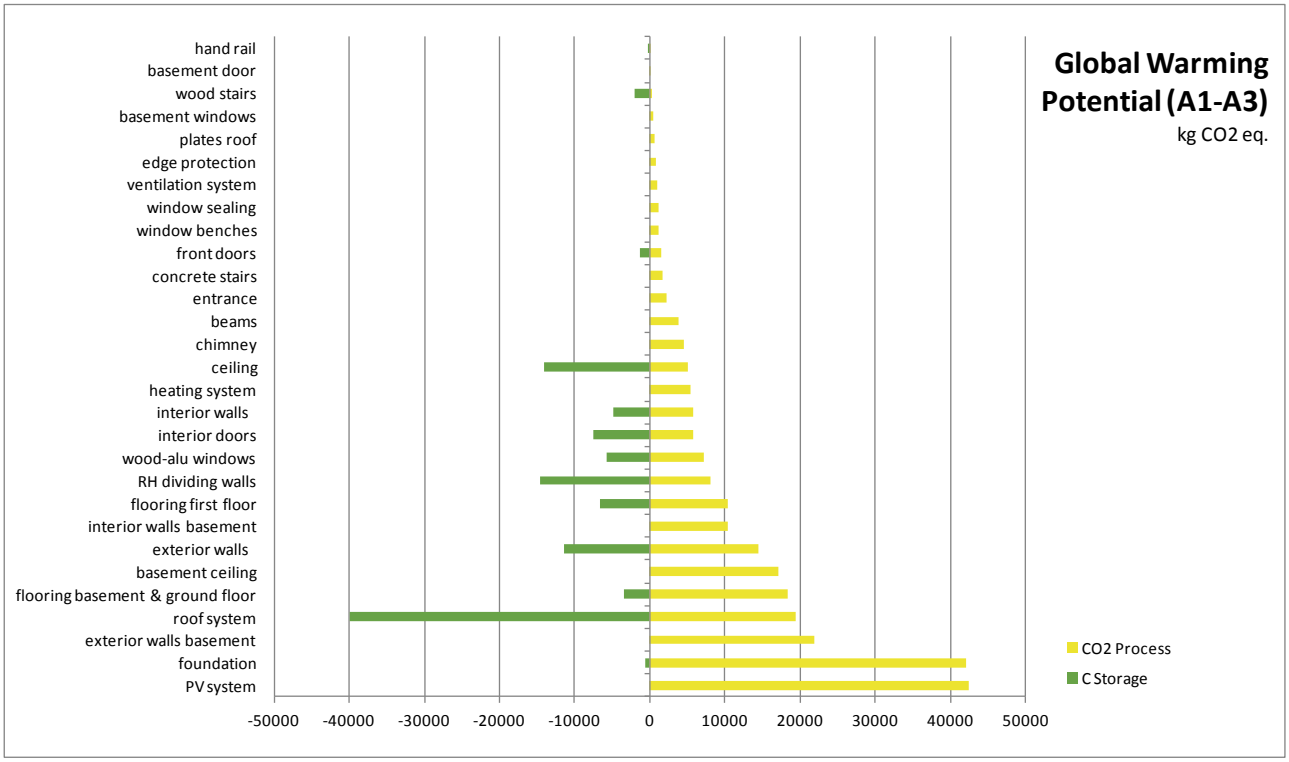


Figure 4: Dominance analysis of GWP from the production of RH components (own analysis)

Figure 5 compares results for the major parts of the buildings in the production phase. However, when comparing results for given three case study buildings it has to be considered that:

- The SFH has an adjoining garage instead of a basement. Impacts of the garage walls, roof, etc. are included in the according building element categories (exterior walls, roof, etc.)

- B6 (energy use) of the row house also includes electricity use for household applications while for the other two buildings this is not included. The electricity use of the row house is almost entirely covered by the PV plant.
- To calculate primary energy of MSB and SFH materials, upper heating values were used while for the SFH lower heating values were considered.

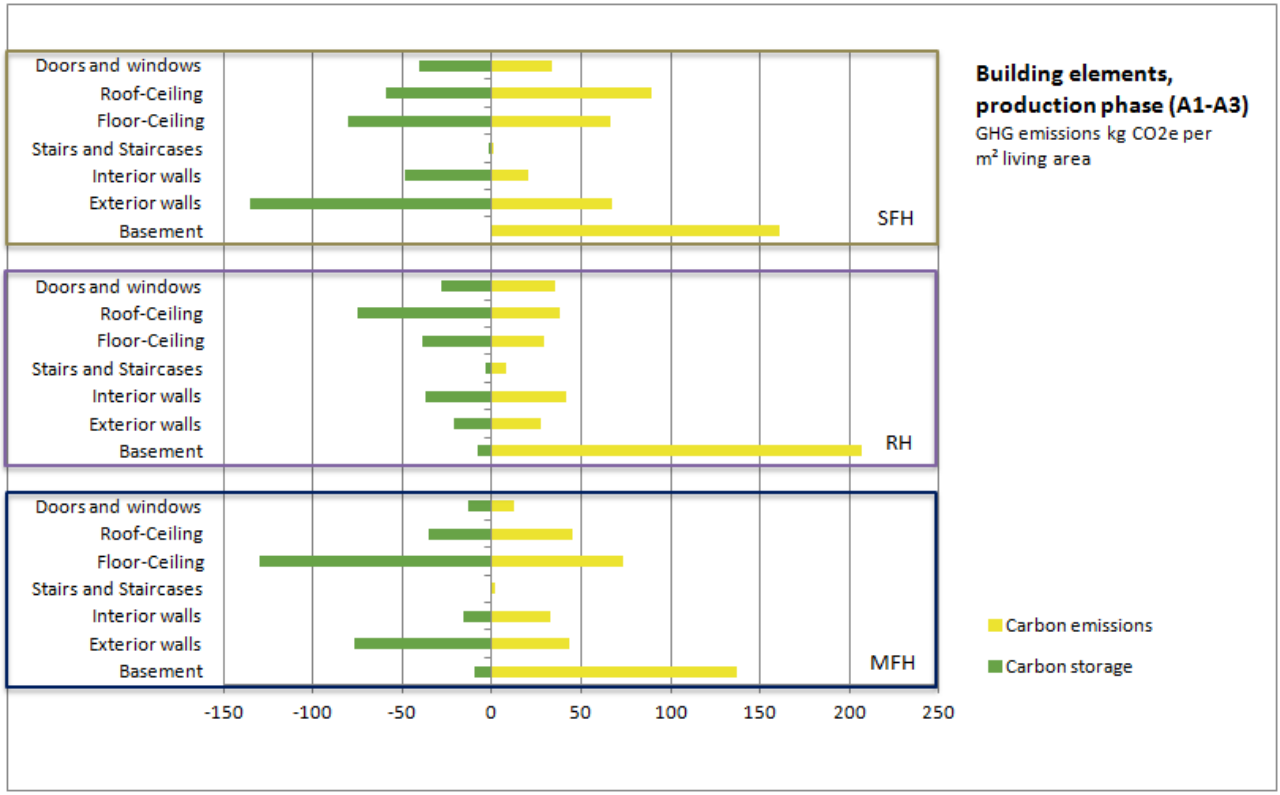

Figure 5: GHG emissions in the production phase (A1-3) for the three case study buildings (own analysis)

Generally more carbon is stored in the solid wood constructions of the MSB and the SFH than in the wooden frame structures of the RH. In all three buildings the non-renewable primary energy use and the GHG emissions caused by walls and roof are increased due to the use of mineral or glass wool and polystyrene as insulation materials. This is especially important for the wooden frame structures since the cavities are filled with glass wool. Alternative insulation materials like cellulose fibres could improve these indicators.

Building service installations are not significant in case of the MSB (gas and solar heating, central ventilation system) and the SFH (heat pump, central ventilation system). However, so far there is only little data available for building service installations and their ancillary materials. Therefore results are subject to uncertainties. More reliable information on building service installations could significantly improve knowledge about the impact of that part of the buildings's life cycle.
When comparing the building concepts of multi-storey building, row house and single family house in terms of primary energy demand per m² in the production and maintenance phase, it is obvious that the dense architectural concept of MSB is the most efficient one.

In figure 6 all life cycle phases over an assumed service life of 50 years (according to €CO2 agreement) for the three case study buildings are compared. Due to this assumption the replacement of materials covered in phase B4 is not very significant. This is due to the presumption that only windows, outside sealing and surface coverings, floor covering and HVAC get replaced once in this period. For all other materials and elements an assumed service life of 50 years and longer is foreseen. It is most significant for the row house as the energy intensive produced PV-plant is exchanged once within the 50 year period. An assumed service life of 100 years significantly in-

creases the primary energy input and GHG emissions for phase B2-5 to a higher level than production phase A1-3, as can be seen in figure 6. In that case production and maintenance phase together may become more important than the energy use of the building. This is a clear indicator that building materials have to be focus of future energy efficient building concepts in the future.

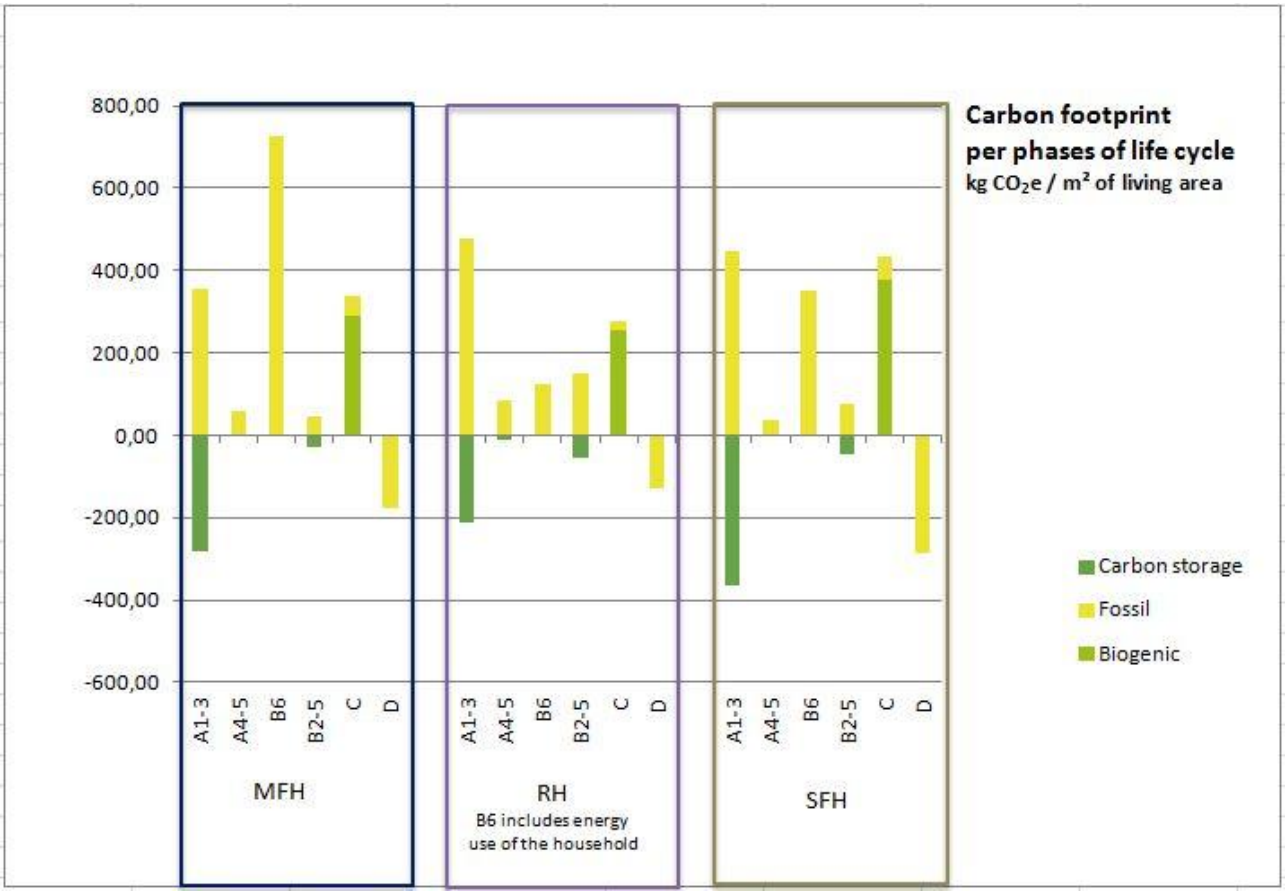

Figure 6: Carbon footprint per phases of life cycle (assumed service life of 50 years) for the three case study buildings (own analysis)

The three buildings are equipped with different building service systems. This has a significant impact on phase B6 (energy use) of the life cycle. The MSB is equipped with a central gas boiler and a solar thermal system which reduces the demand for gas. Nevertheless the non-renewable primary energy demand is quite high compared to the other buildings and contributes to higher GHG emissions. The SFH is heated by a heat pump, the electricity mix is the European UCTE mix. The RH has been designed as a Nearly Zero Energy Building (NZEB) according to the available definitions [25]. The PV-plant has therefore been designed to cover most of the non-renewable primary energy demand of the building for heating, ventilation and household appliances. Nevertheless the total primary energy demand (largely renewable from pellets) for heating and sanitary hot water production is quite high compared to the other buildings. This is due to the low seasonal efficiency of the small scale pellet boilers used for heating and sanitary hot water production. Nevertheless GHG emissions in phase B6 are significantly lower for the RH. This adds again to the future importance of building materials and construction methods (represented in phases A1-3 and B2-5).

The influence of a longer service life (100 years) is apparent from figure 7. This figure compares the results for the primary energy demand of the reference case of the RH over an assumed service life of 50 years (NZEB 50) and 100 years (NZEB 100) with a low energy building alternative (LEB 100 and 50). While the primary energy demand of the production phase remains the same for a 50 and 100 years service life, differences are most visible for energy use and maintenance in

phase B. Generally a longer service life of a building is more energy efficient but service life often depends on socio-economic considerations instead of technical ones.

When comparing the NZEB concept with the LEB concept it is noticeable that non-renewable as well as renewable energy demand are significantly lower for the NZEB. This is due to the additional PV system (non-renewable energy demand) and the surplus insulation and mechanical ventilation system (renewable energy demand). In return primary energy demand in the production (A1-3) and maintenance (B1-5) phases is higher for the NZEB. Nevertheless the NZEB concept pays off in terms of primary energy demand and GHG emissions over the life cycle.

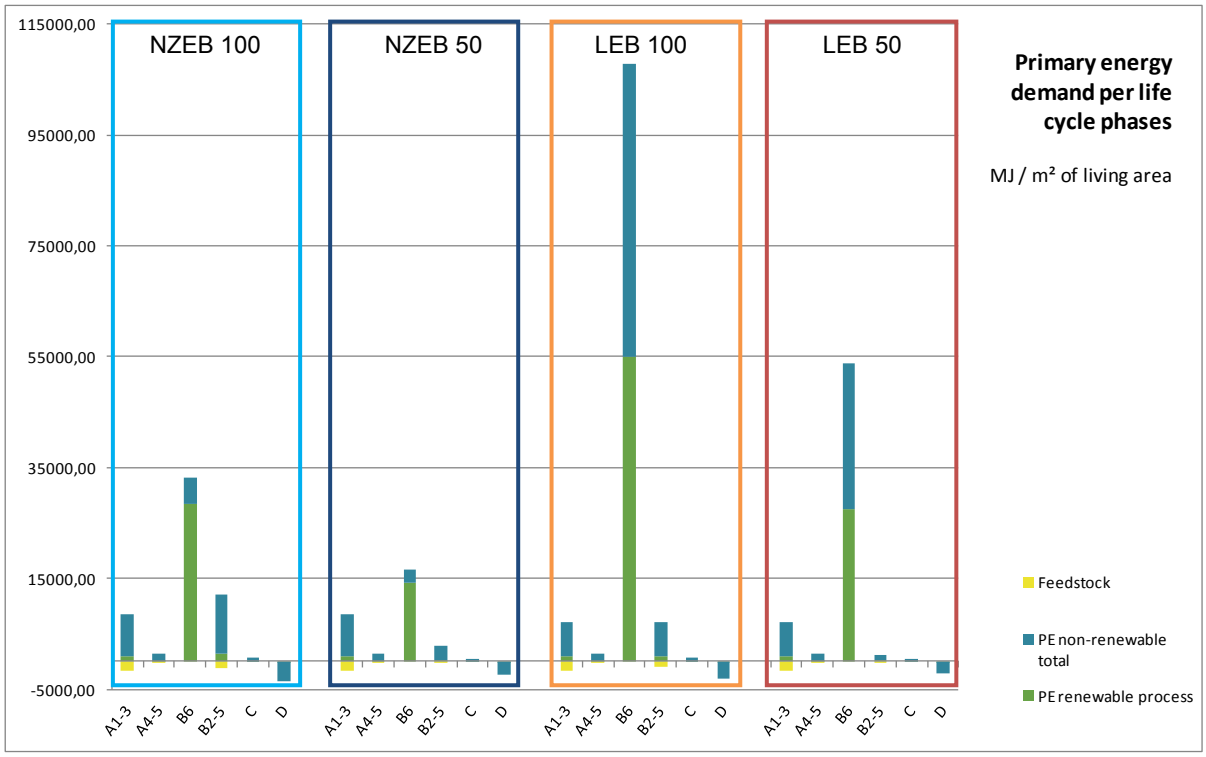

Figure 7: Primary energy demand per phases of life cycle for the RH (own analysis)

5. Conclusions

The projects €CO2 and EcoTimber allowed to discuss methodological issues on LCAs of wood products and buildings within an expert consortium and also add to the knowledge base on wood in the construction sector.

The following lessons have been learned from the Austrian LCA building case studies:

- Energy recovery from wooden residues can be a remarkable benefit for choosing wood for construction material. Nevertheless methodological discussions on how to balance these benefits (e.g. on substitution of fossil fuels) and on how to account for the temporal Carbon storage effect of buildings should not be neglected.
- Wood-framed passive houses with energy-efficient heat supply reduce climate impacts. Generally, massive wood construction systems result into largest amounts of residues and bio-energy potential. More research on the impact of alternative insulation materials would be beneficial.
- High density architecture is more energy and carbon efficient than single family houses. Wood constructions in the multi-storey buildings should therefore be increased. Further research also covering non-residential buildings would be beneficial.
- There will be a shift in the lifecycle carbon efficiency of buildings from use phase to production phase. This is because buildings require less energy for their operation.

- Including all building service installations with their ancillary materials may be very time-consuming and include large uncertainties. Further research is necessary to better cover the environmental impacts of building service installations.

Further important findings from case studies carried out by the other project partners are:

- Site works and foundations seem to have high impact on carbon footprint and primary energy demand. Especially the use of concrete, re-bars and hard insulation boards cause emissions.
- Emissions from construction work and transportation are very case specific. Energy demand from construction work can vary highly depending on the outside temperature, because heating half-finished buildings or pre-fabrication facilities seems to be very energy consuming. Nevertheless, pre-fabrication facilities seem to require less energy than frequent personnel transport to construction sites.
- Design phase does not typically give enough information for carbon footprint or primary energy assessment that is required in standards (EN 15978). Therefore a more flexible assessment scheme for enabling assessment in design phase would be needed.

Short Summary

The purpose of this study is to investigate environmental impact for construction process of wood-based building. Detailed data collection from construction work is conducted on three multi-story wooden buildings. Greenhouse gas (GHG) emission value is calculated for production stage (material production and construction) and operation stage of the buildings, and a ratio of the emission from construction process is observed. The results present that construction phase holds about 20-30% of GHG emission in the production stage. In addition, it is shown that material production phase, construction phase and operation phase of the buildings account for approximately 16-35%, 6-10% and 55-78% of the total GHG emission, respectively. Based on the results, feature of the impact for wood-based construction and an issue regarding the data collection are discussed. This study demonstrates a relevance of construction process in a life cycle assessment of buildings. Since the result of environmental assessment is beneficial for the industry in order to optimize their work environmentally, simple and reliable assessment method is required based on further research.

Keywords: Life cycle assessment, Building construction, Wood-based building, Greenhouse gas GHG emission

1. Introduction

In life cycle assessment (LCA) of a building, major attention has been paid on a use phase of a building due to its high share of environmental impact in the life cycle. The reduction of environmental impact during operation of a building has been main target so far. As a result of the effort, the impact from the use phase has been mitigated and importance of the other life cycle stages has increased [1]. In general, construction material production phase has been regarded as the next target of mitigation and the other phase, such as construction phase, have not had priority because of its small proportion of the life cycle environmental impact [2, 3]. It has been reported that the construction phase contributes 2-26%, in many cases less than 10%, of overall life cycle impact of a building [4-10].

However, recent researches mentioned that the construction phase has relevant impact, and the trend of GHG emissions from construction equipment has increased significantly in the last decades [11-14]. They indicated that the process should not be underestimated and attempted to establish the framework for environmental management during the construction phase. The environmental impact of the process should be known to enable to optimize it in practical level.

The objective of this study is to review environmental impact of construction process. Detailed data collection and the assessment in terms of GHG emission for construction process are conducted with wood-based reference buildings. To make a comparative study with reliable data, GHG emission from material production and construction phase of wooden building elements of the buildings are assessed and compared. Manufacturing and installation of all building service equipment and basement are excluded from the assessment. In addition, the emission from operational energy use of the buildings is assessed and a ratio of the emission from construction process is observed.

2. Environmental impact of construction process

In the last two decades many LCA study on buildings and construction have been conducted. In general, building use phase has been dominant in the life cycle environmental impact of a building in terms of energy consumption resulting in GHG emissions. However, in some cases the construction process seems to have relevant impact with a great potential of reducing the environmental burden of buildings. For example, it has been reported that the use phase accounts for 70-98% of life cycle energy use of a building [15], while the construction phase holds 2-26% of the energy use, depending on case studies [4-10].

Some of the most recent researches mentioned that GHG emissions from construction process should not be underestimated. Ahn et al. [14] found that the decentralization of construction processes, which involves often several subcontractors, leads to critical issues in measuring the significance of GHG emissions from construction processes. Furthermore, the uniqueness of each project and the high fragmentation of the building industrial sector make every improvement difficult to pursue. Mora et al. [13] concluded that GHG emission from construction activities is significant and the trend of GHG emissions from construction equipment increased significantly in the last decade.

Gangolells et al. [16] stated that transportation and construction equipment, waste production, and water consumption have significant environmental consequences, implying that any improvements in these areas could be priority targets for reducing the overall life cycle impact of the building. Bilec et al. [17] found for a concrete parking structure that transportation of concrete to the site, particularly for the precast pieces, is the most significant construction process. Guggemos and Horvath [18] reported that work on the structural frame has the largest impacts in the construction phase, mostly due to heavy use of diesel equipment. This finding was also corroborated by Junnila and Horvath [19].

There is an open discussion of the implications of off-site construction as opposed to typical on-site construction. A relevant study was carried out in northern Japan by Nishioka et al. [20], who considered the environmental trade-offs in vertically integrated factory-built housing, which required more materials than a typical home but also performed better. The authors found that the energy and carbon debts incurred by the additional materials are paid off through efficiency gains in less than six years, well below the average lifetime of homes in that area. Kim [21] compared life cycle impacts of a modular and a conventionally constructed home in Michigan, analyzing energy use, material consumption, GHG emissions, and waste generation. This work suggested that solid waste generation, transportation energy, and GHG emissions are significantly lower when modular construction is used.

Quale et al. [22] carried out a comparative analysis of the two different construction methods considering different scenarios and transportation distances. From the results the GHG emission from the use of prefabricated modular systems is lower than traditional systems due to a limited duration of on-site activities, which leads less waste and worker transportation.

3. Methodology

3.1 Reference buildings

Three multi-story wood-based residential buildings are assessed in this study. Basic information of the reference buildings is summarized in Table 1. Functional unit is one m^2 of living area. Although context of the buildings differ each other, the assessment is conducted with the same methodology and accuracy according to the purpose of this study.

Table 1: Basic information of the reference buildings

Name	Location	Structure frame	Gross area (m^2)	Living area (m^2)	Floors	*Operative energy use (kwh/m2/a)
Building A	Germany	Sawn timber panel	726	488	5	63
Building B	Finland	Cross laminated timber	730	548	3	59
Building C	Italy	Cross laminated timber	1840	1398	5	43

*Operative energy use is the secondary energy including electricity and heating/cooling energy

3.2 Impact assessment and system boundary

GHG emission value for material production, construction, and use phase of the reference buildings is calculated. According to normative standard EN15978 [23], included life cycle phases are defined as shown in Table 2.

Table 2: Included life cycle phases and its abbreviation according to EN15978

Product stage (Module A1-3)			Construction process stage (Module A4-5)		Use stage (Module B)
A1	A2	A3	A4	A5	B6
Raw material supply	Transport	Manufacturing	Transport	Construction	Operational energy use

Since specification of basement differs significantly between the buildings and there are several uncertainties in non-wooden building element (e.g. prefabrication of steel staircase), the results of the assessment for the module A are limited to wood-based building element of the buildings in order to make the results comparable.

3.2.1 Module A1-3: Material production

The inventory is carried out from working drawings of the architects and structural engineers. Calculated mass of each component is cross-checked with material order list provided by the constructor. Building service equipment and furniture are excluded from the inventory, even if those are integrated to the building element, due to lack of information. The included inventories are summarized in Table 3.

Table 3: Mass of used materials in wood-based building elements (kg/m^2 of living area)

Material	Building A	Building B	Building C
Sawn timber	133	40	19
Cross laminated timber	20	151	241
Laminated veneer lumber	16	5	2
Glulam	82	40	
Plywood		7	
OSB		7	

Wood fibre board		16	
Gypsum board	82	60	78
Rock wool	12	33	10
Cork			4
Cellulose fibre		5	
Particle board	8		28
Ancillary material	23	2	11
Vapour barrier sheet		0,4	
Water proof sheet	1	3	6
Cement fibre board			14
Window and door	39	57	43

3.2.2 Module A4: Transportation

All information regarding the construction stage is collected by monitoring of construction work and machines and interview with the constructor. Transportation of building components and elements is taken into account according to the real case. The impact from transportation process is calculated by multiplying distance (km) and mass of deliverable (ton) as taking vehicle type into account. Worker transport to the factory or construction site is not included.

3.2.3 Module A5: Construction

Energy consumption during prefabrication of the wood-based element in the factory and on-site assembling of the prefabricated element is monitored. Possible data collection method is case specific due to working system of the constructors. Different methods, which seem to be the most relevant in each case, are applied. In case of building A, real monitoring data of the prefabrication factory and the interviewed information from the constructor were main source. In case of building B, a researcher has been stationed on the construction site and monitored the process everyday with the constructors. Monthly energy consumption data of the prefabrication factory and spent working time for the project in the factory were monitored by the prefabrication company. In case of building C, a special agreement was signed between the client and constructors regarding construction schedule. Therefore, each constructor planned detailed working activity in advance, which helped to collect relevant data.

3.2.4 Module A5: Waste management

Waste from prefabrication and on-site construction work is also considered based on the real case and literatures [24-27]. Waste management methods and transportation to waste treatment facilities are taken into account based on the interviewed information.

3.2.5 Module B6: Operational energy use

The calculation of operational energy use is based on the estimated electricity and heating/cooling energy demand of the buildings. Aggregated annual operational energy demand is summarized in Table 1. National energy mix is applied to the case of building A and C, and actual energy mix of the location is applied to the building B.

3.3 LCA Data

All calculations are conducted with Ecoinvent database V2.2. [28]. Ecoinvent is one of the most well-known LCA database which consists of process based life cycle inventory (LCI) data. Temporal representativeness is year 2000-2007 as annual average. Basically stored data is based on an average of current used technology. European average data is applied to the assessment of the module A1-3, and country average data is applied to the module A4-5. In principle, exact material data is applied for building materials from the database. However when there is not exact data in the database, most relevant material data is applied (e.g. plywood data instead of LVL).

3.4 Uncertainty

Several assumptions regarding the energy use during construction are applied in each case study when certain data is not available. This uncertainty would affect the result to some extent, although it was not estimated. However, every assumption is based on monthly data of the factory, data from similar production line, literature or interviewed information. Therefore, it is supposed that the associated error is not significant in this case.

4. Results and Discussion

4.1 Dominance analysis of the module A

Figure 1 shows GHG emission, from both fossil and biogenic fuel separately, for each phase in the module A of the three reference buildings. Although absolute value of the buildings differ each other significantly, similar trend can be seen. The module A1-3 accounts for 70-80% and the module A4-5 holds 20-30% of the total impact. In addition, the module A4 has relatively high share in the module A4-5, approximately 30% in the case of building A and more than 50% in the case of building B and C. It is remarkable that transportation of building components has higher impact than the actual construction work in the factory and on construction site in the two cases. This result originates in long transportation distance of some building components. For instance in the case of building B, Cross laminated timber (CLT), which is main building component, is delivered from Austria to Finland by ferry and truck. This would be exceptionally long transportation in an ordinary construction process. In the case of building C, there are also several components delivered from abroad. In the case of building A, most of components are delivered from Germany within 400km by truck.

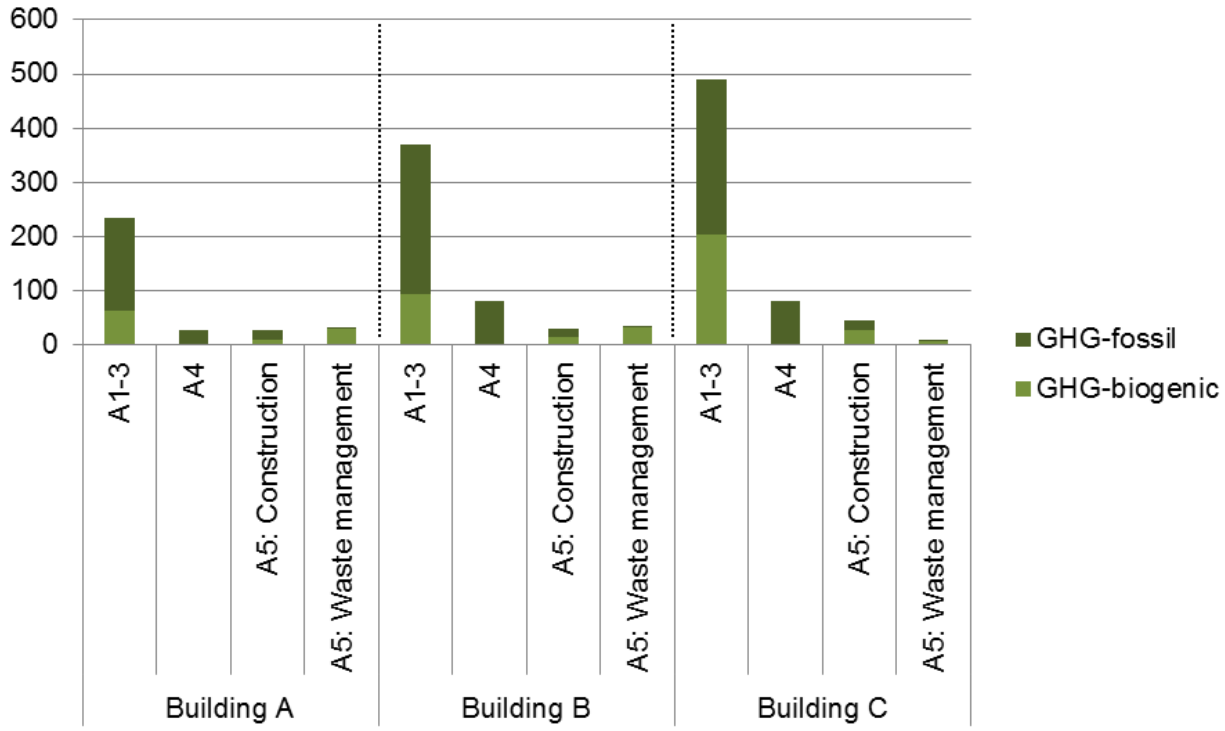

Fig. 1: GHG emission for the module A ($kgCO_2$-eq./m^2)

The module A5: prefabrication process and waste management also have relevant impact. However as shown in the figure, GHG emission from those phases consist of mainly biogenic GHG, which originates in a combustion of wood process residues. Therefore, the emission from the phases decreases significantly if biogenic CO_2 emission is regarded as zero based on the idea of carbon neutrality. This would be a main environmental feature of wood-based construction process. This result would also indicate the importance of the module A4.

4.2 Share of the construction stage

Figure 2 shows GHG emission for the module A and B6 of the three reference buildings. The module A1-3, A4-5 and B6 account for 16-35%, 6-10% and 55-78% of the total GHG emission, respectively.

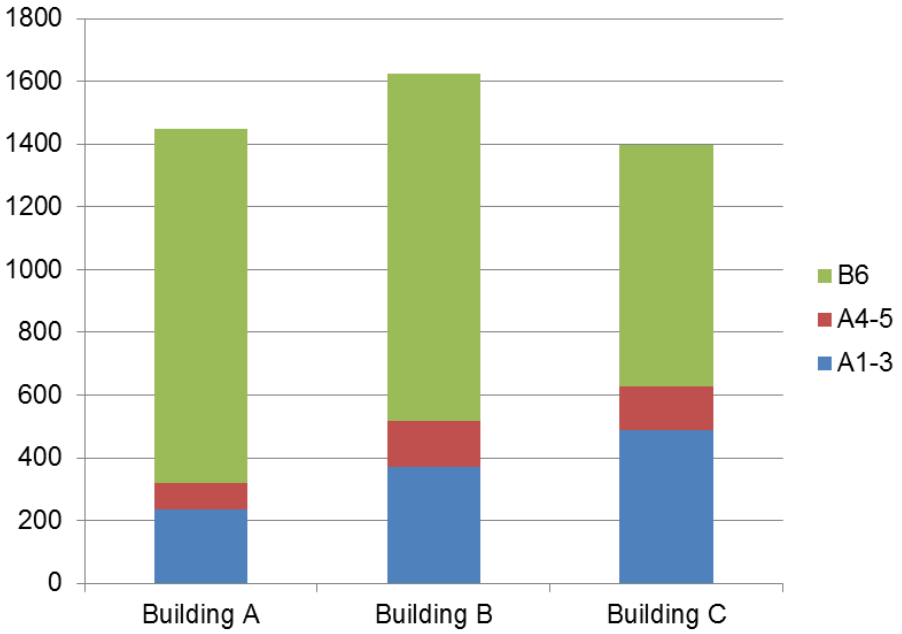

Fig. 2: GHG emission for the module A1-3, A4-5 and B6 ($kgCO_2$-eq./m^2)

The construction stage (A4-5) holds up to 10% of the total sorely. Naturally the share is increasing for the building with lower operational energy demand. This result will change when the other life cycle phases are included in the assessment to some extent. However, the ratio of the module A will also increase when the excluded construction materials and works (e.g. foundation and building services) are incorporated. Since the reference buildings are not high energy standard building, this result deserved to consider further.

Although the sample size is small, the module A4, transportation of building components and elements, seems to have higher priority to mitigate rather than actual construction work, the module A5, in the construction stage of wood-based building elements. Normally, loadage is optimized from economical reason. However, transportation distance is not always in proportion to a price of a product. Thus sometime it would happen to buy a product from far country due to cheaper price, although the same product could be available in a neighbouring city. From environmental aspect, it would be the worst case to order high impact products due to, for instance, inefficient manufacturing technology from far, because of a low price. Some products may be only available from specific location. But except such situation, it is good starting point to consider a balance of cost, environmental impact of product manufacturing and transportation distance and method when deciding construction material in order to mitigate the impact from the construction stage.

4.3 Data collection

It is experienced that data collection from transportation process and waste management is rather simple, while prefabrication process and on-site construction work is difficult to monitor. This difficulty seems to mainly originate in a situation of the industry, for instance rack of resources and time. In addition, data collection from on-site construction work may require special knowledge regarding construction work. In this context, proper planning of construction process is fundamental requirement in order to collect necessary information efficiently.

Since several projects or works happen at the same time in a factory and construction site,

allocation of energy use is one critical issue. Monitoring of each process or production line with, for instance, electrical measuring instrument is relatively easy and accurate way. Recording of working hour for the process or project is also relevant in order to allocate aggregated information, such as monthly electricity and heating energy consumption in the factory.

5. Conclusion

GHG emission for the product, construction and use stage of the three reference wood-based buildings are assessed. Detailed data collection is conducted with the help of the constructors. Since every construction is unique, different data collection method are attempted in each case study according to the situation. The results show that the construction stage has relevant impact and especially transportation process is significant to mitigate GHG emission from the process.

Although an optimization of the construction phase may not have a significant effect on overall life cycle impact of a building, it would have a major impact at an industrial (aggregated) level. The environmental impact of the process should be known to enable to optimize it for constructors and designers. Further study is required in order to collect sufficient samples and pile up the experience in order to set a practicable and reliable assessment method for the construction stage.

Abstract

In consideration of sustainable buildings, closing life cycle loops becomes more and more important. Up to now reuse and recycling is taken rarely into account in building processes. With rising consumption of wood for energetic use recycling of material becomes more important.
Up to now there are various studies in EU market ([1], [2], [3]) which quantify the usage of wood in market shares. Explicit calculations on recycling of wooden material in the building sector have not yet been done. In general the demand for reclaimed wood products in the building sector will rise due to the fact that the thermal use of wood is the last option in the cascade of use. The preferred option has to be the reuse and the recycling of reclaimed wood. On this option the refinement of reclaimed wood for innovative products as well as the broadening and enhancement of the cascades of reuse and recycling is strongly needed for the timber construction industry. Long-term and resource efficient use of wood from premium quality (like laminated wood, plywood, timber frame construction) is necessary to ensure sustainable construction with wood. In the process of planning wooden construction the deconstruction and reuse / recycling of the products has to be considered too.
This article also shows different recycling scenarios for waste wood management due to the contamination problem of particular fractions. The different waste wood fractions in strength, scale and size will tolerate certain processing options with an emerging range of recycling products.
Aim is a realistic estimation of theoretical scenarios for end of life and their influence on planning processes as well as the influence on life cycle assessment according to EN 15978. In this paper outcomes of the woodwisdom-net research project ECO2– wood in carbon efficient construction – as well as calculations on wood consumption of wide-span timber structures and investigated case studies on a very detailed level are brought together to show the state of art and theories to improve resource efficient usage of wood. In another approach the total demolition of an old wooden house in the Alps was evaluated. It is a typical example for a long-used construction with numerous repair intervals, changes, and additions. This leads to a wide variety of fractions and often to a contamination of wood from preservatives. The fractions of the demolished house mainly consist of small bits and pieces dedicated to different recycling options than wide span structures. The different waste wood fractions in strength, scale, and size will tolerate certain processing options with an emerging range of recycling products.
A better management of its renewable resources supports the material supply of the wood sector to ensure a long-term availability of solid wood products at reasonable prices. This will allow preservation and also gain market shares now and in the future.

Keywords: Life cycle; end of life; reuse; recycling; timber structures; ECO2-project

1. Introduction

With a growing importance of wood as significant biomass component of the renewable energy supply, there might be a shortage in the availability of wood in the future [4]. The European Commission therefore proposed inter alia to increase the efficiency in the production and the use of wood. [5] A better management of its renewable resources helps the wood sector to ensure a long-term availability of solid wood products at reasonable prices. This will allow preserving and also gaining market shares now and in the future. Solid and glued wood products should have the chance of a second, similar product life instead of recycling without preservation of solid wood properties. Today's most important challenge is to activate the potential of the wood sector to provide construction products fulfilling these requirements.

In consideration of sustainable buildings closing life cycle loops becomes more and more important. Up to now reuse and recycling of existing buildings are not examined widely. Reuse and recycling is taken rarely into account in building processes which is centred on the production, erection and operation of constructions. There is a lack of competitiveness of products within the forest-wood chain concerning the end-of-life strategies. The advantage of wood as a carbon storage can be obtained through reuse and recycling of the material. Only after all options of recycling are exploited the additional advantage of energy recovery should be used. This has a positive effect, which will lead to improved lifecycle assessment (LCA) indicators for wood based products. Finally the production and use phase of existing wood based products can be improved by consequently enhancing the cascades of utilisation.
On the other hand there is a clear need for a life cycle oriented observation of constructions. This includes the dismantling and end-of-life of the buildings. This paper shows the state of art and theories to improve resource efficient usage of wood. A better management of its renewable resources can help the material wood sector to ensure a long-term availability of solid wood products at reasonable prices. This will allow preservation and also gain market shares now and in the future.
With rising consumption of wood as renewable energy source recycling of material becomes more important.

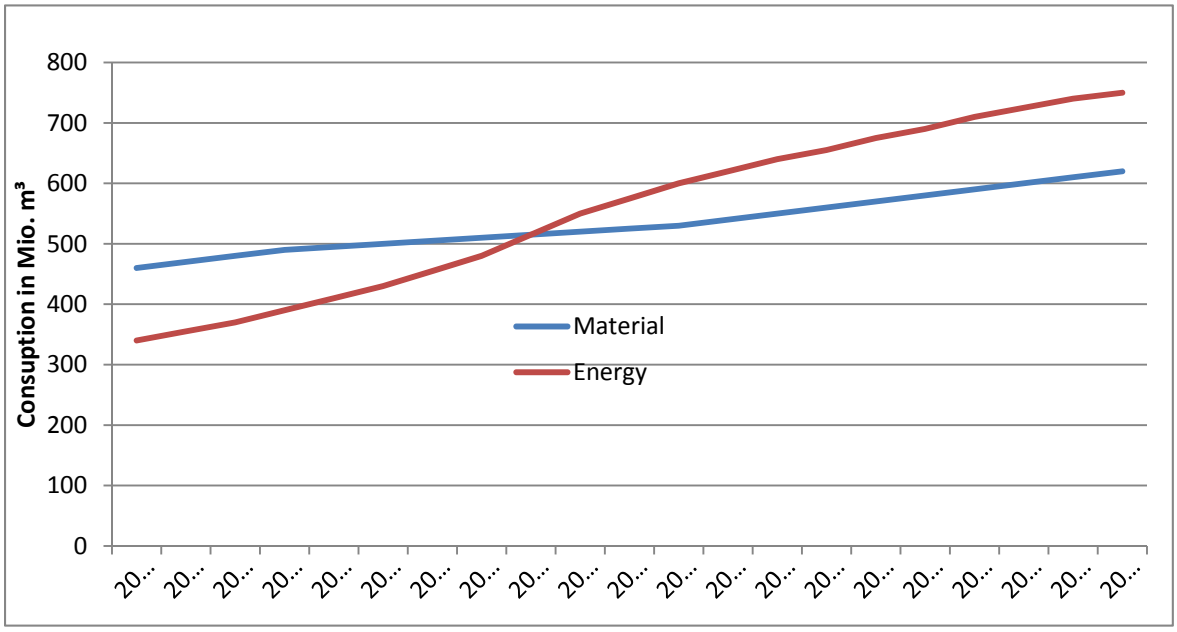

Fig. 1: Consumption of wood for energetic and material use in Europe [6]

As shown in [6] the consumption of wood for material use will rise slowly in the future, whereas the consumption of wood for energetic use will rise dramatically. In Germany wood for energetic use already exceeds the material use in 2012, five to six years earlier as actual calculations from Mantau have predicted in 2010.

This fact causes a rising share of fresh wood thermally used, and a shortage and in long run rising cost for raw material supply of the timber construction sector. The use of good quality, recovered wood not only as energy source reduces this economic pressure. Old buildings can provide the necessary dimensions and quantities of wood. Other sources rely on much smaller dimensions and are less useful. The scope of this paper is an estimation of the quantities and qualities of recovered wood. Additionally there are other fractions a building consists of, which are only side products in this study.
Therefore various research was done estimating the amount of usable material for recycling in wooden buildings and wide-span timber structures. On the other hand related outcomes of finished woodwisdom-net project ECO2 – wood in carbon efficient construction are included in this paper.

2. General framework on recycling of wood

The EU Directives as well as the national laws in many European countries aim at a higher rate of re-use and recycling, which leads to reduced amounts of wastes to be landfilled. The basic principle in the European waste management directive is that materials should be primarily recovered for secondary use, and not until a secondary option, they can be utilised as energy. It is evident that burning for energy is not accepted as recycling anymore in the future. The general idea of the legislation is to prevent waste generation, facilitate its utilisation, and reduce the disadvantages caused by waste management. Materials can be landfilled only if their utilisation is either technically or economically impossible.
The European Union has set an objective to develop itself as a recycling society, where waste generation is avoided, and wastes generated are utilised as a resource. The latest waste directive from 2008 [7] contains an article for re-use and recycling of materials. Among other things, it requires that the member countries have to proceed with necessary actions to recycle materials and products. To fulfill the normative requirements, the industries and R&D are in charge to develop products that can be easily recycled. In the wood product sector, the waste hierarchy is largely underdeveloped, so far. A lot of wood products that could be utilised in secondary product life cycle are burned for energy or are down cycled that they lose material properties of solid wood. On the one hand, this reduces the competitiveness of wood as a construction material not only from the ecological, but also from the business point of view. On the other hand, it offers an obvious opportunity for innovative companies to create new business models, processes and products.
To reach the requirements for recycling, the knowledge about the sources, the quantity and quality of reclaimed wood is necessary.

There are various studies in EU market, which quantify the usage of wood in market shares [1],[2],[3].Up to now no exact evaluation is confirmed on how much recycled wood exists in our building stock and how high the potential of reuse or recycling is from this material source. There is already a small amount from recovered wood used in the production of particle boards or wood fibre products but it is a small share. Explicit calculations on quantities of recovered wooden material in building sector have not yet been done.
Beside precise evaluation about volumes of wooden material for reuse purpose, reuse and recycling faces other obstacles. Wooden material can only be reused if it is not contaminated with harmful substances. Timber has been treated with poisonous chemicals since the beginning of the 20th century, to reduce the risk of mould or to impregnate it against insects. This fact decreases the possibility of reuse and even recycling of reclaimed wood nowadays. For reuse purposes the contaminated wood has to be identified and its amount has to be quantified. Additionally the type of chemical treatment has to be analysed for bio hazardous substances and human-hazard toxicity of treated timber construction. These quantities have to be sorted out and treated according to the rules for hazardous wastes, in Germany the recovered wood regulation [8].
According to German law the term used wood (Altholz) means used wood from production and end user, as far as it is covered by the German life-cycle Resource Management Act.
The used wood is divided up in four categories, in order to decide which wooden material is usable for which waste scenario.
a) *Waste wood category A I:*
Waste wood in its natural state or only mechanically worked that during use was at most insignificantly contaminated with substances harmful to wood

b) *Waste wood category A II:*
Bonded, painted, coated, lacquered or otherwise treated waste wood with no halogenated organic compounds in the coating and no wood preservatives,
c) *Waste wood category A III:*
Waste wood with halogenated organic compounds in the coating with no wood preservatives,
d) *Waste wood category A IV:*
Waste wood treated with wood preservatives, such as railway sleepers, telephone masts, hop poles, vine poles as well as other waste wood which, due to its contamination, cannot be assigned to waste wood categories A I, A II or A III, with the exception of waste wood containing PCBs [9].

Reuse of construction parts is problematic because of a wide spread of unplanned demolition. For optimal reuse the available construction parts have to be identified and classified at least for different end-of-life scenarios. Construction wood and engineered wood products can be dismantled easier than most other parts, because they are used in dedicated layers, they are often used in modular assemblies and they are light-weight. The wooden parts are mostly serialized and the dimensions of certain parts are identical. All these themes make wood suitable for reuse. After the planned dismantling process of removable parts, the rough demolition of monolithic portions can take place. Such fractions may contain smaller amounts of wooden bits and pieces which are reserved for recycling or thermal use.

3. Related outcomes of ECO2-project: wood in carbon-efficient construction

The European woodwisdom research project ECO2 – wood in carbon efficient construction focused on creating holistic understanding of carbon efficiency in the full life-cycle of wooden building and defining technical potential and obstacles for the use of wood in carbon efficient construction. Aim is a clear minimisation of carbon emissions during production, construction and in the full life-cycle. Different case studies on life cycle of wooden products and buildings were examined and energy and carbon balance examined.

3.1 General framework on lifecycle assessment in buildings

According to the standard EN 15978: *sustainability of construction works – Assessment of environmental performance of buildings – Calculation method* the lifecycle of a building is divided up in different modules from A to D. Figure 2 shows the division in phases and the input of residues in lifecycle. In that context all scenarios for recycling and in general end of life of a product are integrated in module C. Modules include deconstruction / demolition (C1), transport to the product's waste processing (C2), waste processing for reuse, recovery or recycling, recovery and/or disposal (C3), disposal (C4).
To show possible benefits and loads of materials beyond the product system boundary, an additional module D is introduced. This means that in module D the recycling potential, the persistence of mineral building products, avoided impacts of thermal energy recovery, embedded renewable energy or carbon stored in the product can be shown. Up to now end-of-life scenarios for wooden products nearly only consist in incineration and energy recovery.

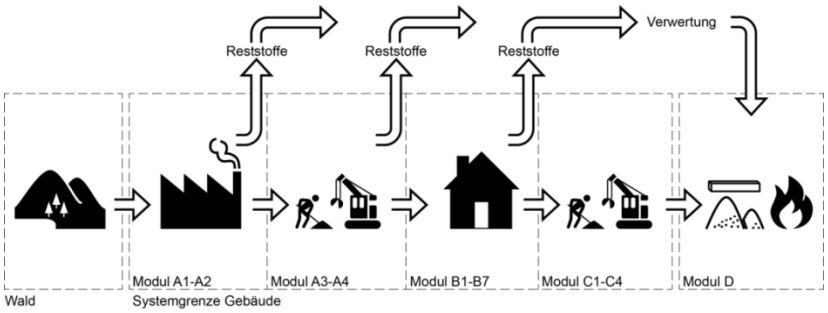

Fig. 2: residues from wood production in different phases of lifecycle

Therefore the treatment of carbon in life cycle analysis is a crucial factor which is not handled equally in LCA calculations up to now. System boundaries for calculation of building LCA were defined. The red line in figure 3 shows a simple system boundary for practical implementation of carbon footprint analysis. An assessment of this system provides information about the impacts of processes to produce, consume and disposed of a unit of a product / building. This approach aims at describing environmental properties of a building in its life cycle. But it does not include induced effects from changes in outputs such as shifts in production and emissions from other products that are displaced by the product being assessed. [11]

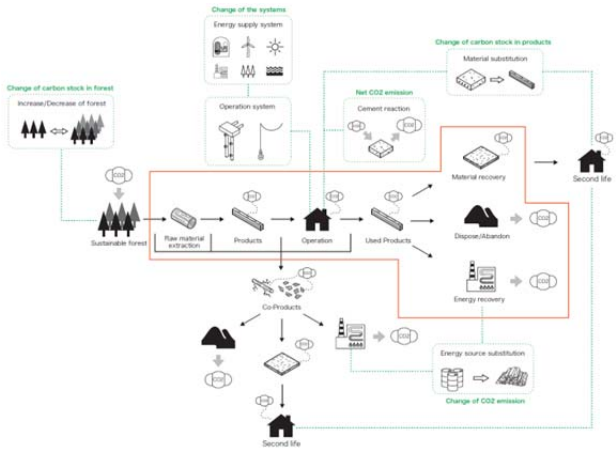

Fig. 3: Holistic picture of carbon footprint related to a wooden building system and simplified system boundary for the system building including only direct environmental effects.

Growing trees in the forest embed carbon in the material. Wood from forest is counted with negative greenhouse gas emissions in module A due to the carbon stored in the product. The biogenic carbon emissions directly attributed to a woodbased product result either from the use of biomass energy in production phase (module A) or from combustion of the product after end-of-life (module C). These emissions are equal to the amout of carbon sequestered in the growing tree which provides the biomass for the wood or the energy used. Prerequisite for that is always that sustainable forestry is applied. Several LCA calculations therefore regard wood as GHG neutral and don´t calculate them at all. This is only the case if calculations include the whole life cycle from production to End-of-life, if the wood is not leaving the forest system and if these forest are not being harvested. LCA calculations done according to the standards of EN15804 and EN15978 do not give instructions for the handling of wood and sequestration of carbon. But according to these standards the carbon and primary energy have to be accounted separately in the different modules. This requires that carbon balance is shown divided up in the modules. Hence wooden materials become a negative value in module A1 and a positive value in C4. Energy gains and the carbon stored in the product (if it is reused or recycled) have to be shown in module D. The overall carbon balance is still zero, but it can be divided among the different modules. By recycling or reusing wooden material at end-of-life for asecond life-cycle, carbon storage gets prolonged.

3.2 Characteristics of wood in end-of-life of LCA

While buildings are seen as a whole in the use phase, for end-of-life it comes down to the specific construction and the materials they are made of. Building components can be decomposed into different layers to get a deeper understanding of their impact at end of life, compare Figure 2. The layers of the building have different exposures, durability and therefore a different life span. The disassembly allows the identification of required service life of building parts and has to be considered in maintenance, inspection, end-of-life scenarios. In modern (timber) buildings different layers are also common to fulfill a wide variety of technical requirements.
Figure 4 shows the different layers of a façade divided into its technical and functional layers. The

primary construction needs to outlast the whole life span, wooden primary construction has high mass and can store a high amount of carbon over this period. The other layers e.g. cladding will be replaced many times and therefore are relevant in terms of recycling potential and burdens / benefits at EoL stage. This can be used as design methodology for the improvement of environmental performance. Through the interdependency of use- and EoL-scenarios, the different layers can seperatly be optimized more easily and then be designed for reuse. The jointing between layers and the frequency of renewal are additional criteria for the end-of-life phase apart from the material impact. [11]

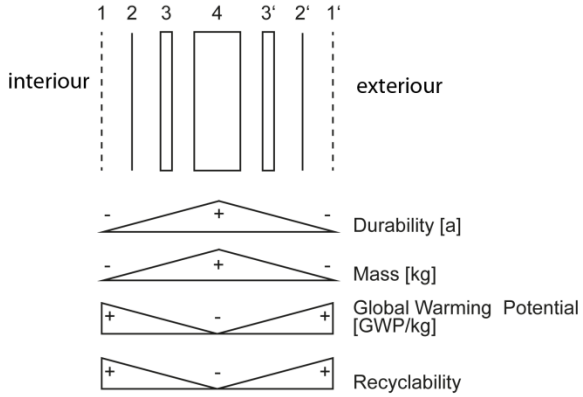

Fig. 4: Sequence of technical and functional layers and weighted influence on EoL impact below. 1) paint 2) cladding 3) functional layer 4) load bearing structure. [10]

In general the options for end-of life module for wooden products are:
Energy recovery:
Energy recovery means that the material gets burned in incineration plants. Then the embedded primary energy stored in wooden products gets released and a heating value is generated.
Incineration with energy recovery is useful for various materials like:
- Wood contaminated with paint / lacquer
- Wood contaminated with toxic substances (like PCP, impregnation)
- Small wooden parts which are bound together with glue
- Other materials that cannot easily be separated.

According to the German used wood categories described previously, energetic recovery is feasible for categories A III to A IV and in parts A II. Module D would contain avoided impact of electricity production and thermal energy recovery and emissions associated with wood combustion.

Material recycling:
"Recycling" means any recovery operation by which waste materials are reprocessed into products, materials or substances; whether it is for its original or new purposes. It includes the reprocessing of organic material but does not include energy recovery and the reprocessing into materials that are to be used as fuels or for backfilling operations" [7].
Material recycling can only be applied for wooden materials in category A I, and there must be a strict selection process to ensure that no contaminated material gets reused. Up to now the selected material for recycling gets used for soft board production only. Module D would contain avoided impacts of forestry, harvesting, wood chips preparation and drying.

Reuse:
"Re-use" means any operation by which products or components that are not waste are used again for the same purpose for which they were conceived." [7]
Reutilization: For example, massive timber construction is deconstructed and reused for the same purpose.
Subsequent use: For example, solid timber construction is deconstructed and then cut into parts to be used as beams for roofing. The compounds are down cycled but the material still has some of

its properties.
This reuse is only useful for wide-span structures and laminated beams that have no material faults. For reuse, it is important that no preventive wood protection is applied to constructions; while for easy deconstruction it is beneficial to screw joints rather than nailing and clipping. This means that recommendations need to be made for design for reuse / recycling [11].

4. Case study on an existing wooden building for calculation of quantities

Aim of this study was a realistic assessment of the material fractions to overcome rough estimations and theoretical scenarios for end of life. Exemplary investigations and calculations are done on an existing cottage in the Alps (Höllentalangerhütte), which is located in a sensitive natural environment. Focus of the study is the primary loadbearing construction, the related claddings, surfaces of interior and exterior and the quality of the parts.
For realistic estimation of material content the methods of building survey, classification of components, parts, materials and documentation for reuse, recycling and disposal of existing constructions were presented in [12]. Results are summarised here.
Basis for the examinations are an overall inventory analysis and documentation of existing construction with classification in qualities and quantities. Used methods were: research with existing planning material, survey on site and examination of material samples for hazardous substances. The work was divided in two parts:
The first part was of theoretical nature and based on a research in the archives for information about the history of the cottage, the development stages over the lifecycle with repairs, refurbishments and extensions. First calculations are done according to existing drawings to get knowledge about quantities and material usage.
In a second part a survey on site checked material dimensions for quantity surveying and also results in drawings of construction details with focus on materials. Damages of construction and possible use of harmful substances were besides documented on site. Material samples were taken to analyse them on harmful substances and wood moisture content was checked as well.

4.1 Case study of a cottage dedicated to demolition

The Höllentangerhütte is located in the northern Alps close to Garmisch-Partenkirchen. It is situated at a height of 1387m above sea level and can only be reached through a small and steep foot path. The cottage was built and completed in for stages and consists of a wooden log house, two-storey timber building with a post and beam construction on a stone masonry cellar and an additional stone building with masonry walls from light-weight concrete blocks. The first part was built at the end of the 19th century, the follow-up building phases were in the beginning and middle of the 20th century. The overall gross external volume is 1650 m³, the net floor area is 511 m².

The amount of wood contained in a historic cottage in the Alps, dedicated to demolition, was evaluated. It is an example for construction with a long life cycle with numerous repair intervals, changes, building extensions, and a conglomerate of different materials.
Thereby reusing and recycling is not possible without a careful separation of the materials, which are non-toxic and toxic. Via pyrolysis and use of spectroscopy harmful substances like polycyclic aromatic hydrocarbon (PAK) and Pentachlorphenol (PCP) in coatings were detected. Result of the analysis showed, that the main part of the timber construction could be reused as further components. Only parts of the façade cladding and materials included in the construction phase of the 1960s contained hazardous substances. Most material from the original cottage is free of harmful substances and is also in good and dry condition. 6.7% of wooden material contains harmful substances, mainly the cladding which is exposed to painting in the last decades of the 20th century.

4.2 Results

Although the cottage Höllentalangerhütte is an example for buildings mainly built from wooden material results show the following. Analysis of material fractions in mass and volume show a high

percentage of massive material in the cottage. The share of wooden material reaches a share of 38% in volume with very simple wooden constructions and a mass of 14 per cent. The main mass is 63% concrete / stone. Complete analysis of construction is shown in figure 5.

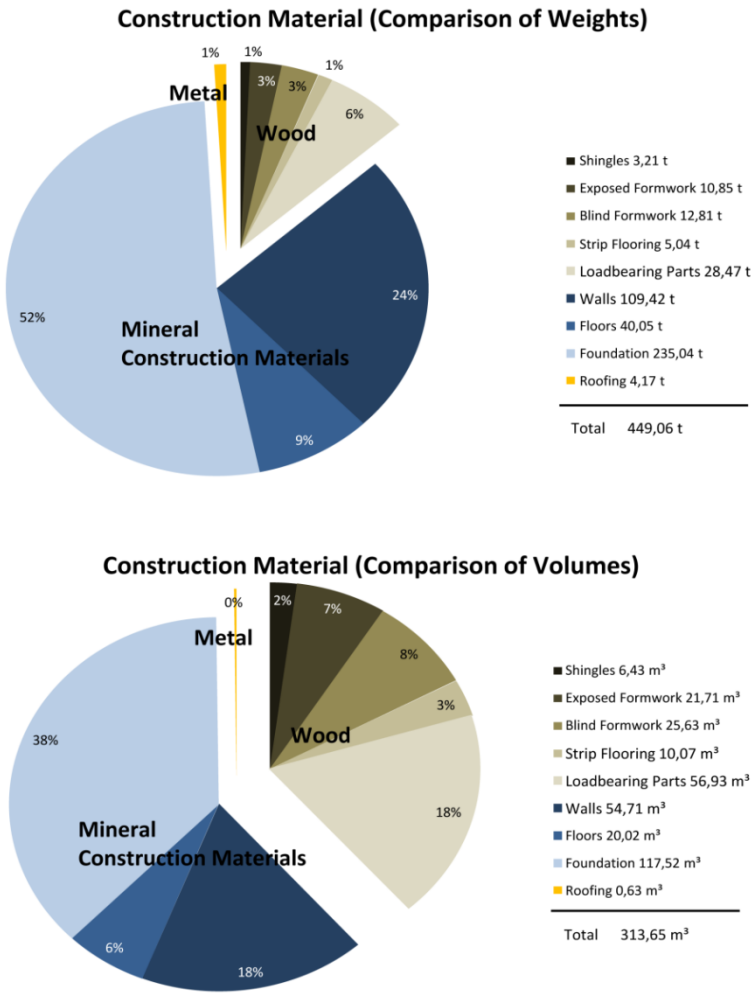

Fig. 5: Construction material – different fractions. Comparison of volume and mass [12]

To compare results to calculations done in chapter 5 a combined value of m³ wood per m² gross floor area is introduced. It is 5,1 m²/m³ or as a reciprocal value 0,20 m³ wood per m² gross floor area. This value shows the amount of used wood in comparison to the m² of gross floor area.

5. Analysis of wide-span timber structures

The problems of the reuse of contaminated wood shift the focus on younger buildings without chemical treatment of the timber construction. Especially the high quality engineered wood products like glulam, solid wood panels or CLT are in focus during data mining. The collection of data is limited to roof structures made of wood, as they are relatively easy to evaluate, compared to wooden buildings, empowering them to make a more meaningful statistic. The available beam dimensions and products of wooden roof structures are well suited for reuse. For evaluating 116 hall structures, as well as other large-scale structures, a wide range of use, size and age, are recorded in tabular form. A comprehensive evaluation but also a heterogeneous result is achieved with these data. The evaluation is adapted as a whole as well as on the individual vehicle types and assessed collectively in the summary statements.
The classification of the parameters starts with the desired result, the amount of used wood. To estimate the amount of used wood, span, beam depth, truss spacing and truss number as input variables are necessary in addition to the truss form and design. To describe the use of wood in a structure sufficiently accurate, it is necessary to explain it according to its shape-defining parameters. This is the consumption of wood in structures in relation to the footprint of the structures. This ratio m²/m³ allows a comparison of the trusses with each other. The relationship is suitable for a general assessment of the truss, since it contains all necessary parameters; with the counter, namely the footprint, which includes span, truss number and spacing, as well as the denominator, consumption of wood. The representation of wood consumption in relation to the floor space for each type of structure is calculated as an own indicator from the averages of the demand for wood and lined up floor spaces according to, compare figure 6. The nominal size of this factor increases the resource savings. With the inverse value one get the amount of exploitable secondary wood/recyclable material per square meter floor space.

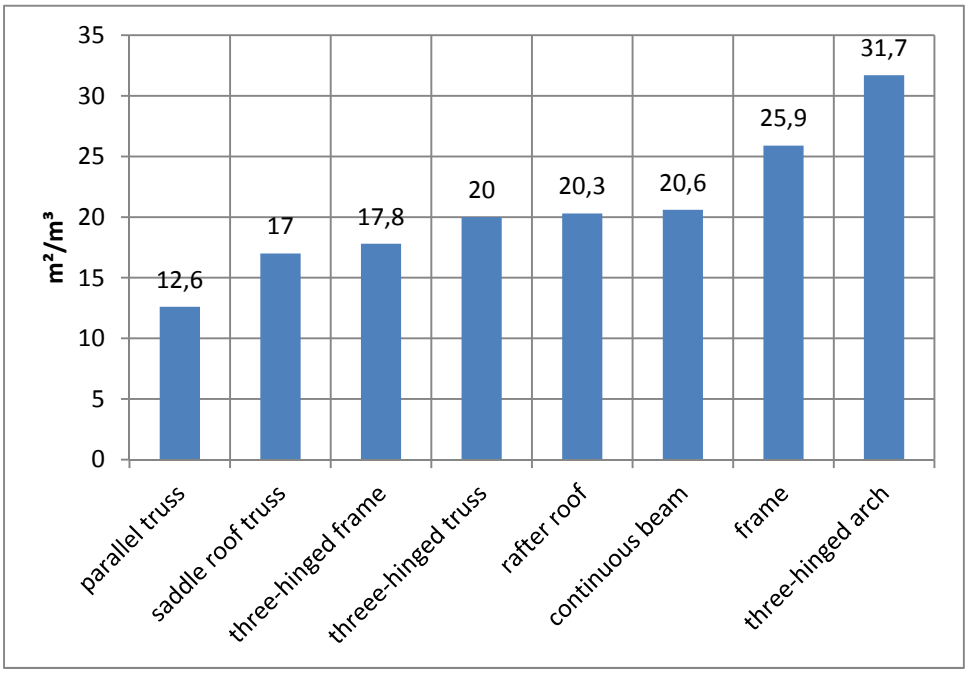

Fig. 6: Comparison of wide-span roof structures shows the covered floor space in relation to 1 m³ of used wood.

The evaluation could be completed with the statement, that the most used trusses have the lowest covered floor space in relation to 1m³ of used wood and therefore have the highest wood consumption. But there is far more to gain from the summary information. The vast distribution of values around the 20 m²/m³ mark shows that regardless of truss type evaluation evenly and properly worked. For the individual systems, no major differences have been expected. The values with the highest deviation of parallel trusses and three-hinged arch trusses are to be clarified separately. Other truss systems are better adapted to the load, such as the saddle roof truss, in

which the distribution of the bending moment is optimized by an increased cross-section at mid-span. Parallel beams, in contrast, will have to bear higher bending stresses due to their constant cross-section; here, an increase in bending moment due to wider spans is simply countered by increasing the dimension of girders or higher trusses. This consequently increases the consumption of wood due to the increased volume over the entire beam length. The three-hinged arch also features a uniform cross-section, but since the load transfer is primarily realized through normal forces instead of bending moment, the structural system can be realized with a smaller cross-section.

6. Results

For future planning the reuse and recycling of existing buildings has to be integrated quite early in the planning process to be able to reuse the materials in the best way. Small scale drawings also show how components are built in and how jointing is done. This information is useful for dismantling.
With existing building documentation fictive mass calculation could be produced which then can be updated by partial surveys. In future architects contracts have to be enlarged to include also reuse of material in early planning stages.

The Höllentalangerhütte, as a case study, reveals that the more than 120 year old wooden construction still is in very good condition and could be reused in large parts. In parts where no maintenance and repairs were applied, like running water around broken rain gutter, the construction is mouldered and cannot be reused. Problems for recycling arise in the usage of harmful substances in paints. Here exact material testing is necessary. In general conclusion can be drawn that this Alpine cottage is an example for a simple building with a minimized construction which allows a high level of reuse. A reduced conglomerate of fractions makes separation easier and the additional economic effort could be limited.
The analysis of wide-span timber structures shows that there is an average amount of 0,05 m^3/m^2 of wood in these structures which equals about 21 kg/m^2 of softwood. Although there are losses due to the removal of construction joints and areas with dowels or nails, there is still a reasonable amount of quality engineered wood which can be reclaimed for a second use phase.
In the planning process for new timber structures design and construction has to integrate various possibilities to extend the life cycle of a product or material:
- Design for reuse
- Modularity of the structural system from components to the structural system
- Use screws instead of nails, clippings
- Extend the life span of the building and the durability of the products
- Easy dismantling of the buildings (connecting devices)
- Avoidance of composite materials
- Avoidance of toxic substances
- Use of waste wood fractions A I (only in parts A II)
- Maintenance, repair, renewal of surfaces (exterior and interior)
- Keep information about existing building through building passport (or sustainability certification)
- The prefabrication in the wood process is an advantage for durability and the end-of-life phase, as the construction has to be designed in modular elements. The replacement of single layers is possible through straight joints, so recycling becomes much easier.

Cascaded use of wood can affect the LCA positively, as carbon storage is prolonged. The material choice for wooden products will be influenced more positively, if the used wooden material is not burned immediately, but used as materials. Therefore, there is a need of a recycling proof and elimination concept for a future use of reclaimed wood of high quality.

7. Conclusion

The European Commission proposed to increase the efficiency in the production and the use of wood [5] and resource efficiency in general [13]. The overall goal must be to increase the long-term availability of renewable but at the same time limited resources for the wood cluster. The

competition for raw materials between stakeholders in the wood cluster will be reduced and the wood utilization with immanent positive effects on climate protection will be optimized. An approach for higher resource efficiency is the implementation of a material flow management in the entire process of timber construction.
The latest waste Directive from 2008 [7] contains an article for re-use and recycling of materials. Among other things, it requires that the member countries have to proceed with necessary actions to recycle materials and products. To fulfill the normative requirements, the industries and R&D should develop products that can be easily recycled.
A better management of its renewable resources helps the wood sector to ensure a long-term availability of solid wood products at reasonable prices. This will allow preserving and also gaining market shares now and in the future.
For recycling of existing buildings exact calculation of actual mass and volume as well as building condition is necessary. Therefore drawings (as built) help to calculate overall quantities. They need to be checked on-site with survey. On-site survey focuses on quality of materials. Only on-site reliable information on the qualities of wood and usage of harmful substances can be gained. These analyses are important to choose material for recycling without introducing critical substances in the recycling process. For reuse the classification system has to be improved to the same level as the reclaimed wood classes regarding the contamination. This could be difficult, because the way of reuse is unclear and needs further development.

Short Summary

Thermal comfort and indoor air conditions have been studied in model passive house office spaces comparing several heating, cooling and ventilation concepts. Thermal building simulation and computational fluid dynamics (CFD) simulations have been coupled to building and system simulation.
Results indicate that

- regulation of heating and cooling ceilings and floors require considerable heating/cooling capacities in passive house office conditions
- displacement ventilation gives leeway to decreasing ventilation volumina below the level assumed for mixed ventilation

Keywords: Passive house building standard; office buildings; displacement ventilation; surface cooling/heating.

Introduction

Thermal and hygienic comfort problems and increased energy consumption may occur in office spaces built according to the passive house building standard when

- internal and external heat loads entail high energy consumption for cooling in summer,
- high ventilation requirements due to high occupation densitiy produce low relative air humidity – or need for air moisturing,
- heating, cooling, and ventilation appliances are not properly adjusted to each other producing draught, or incomplete air exchange.

Systematic studies on appropriate parameter combinations for office space design have therefore been the aim of a major project [1, 2, 3, 4].
From a follow-up study this contribution selects two topics

- regulation strategies for heating and cooling ceilings and floors
- potential of displacement ventilation for decreasing ventilation volumina below the level assumed for mixed ventilation

Methodology

Thermal comfort
Thermal comfort has been assessed according to ISO EN 7730. This includes the concepts of

general thermal comfort evaluation predicted mean vote PMV, predicted percentage of dissatisfied (PPD), and criteria of local discomfort

- Percentage dissatisfied due to local discomfort from draft (DR)
- Allowable radiant temperature asymmetry
- Allowable vertical air temperature difference between head and ankles
- Allowable range of floor temperature

Air quality, ventilation quality

Air quality has been estimated according to EN 13779:2008 as CO_2 concentration of indoor air with classes IDA 1 to 4 referring to CO_2 concentrations ranging from < 800 ppm to < 1900 ppm CO_2. Ventilation quality is described as normalised air age (air exchange index), with values of 1 for ideal mixed ventilation. Values > 1 indicate efficient air supply often found in displacement ventilation, values < 1 point to locally insufficient air exchange.

Model Spaces and HVAC specifications

Using model spaces, several heating cooling and ventilation concepts have been studied.

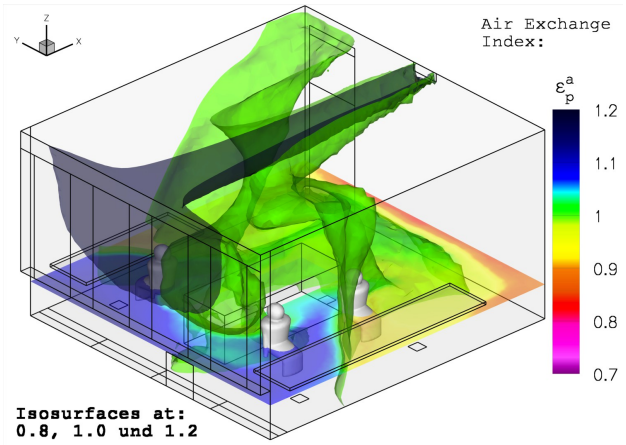

Fig 1. Model office space showing 3 seated persons, furniture and isosurfaces of air exchange index.

The office is occupied from Monday to Friday between 08:00 and 18:00 by three persons with some technical equipment. The heat output of the persons is dependent on the temperature (around 75 W). The technical equipment produces a heat output of 300 W and the heat emission of the light is set to 15 W/m². The inner heat load is reduced to the half from 08:00 to 08:30 and 17:30 to 18:00.

The heat emission of the persons takes place in a cylindrical volume around each person. 20 l CO_2 per hour is exhaled by each person in a cylindrical volume around their heads. In contrast, the heat output of the technical equipment is not localized, only the input of the light is restricted to a volume close to the ceiling by 60 % convection and 40 % radiation.

Systems compared include

- thermally activated ceilings
- plaster ceiling cooling/heating
- suspended overhead cooling/heating panels
- underfloor cooling/heating

differing in their levels of thermal inertness resp. in cooling/heating capacities.

Starting from an initial set of parameters following parameters were varied:

- Set temperatures at the thermal sensor
- Lowering set temperatures during nighttime or during daytime
- Earlier start of heating/cooling facilities (00:00 or 02:00 instead of 06:00)
- Supply air temperatures floating with thermal sensor temperatures with a fixed temperature

difference or
- Fixed supply air temperatures.

Criteria of evaluation were
- courses/trends of air and operative temperatures resp. PMV and PPD values during the coupled phase (24 hours)
- Prevaillance of local discomfort especially draft risk and allowable vertical air temperature difference between head and ankles. (No cases of discomfort resulting from radiant asymmetry or floor temperatures were observed.)

Thermal Building and CFD Simulation Methodology

The simulation method applied here is a combination of dynamic building and system simulation with indoor air flow calculation. Building simulation provides the energetic balance for rooms for periods like weeks, months or years. By coupling with the indoor airflow simulation it is possible to analyze the structure of the flow and to calculate heat and mass transfer in detail for short time periods like some hours or some days. The building and system simulation is carried out by a special version of the commercially available program TRNSYS [5], named TRNSYS-TUD [6] because of the extensions done at TU Dresden. For the transient, nonisothermal and turbulent indoor airflow simulation, the Finite Element Computational Fluid Dynamics (CFD) code ParallelNS is applied, developed at University Göttingen and TU Dresden [7]. Both programs are coupled via PVM (Parallel Virtual Machine [8]) to a calculation system, see fig 2. After a period with pure building simulation for only energetic balance (denoted by the arrow on the left hand side in fig.2) the fully coupled phase including the air flow simulation starts at time $t_{0,0}$. Therefore the calculated wall temperatures ϑ at the defined interface walls will be sent to the CFD-code, which is calculating the heat flux Q between those walls and the indoor air. With these data about convective heat transfer the building simulation program generates a new energy balance (including radiative heat transfer) for the next time step and so on. In addition, the system simulation is coupled in a similar way. Detailed information about radiation and convection at selected sensor positions is sent by ParallelNS to TRNSYS-TUD which calculates the appropriate reaction of the heating or cooling system.

The simulation starts with 14 days of pure building and system simulation using simplified weather conditions, constant temperature of -5° C in winter and a permanently repeating warm day with 30 °C top temperature in summer. The fully coupled simulation including CFD starts on the 15th day at 00:00 and is running until 24:00. It should be noted, that this day is a Monday after the weekend. Resulting data comprise temperature and velocity fields, CO_2 concentration and age of the air, all wall temperatures, sensor data and reactions of the technical system for a period of 24 h.

Thermal comfort can be evaluated by using the information of radiation and convection that is available in every computational cell of the calculation domain.

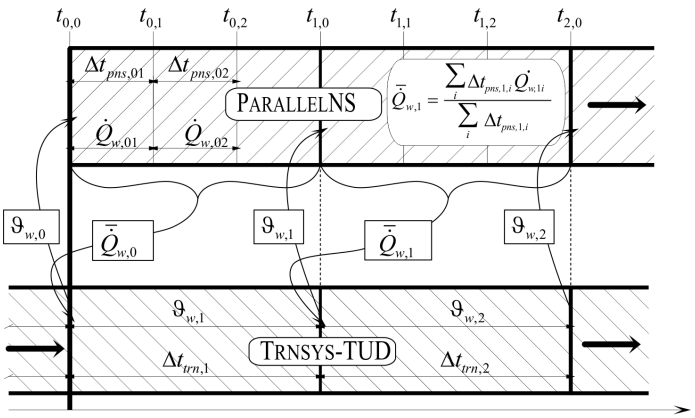

Fig 2. Sketch of coupling strategy between building simulation by TRNSYS-TUD and indoor air flow calculation by ParallelNS in an adaptive time step algorithm.

Four sensors are situated in 0.1 m, 0.6 m, 1.1 m and 1.8 m height between the two persons sitting at one desk, see fig. 1. The operative temperature in 0,6 m height is usually used for control of the systems. In case of concrete core activated ceilings an additional sensor for surface temperature is applied for system control.

Results

Regulation strategies for heating and cooling ceilings and floors

Cooling

Fig 3–6 show PMV values during the coupled phase comparing thermally activated concrete ceilings, plastered ceilings with integrated tube mat, suspended cooling ceiling panel, and underfloor cooling. An initial parameter set and an optimised configuration is shown.

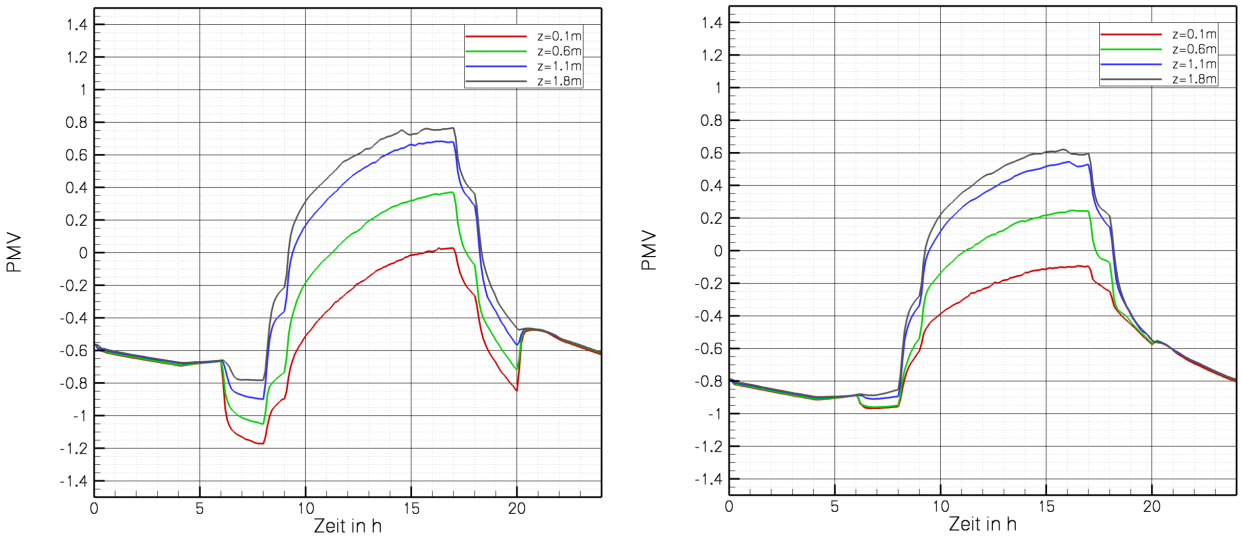

Fig 3. Concrete core activated ceiling, cooling capacity 40 W/m² of 90 % of ceiling area. Temperature sensor in the ceiling surface. Ventilation: Floor swirl diffusers. Left: Set sensor temperature 23 °C, temperature of supply air 4 K below sensor temperature. Right: Set sensor temperature 22 °C, temperature of supply air 1 K below sensor temperature, floating, but max. 22 °C.

The highly inert activated concrete ceiling characterised by rather low cooling capacity produces cool temperatures in the morning. As office activities start, temperatures rise sharply, and cannot be stabilised at a set PMV level of close to zero (left).
In an optimised configuration (right) the decreased set sensor temperature keeps temperatures (and PMV values) at lower levels, but the general situation remains the same. Smaller temperature differences of supply air are visible in the morning around 06:00 to 08:00 with higher PMV values. But as temperature is limited to max. 22 °C supply air takes a role in cooling the model room, indicated by a still high spread of PMV values at different room heights during daytime.

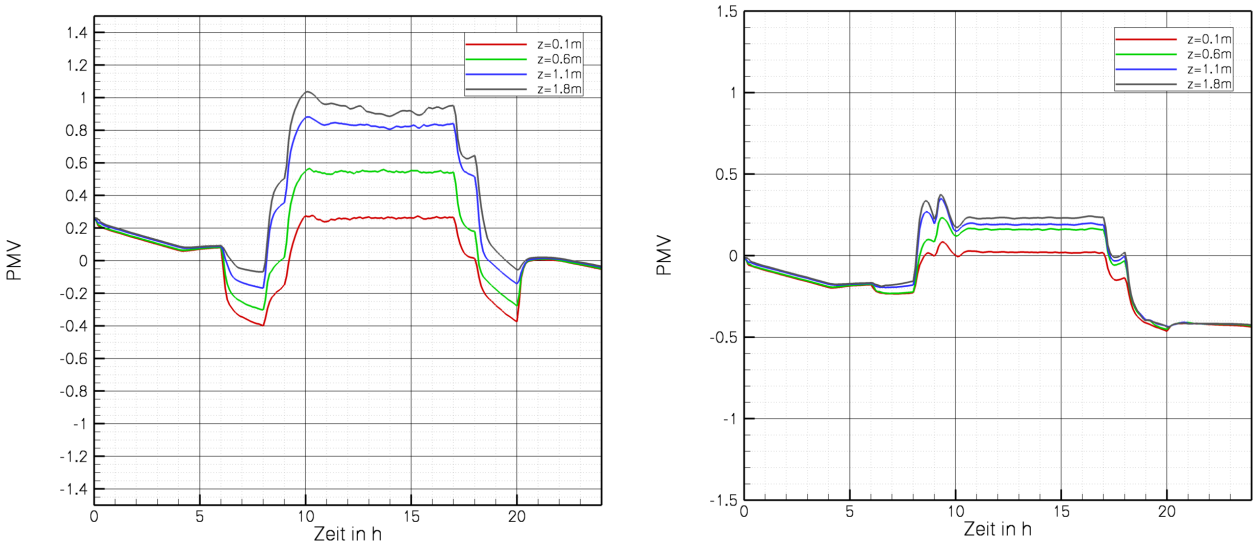

Fig 4. Plastered ceilings with integrated tube mat, covering 85 % of ceiling area, cooling capacity max. 80 W/m², thermal sensor situated at a level of 0.6 m between seated persons. Ventilation: Floor swirl diffusers. Left: Set sensor temperature: 26 °C, temperature of supply air: 4 K below sensor temperature, floating. Right: Set sensor temperature 24.5 °C, temperature of supply air: 1 K below sensor temperature, floating.

The impact of a doubled cooling capacity (80 W/m² vs. 40 W/m²) shows clearly in fig 4. The plastered ceiling with integrated tube mat achieves an even level of temperature (and PMV) which, in the initial configuration (left), is still too high. A considerable spread of PMV values at different room heights indicates additional cooling by supply air due to a temperature difference of 4 K. An optimised configuration (right) with lower set sensor temperature brings PMV values down to levels close to PMV = 0. Supply air temperature difference lowered to 1 K brings PMV values in different room heights close together indicating an homogeneous room climate.

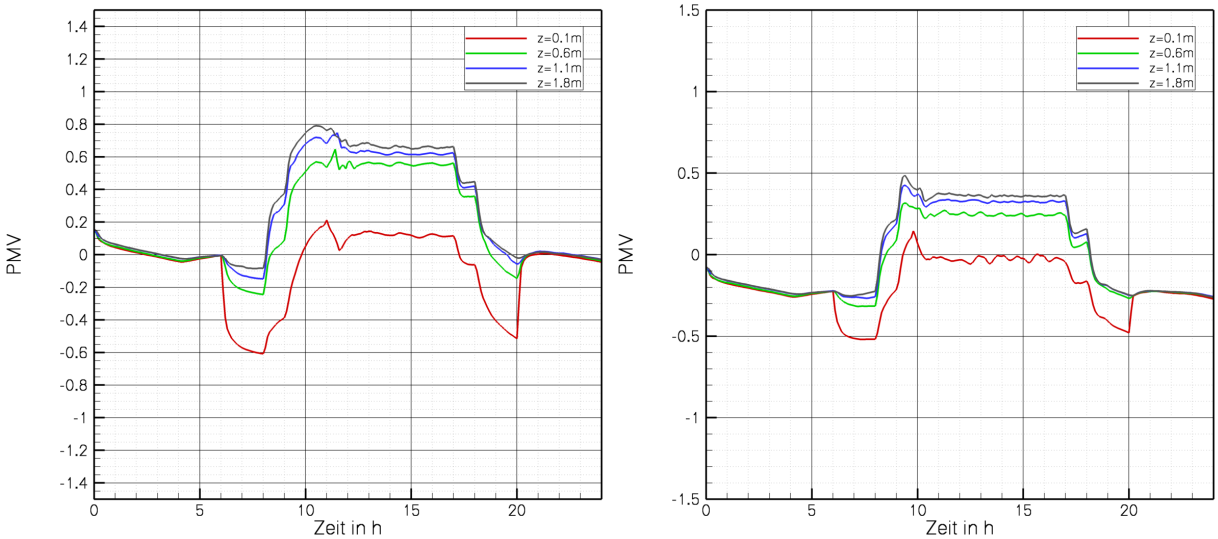

Fig 5. Suspended cooling ceiling panel, cooling capacity 150 W/m², covering 50 % of ceiling area, temperature sensor situated at a level of 0.6 m between seated persons. Ventilation: Displacement flow diffusers. Left: Set sensor temperature: 26 °C, temperature of supply air: 4 K below sensor temperature, floating. Right: Set sensor temperature 25 °C, temperature of supply air: 2 K below sensor temperature, floating.

Quite similar results as in the case of the plastered ceiling (fig 4) are produced by the suspended cooling ceiling panel. Reducing both set sensor temperatures and supply air temperature differences lower both levels and vertical gradient of PMV values.

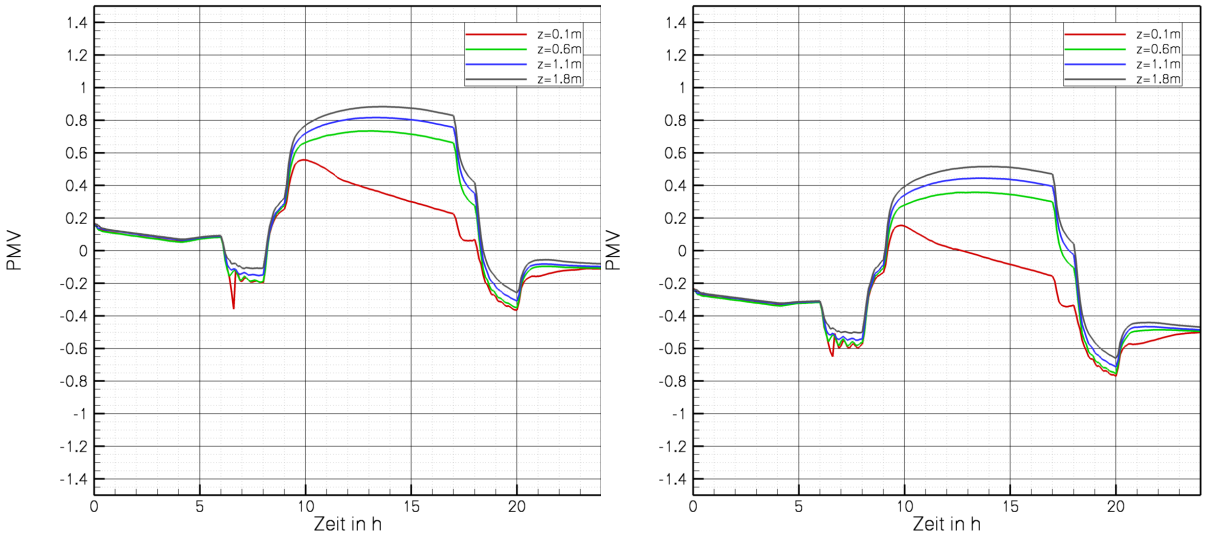

Fig 6. Underfloor cooling, cooling capacity max. 30 W/m², temperature sensor situated at a level of 0.6 m between seated persons. Ventilation: Air grill. Left: Set sensor temperature 26 °C, temperature of supply air: 6 K below sensor temperature, floating. Right: Set sensor temperature 24.5 °C, temperature of supply air: 6 K below sensor temperature, floating.

Despite of a rather low cooling capacity of underfloor cooling the system is capable of producing an even level of PMV values during the day (left) which can be adjusted with a lower set sensor temperature (right). PMV values at floor level (0.1 m) are influenced by the cooled floor surface, at higher height levels of 0.6 m to 1.8 m the influence of a mixed ventilation via an air grill is dominant.

Heating

Fig 7–10 show PMV values during the coupled phase comparing thermally activated concrete ceilings, plastered ceilings with integrated tube mat, suspended heating ceiling panel, and underfloor heating. An initial parameter set and an optimised configuration is shown.

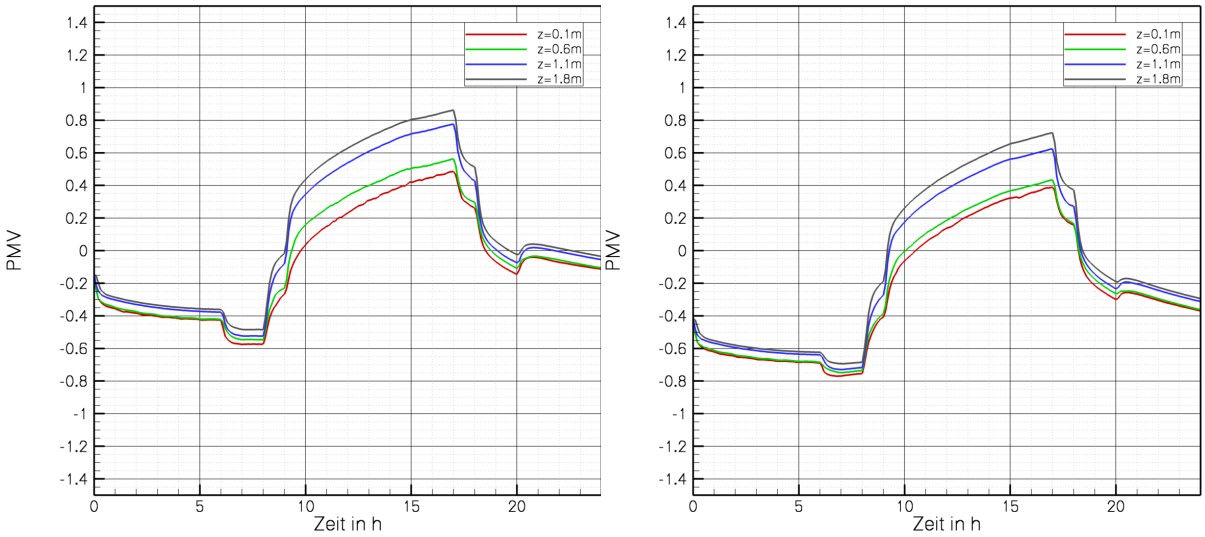

Fig 7. Concrete core activated ceiling, heating capacitiy 30 W/m². Temperature sensor in the ceiling surface. Ventilation: Floor swirl diffusers. Left: Set sensor temperature 24 °C, temperature of supply air 2 K below sensor temperature. Right: Set sensor temperature 22.5 °C, temperature of supply air 2 K below sensor temperature, floating.

Like in the cooling situation (fig 3) the concrete core activated ceiling has no sufficient heating capacity to keep temperatures and PMV values at an even level during the day.

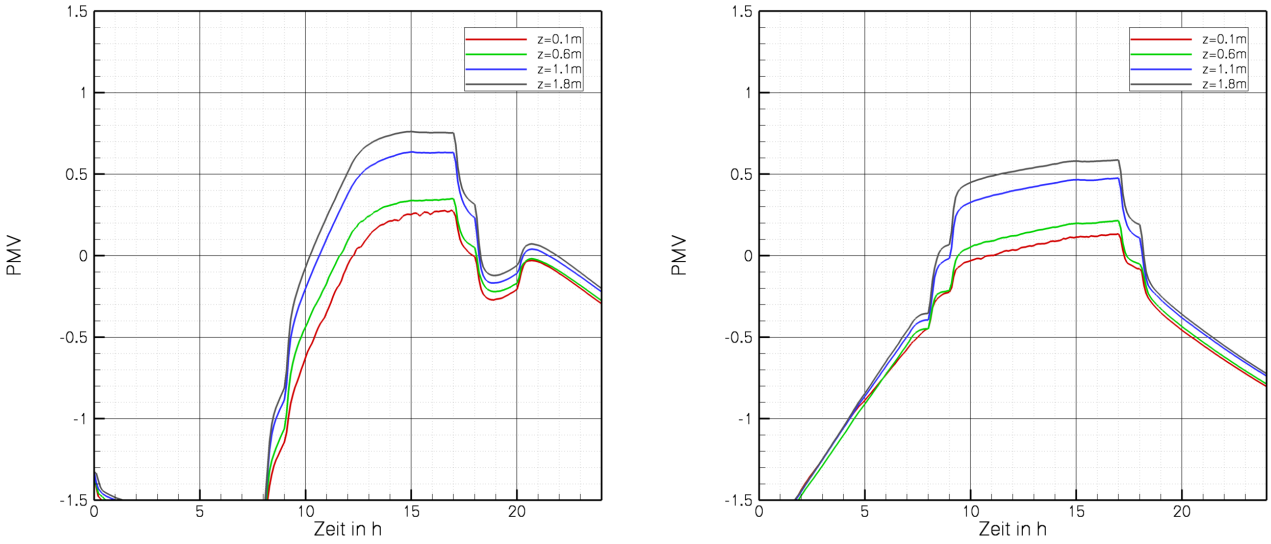

Fig 8. Plastered ceilings with integrated tube mat, heating capacity max. 52 W/m², temperature sensor situated at a level of 0.6 m between seated persons. Ventilation: Floor swirl diffusers. Left: Set sensor temperature: 22 °C, temperature of supply air: 2 K below sensor temperature, floating. Start of surface heating at 06:00. Right: Set sensor temperature 20 °C, temperature of supply air: 2 K below sensor temperature, but limited to 20 °C. Start of surface heating at 00:00.

Start of surface heating only 2 hours in advance of office hours is not sufficient to generate thermal comfort in the morning after a weekend (left). With start of heating at midnight an almost even level of thermal comfort is achieved during the day.

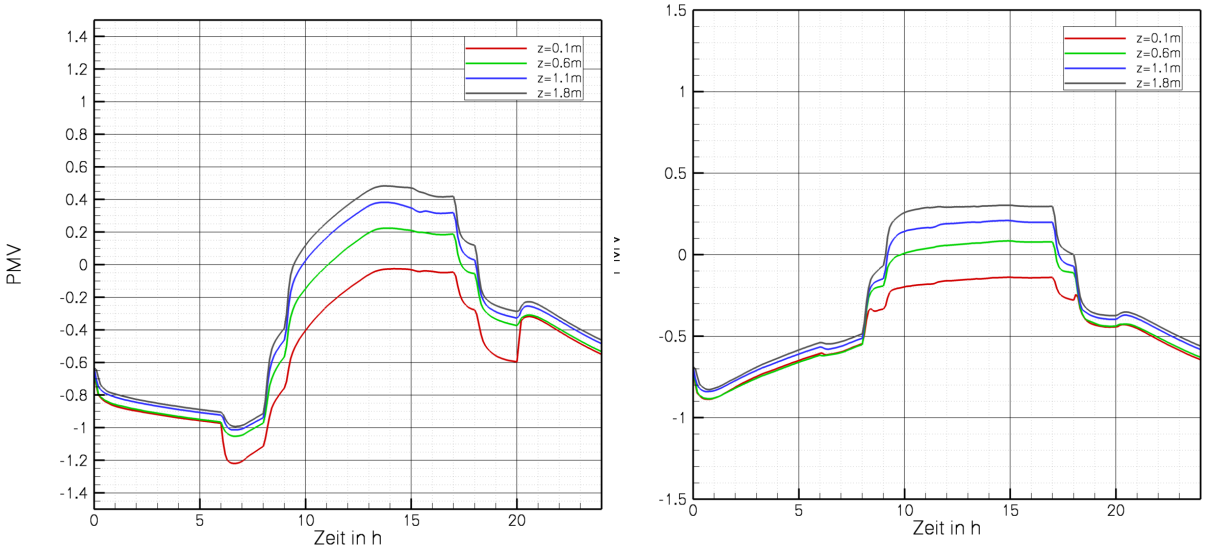

Fig 9. Suspended heating ceiling panel, heating capacity 55 W/m², temperature sensor situated at a level of 0.6 m between seated persons. Ventilation: Displacement flow diffusers. Left: Set sensor temperature: 22 °C, temperature of supply air: 2 K below sensor temperature, floating. Start of heating facilities at 06:00. Right: Sensor temperature 21 °C, temperature of supply air 2 K below sensor temperature but limited to 20 °C. Start of heating facilities at 00:00. Set temperatures lowered from 21 °C to 20 °C during daytime.

It needed a whole set of changed parameters to produce an even level of comfort during daytime with the suspended ceiling panel. Earlier start of heating, lowered set sensor temperature, lowered again by 1 K during daytime, supply air temperature fixed to max 20 °C.

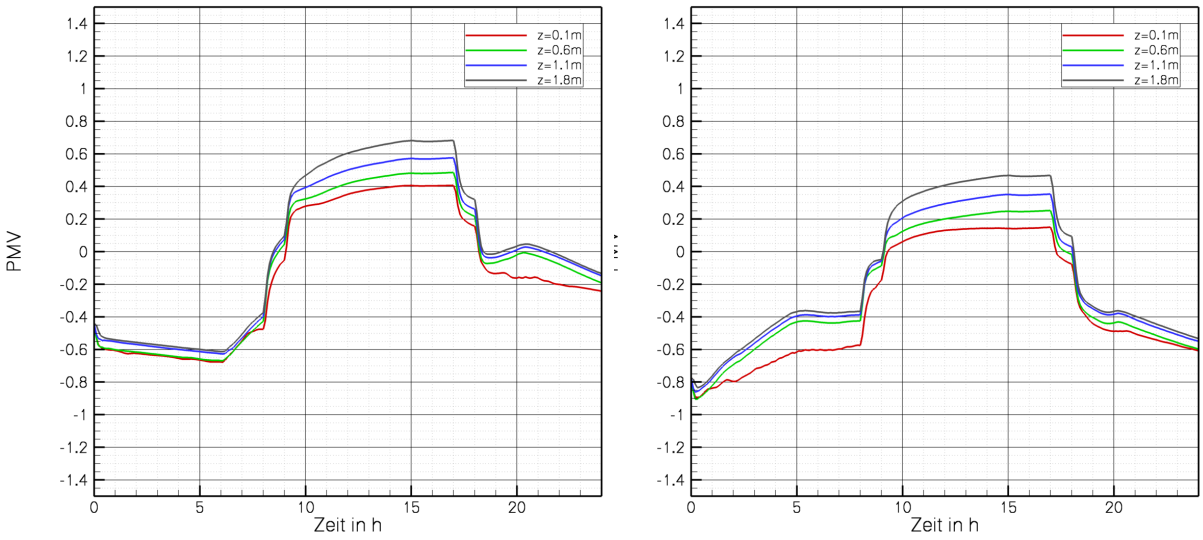

Fig 10. Underfloor heating, heating capacity max. 50 W/m², temperature sensor situated at a level of 0.6 m between seated persons. Ventilation: Air grill. Left: Set sensor temperature 22 °C, temperature of supply air: isothermally floating with sensor temperature. Right: Set sensor temperature 20 °C, temperature of supply air: isothermally floating with sensor temperature. Start of heating facilities at midnight.

Like in the cooling case (fig 6) underfloor heating generates even levels of thermal comfort during daytime. Lowering the level of set sensor temperature and fixing supply air temperature at max. 20 °C decreases PMV to values close to zero.

Potential of displacement ventilation for decreasing ventilation volumina below the level assumed for mixed ventilation

Ventilation rates are set to standard rates of 35 m³/person.h. Results indicate that displacement ventilation seem to be able to transport unmixed supply air along the surface of bodies of persons (and equipment) with low CO_2 concentration in a “convective plume”. Could displacement ventilation give the advantage of using reduced ventilation rates?
Shown below are CO_2 concentrations in ppm at levels of 0.1, 0.6, 1.1 und 1.8 m in the room.

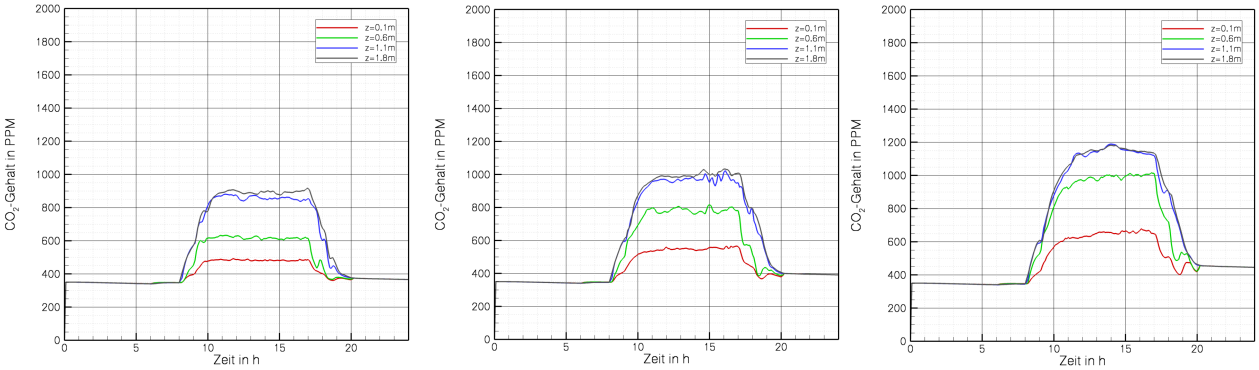

Fig 11. Floor swirl diffusers, concrete core activated ceiling, cooling mode. Left: Standard ventilation rate 35 m³/person.h. Centre: Ventilation rate reduced by 15 %. Right: Ventilation rate reduced by 30 %.

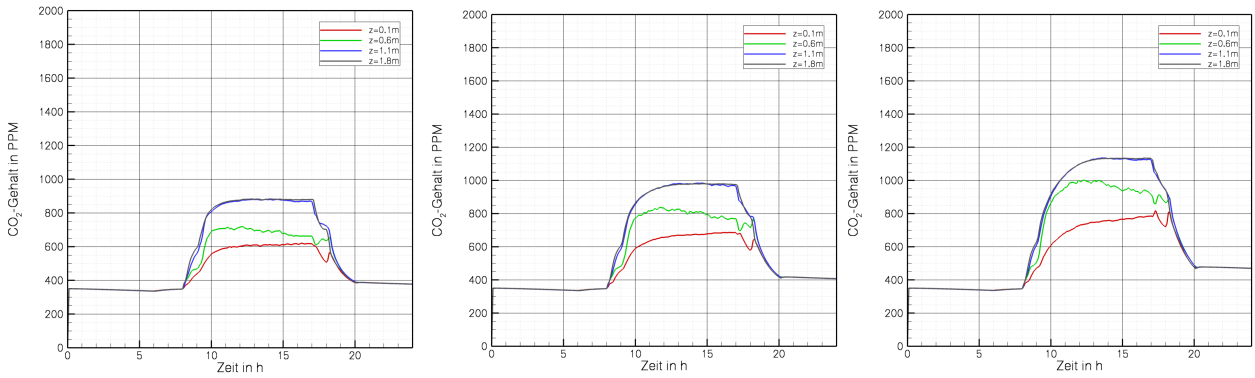

Fig 12. Floor swirl diffusers, concrete core activated ceiling, heating mode. Left: Standard ventilation rate 35 m³/person.h. Centre: Ventilation rate reduced by 15 %. Right: Ventilation rate reduced by 30 %.

In displacement ventilation situations CO_2 concentration levels experienced by seated occupants can be estimated using values in 0.6 m height (green). Air in this region is about to ascend by convection to the faces of occupants. Values in 1.1 m height represent the breathing zone of seated occupants and are usually not different from values in 1.8 m height (blue, black). In mixed ventilation situations at standard ventilation rates (35 m³/person.h) CO_2 concentrations are quite uniformely at levels of 850 ppm (not shown). In fig 11 (cooling situation) and fig 12 (heating situation) levels at 0.6 m are at 600 ppm, and 700 ppm respectively. Lowering ventilation rates by 15 % (center) still ensures lower CO_2 concentration at 0.6 m height than in the case of mixed ventilation at standard ventilation rates. At ventilation rates reduced by 30 % CO_2 concentration rises to moderate levels around 1000 ppm.

Discussion, conclusions

Passive house office conditions are characterised by low heat losses but high heat gains from occupants, electrical equipment and lighting. Such heat gains develop quickly in the morning, vary with varying room occupation and thus disapear in the late afternoon. Quick responses by heating and cooling facilities are required to achieve constant – and avoid rising – temperature levels during the day.
Displacement ventilation gives leeway to decreasing ventilation volumina below the level assumed for mixed ventilation. This is especially welcome in winter conditions when low relative humidity of indoor air tends to cause comfort problems in passive house environments [1, 3].

Merten Welsch works in the Office for Sustainable Building in the German Federal Institute for Research on Building, Urban Affairs and Spatial Development (BBSR) in Berlin. The Office for Sustainable Building is an interface between politics, science and building industry. He is responsible for a wide range of tasks involving research projects for sustainable building. To establish the sustainable building instrument “BNB” as a new standard in the public sector he was responsible for managing the first education courses to the BNB in the federal construction administration and meanwhile trains architects and engineers at several chambers of architects and engineers as well as students at the Beuth University of Applied Sciences in Berlin. Additionally he works in the conformity review body for the certification of federal buildings.

Sustainability in Competitions: New German Federal System to verify the Qualities of Sustainability in Planning Competitions (SNAP)

Short Summary

With the establishment of sustainability requirements for public buildings as well as buildings in the private sector new demands on planners and the planning processes in Germany have arisen. These new quality requirements have to be integrated in architectural competitions. Therefore the new instrument “Classification for Sustainability Requirements in Planning Competitions” (SNAP) has been developed.

Keywords

assessment system for sustainable building (BNB) of German government; architectural competition; new tool; sustainable requirements for competitions

1. Introduction: Sustainability Requirements for Federal Buildings

The federal government is the largest public client and owner and therefore has an exemplary role according to sustainable building. With the establishment of sustainability requirements for public buildings as well as buildings in the private sector new demands on planners and the planning processes in Germany have arisen.

For example, with the introduction of the new “Guideline for Sustainable Building” [1] and the “Assessment System for Sustainable Building” (BNB) [2] for federal construction measures in May 2012, the higher quality standard "Silver acc. to BNB" has to be adhered for all new office buildings. Similar higher quality requirements should also soon be defined for renovation measures

in office buildings or for new schools or laboratory buildings for the federal public sector. In addition there is a steadily growing demand from private investors and developers for certain categories of buildings for building certifications.

Sustainable building is not an independent discipline that could be added up to the usual competition requirements. Sustainable building is based on the principle of integrated planning and holistic qualities of the building throughout its whole lifecycle.

2. Sustainability in Architectural Competitions

2.1 Research Project

Some aspects of sustainable building are always considered in architectural competitions. These can be functional requirements such as the accessibility or economic aspects such as the construction costs or the space efficiency. For special projects also energetic aspects are discussed in competitions. But in general the holistic approach of sustainable building according to the “Assessment System Sustainable Building” (BNB) was usually not been taken into account.

Concerning the planning processes we have thereby to ask ourselves how these new quality requirements on buildings can be integrated in established competition proceedings. For this purpose, an international research project was carried out commissioned by the Federal Ministry of Transport Building and Urban Development (BMVBS) under the title "sustainability requirements in competition proceedings". The research project was processed by ee concept Darmstadt (Dr. Fuchs) in cooperation with the Technical University Darmstadt (Prof. Hegger) and the architectural office H.R. Preisig (Prof. Preisig). The experiences of other European countries were taken into account in the survey, such as the Swiss method “SNARC”]3] or the Austrian method “IEAA” [4].

In order to anchor sustainability goals and requirements as integral components of competition processes it is considered necessary to point-out recommendations regarding the following four central research questions:

- Which sustainability criteria are applicable and relevant for the respective phases and the overall competition?
- How and in what level of detail should these sustainability criteria examined?
- How should the pre-examination results be summarized and presented to the jury?
- How do competition processes need to be structured and executed in order to ensure that sustainability requirements are met throughout all phases?

To answer these questions the research team developed a method called “Classification for Sustainability Requirements in Architectural Competitions” (SNAP).

2.2 The new “SNAP”- Method

The most important principle of the SNAP method is to provide a flexible system with different proposals from which the participants may choose those aspects and recommendations that fit to their specific kind and specific objective of the competition.

Great value has been set upon the aim that the requirement can be integrated in the competitions with reasonable cost for all parties involved. At the same time the method should allow a profound examination of the complex holistic requirements of sustainable building.

The practical results are now available as follows:

BMVBS broschure "Classification for Sustainability Requirements in Architectural Competitions" (SNAP)
This brochure summarizes for all parties – competition organisers, participating planners, jurors, coordinators, experts - the key recommendations of the "Classification for Sustainability Requirements in Planning Competitions" (SNAP).

Excel tool for the assessment of sustainability qualities in competition entries

User instructions for SNAP instrument
The structure and operation of the Excel tool are explained in detail in this brochure.

comprehensive final report with an explanation of the methodology and documentation of the discussion in the accompanying expert panel

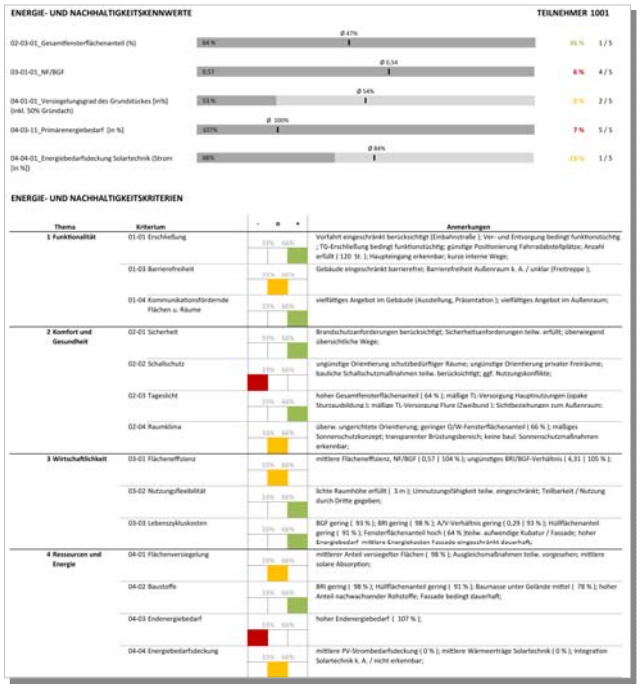

Fig. 1: broschure Classification for Sustainability Requirements in Architectural Competitions" (SNAP)
Fig. 2: results of the pre-examination in „SNAP"

The SNAP method is based on the following principles:

- The SNAP method can be integrated into the established and proven culture of competition proceedings. It constitutes an offer to extend competitions to sustainability aspects.

- Specific recommendations are defined for all phases of planning competitions (preparation, public offer, pre-examination, jury meeting, post-processing).

- Only those 15 sustainability criteria are taken into account that are relevant in this planning phase. These criteria can be demonstrated in competitions with reasonable effort by the planners and can be evaluated with reasonable effort by the preliminary examination.

- The sustainability qualities of the competition entries are assessed by calculations and by design parameters and qualitative assessments of the submitted documents.

- The examiners do the majority of the required calculations. The planners only have to complete a form with selected characteristics.

- Based upon the summarized preliminary results the jury is able to form an independent and profound opinion within a short time.

The following four subject areas can be divided into fifteen criteria with relevance in competitions. For each criteria there can be assigned up to eight additionally specific indicators. The distinction in seven "basic criteria" and eight additional "extended criteria" allows a specification in respect of the relevant competition subject.

subject area	no	criterion (basic criteria underlined)	indicator (task-specific)
design		urban pattern	assessment by jury
		exterior quality	assessment by jury
		building quality	assessment by jury
		image	assessment by jury
functionality	1	infrastructure provision	driveway, supply and disposal, access to underground parking, bicycle parking, visibility of main entrance
	2	public accessibility	public accessibility to building and property, structural requirements for opening internal institutions
	3	disabled access	disabled access for the building and for the outdoor facilities
	4	communication-promoting areas and spaces	internal and external proposal
comfort and health	5	safety	fire protection, safty requirements, clarity, orientation (building and outdoor facilities)
	6	sound insulation	orientation of vulnerable areas against external noise, orientation of private areas against external noise noise abatement measures, conflicts between different uses
	7	daylight	proportion of windows [%], daylightning, relationship of views to outdoor space
	8	indoor climate	orientation of main uses, proportion of windows east / west [%], concept of sun protection, parapets, additional structural sun protection

economy	9	floor space efficiency	effective floor area / gross floor area
	10	flexibility of use	ceiling height, feasibility of conversion, divisibility,
	11	life-cycle costs	realtion of surface to volume [%], proportion of building envelope [%], energy demand [%], energy costs [%], durability of facade, alternative: tool for life cycle costs
resources and energy	12	sealing of land	rate of sealing of the property [%], green roof, solar absorption façade
	13	building materials	proportion of building envelope [%], cubic capacity below terrain [%], renewable resources, durability of facade alternative: tool for embodied energy
	14	energy demand	total energy demand, heating demand, demand on artificial light alternative: tool for total energy demand
	15	covering energy demand	cover energy needs, solar technology (electricity, heat) integration of renewable energy production use of local energy potentials, efficiency of building technology

With the SNAP instrument we now have since January 2013 a new instrument at our disposal. On the one hand SNAP deals with the complex holistic demands of sustainable building in the context of planning competitions, but on the other hand it can be applied practically and without a large investment of time for all parties involved, so that the acceptance of the actors in competitions is ensured.

3. Competitions with sustainability requirements

3.1 Federal Environment Agency at the Bismarckplatz in Berlin

In the competition for the conversion of the office building of the Federal Environmental Agency at the Bismarckplatz in Berlin the claimed sustainability issues in the context of the preliminary review were assessed in detail and interdisciplinary. The jury received profound and comprehensible information about the sustainability qualities of the 20 competition works. Thus, the jury could decide a first place which has very convincing qualities also in terms of sustainability requirements.
.

3.2 Federal Ministry for Education and Research at the Kapelleufer in Berlin

The new building for the Federal Ministry for Education and Research at the Kapelleufer in Berlin is a current project realized in public-private partnership ("PPP"). The building is to achieve the highest level of sustainability of the BNB System in gold.

As part of the PPP procurement process the designs of five selected candidates were therefore assessed very accurately in terms of sustainability requirements.By assessing the works with a holistic view, in particular the expected life cycle costs and environmental impacts the sustainability claim could be considered to a reasonable extent.

The building qualities identified in the sustainability assessment were continuously reviewed and clarified in the planning and construction phase. The relevant compliance auditor from the Office of Sustainable Building in BBSR confirmed after the topping out ceremony that the proposed BNB certification in gold is classified as realistic.

3.3 Federal Environment Agency in Dessau

For the extension of the Federal Environment Agency in Dessau comprehensive sustainability requirements were defined in the competition, including the objectives to design a zero-energy house and reach the quality level "BNB Gold" after completion.

As a result, a contribution was honored as winner of the competition, that pooled extensive individual aspects of sustainable building in high quality in a holistic concept. These include, for example, the compact building envelope, the absence of a mechanical cooling, the use of PV elements on the roof and in the facade and the use of renewable materials (cellulose insulation, clay panels, clay plaster, flax insulation, wool carpet).

Summary

Assessing buildings' contribution to sustainable development requires taking into account economic performance aspects as well. Therefore, it is being discussed on a national, European and international level how economic performance aspects can be integrated into sustainability assessments of buildings and which criteria and indicators are appropriate in this regard. The present paper critically examines the current state of respective standardisation activities, assessment practice as well as possible criteria and indicators. In addition, the paper highlights and discusses open questions and problems which are associated with the attempt of evaluating the economic performance of buildings within the context of sustainability assessments.

Keywords: sustainable buildings, economic performance, valuation, cost, economic value, risk

1. Introduction

Within recent years the discussion and debate surrounding „green buildings" has moved on and has been further developed towards the design, construction and management of "sustainable buildings". This has also lead to a transition from describing and assessing predominantly environmental- and health-related aspects of buildings towards assessing a building's overall performance including an analysis of interrelationships and interdependencies between different partial aspects.

In addition, a commonly accepted understanding of sustainability for the construction sector has meanwhile emerged worldwide which is supported and backed-up through international standardization activities (e.g. ISO, 2008). According to this understanding, a building's or construction work's contribution to sustainable development has to be assessed not only by evaluating compliance with current and future requirements concerning functional and technical qualities but also by equally and simultaneously considering environmental, economic and social performance aspects as well. As a consequence, an evaluation of economic performance aspects now forms an integral part of sustainability assessments of buildings.

Within international standardization activities one economic indicator – i.e. life cycle costs - has already been included into the core list of indicators for sustainability assessments (see: ISO, 2011). On a European level, the indicators „life cycle costs" as well as „value" are currently being discussed (see: CEN, 2012).

In contrast to the assessment of environmental- and health-related aspects, the evaluation of economic performance aspects within the context of sustainability assessments of buildings does not yet have a history of decades of experiences. This discussion is just beginning (see, for example, the European SuPerBuildings project, 2012)
As a consequence, within existing systems and tools for assessing and certifying the sustainability of buildings, economic performance aspects are only partly taken into account. Examples for certification systems that do take economic aspects into account are those of DGNB and BNB which have been developed with the collaboration of one of the authors of this paper, Thomas

Lützkendorf. But also for the aforementioned systems there exists the need to further develop assessment basics and standards as well as appropriate economic criteria and indicators.

The aim of the present paper therefore lies in examining and discussing fundamental questions relating to the description and assessment of a building's economic performance, to possible criteria and indicators as well as to scopes of action and possible solutions. Particularly, the following questions will be addressed within the present paper:

- Which overall areas and goals of protection lend themselves for deducing economic performance requirements?
- What is an appropriate perspective for assessing economic performance aspects – a societal perspective and/or the perspective of individual actors and market participants such as owners, tenants, banks, investors, public authorities, etc.?
- What are the differences and commonalities between a specific economic appraisal tailored to the needs of one single actor and a broader, generic assessment of a building's economic performance?
- How is it possible to take into account the perspective and interests of current and future generations within the context of economic performance assessments?
- What are key areas of concern/interest and how can these be reflected through criteria and partial indicators?
- If one accepts the proposition that economic performance aspects are already (or to be more precise: should be) an integral part of sustainability assessments, how is it then possible to evaluate interrelationships and interdependencies between a building's degree of sustainability and its economic value? Is there a loop and/or a circular argument?

2. Discussion of areas and goals of protection

Following a top-down approach and deducing criteria from overall areas and goals of protection turned out to be appropriate and purposeful for complex ("2nd generation") sustainability assessments systems which comply with the current state of standardization according to ISO and CEN. Consequently, the question relating to areas and goals of protection in the field of the economics arises.

Up until now and if at all, economic performance aspects have been considered by focusing on the costs of buildings during their life cycle. The goal was to minimize these costs and to achieve a favorable trade-off between construction and operating costs. This criterion emerged through a bottom-up approach since the assignment of the criteria to particular areas and goals of protection has not been discussed.

Since financial assets and capital are resources as well, the goal of protecting financial resources can be implied in the first instance. Protecting financial resources also contributes to maintaining the actors'/market participants' (financial) capacity to act. However, it is problematic that besides for owner-occupiers which can follow a total-cost-of-ownership approach, costs of buildings during their life cycle can and must be assigned to specific actors. Consequently, the question of the appropriate perspective arises.

The calculation and assessment of life cycle costs is normally carried out by taking the perspective of planners which is usually identical with the perspective of owner-occupiers or public authorities. But for all other market participants, individual or institutional perspectives dominate any assessment of cost-effectiveness. In addition, regarding the criterion life cycle costs there is a conflict of goals from a societal perspective. On the one hand, the input of financial resources during a building's life cycle shall be minimized; but on the other hand, this input of financial resources generates tax revenues and creates/maintains employment. Against this background it becomes apparent that the application of life cycle costs as a criterion for assessing a building's economic

performance has hitherto taken place without proper methodological deduction and theoretical reasoning.

Another possible goal of protection is the “affordability” of buildings. However, whether or not this aspect lends itself for assessing performance in an economic context deserves further discussion and debate. Without doubt, low construction and operating costs can contribute to the affordability of buildings in the sense of eased access to the rental housing market or to residential ownership. For example, for tenants but also for owner-occupiers operating costs are of particular interest as these costs are not only determined through user behavior but also though several building characteristics such as insulation, water-efficient taps, etc. But in most cases and also regarding other property market actors, the affordability of buildings is overlaid by a variety of other factors. For example, in the case of owner-occupiers, the “affordability of a building” is co-determined, amongst other issues, through household income and financial circumstances. As such, and in a strict sense “affordability” (particularly of residential property) is not a trait of buildings per se but a challenge to society.

In contrast, the economic value of single buildings and of building stocks is a clear commodity of protection. The goal is to protect/maintain and, as the case may be, to increase the buildings’ economic value since this contributes to the stability of the economic system. Therefore aspects like value stability, retainability and value development turn into assessment criteria. However, the problem here is that these aspects have not yet finally been transferred into manageable indicators and that appropriate measurement approaches and standards are still to be developed. A further discussion of the current state of theory and practice will be carried out below.

Economic considerations always also have a regional and macroeconomic dimension. For this reason, questions relating to the contribution of construction activities (and also of single buildings) to regional value creating are also sporadically being discussed. Further goals can be seen in the reduction of subsidy expenses (if applicable) and in the decrease of external costs. From the authors’ point of view, particularly a decrease in external costs is an important goal of protection which has not yet received appropriate consideration and discussion. For example, in ISO 15686-5: 2008 Buildings and constructed assets – Service life planning – Part 5: Life-cycle costing external costs are treated as environmental costs and are assigned to the life cycle costs of a building. This appears to be a feasible approach.

3. Discussion of fundamental issues and questions

In the case of buildings and construction works, the general assessment of the economic performance predominantly takes place (in theory) from a societal/macroeconomic perspective (e.g. impact of construction activities on employment, gross domestic product, CO2-reductions, etc.). Therefore, a fundamental difference exists in comparison to the individual/subjective economic efficiency/profitability calculations of single market participants. In such cases, economic efficiency/profitability calculations (which are usually carried out within the context of investment or other decision making processes) are strictly tailored to a specific case and take into account *individual/subjective framework conditions*. An additional characteristic of such calculations is the occurrence of conflicting goals between the parties involved (e.g. between landlords and tenants).

In contrast, existing sustainability assessment and certification systems for buildings usually set/prescribe *average framework conditions* (in the form of conventions) in order to create comparable assessment and certification results. If and to what extent individual interests and perspectives of single groups of actors could (and should) also be taken into account when assessing economic performance aspects in the context of sustainability assessments has hardly ever been examined in the literature and is therefore open for discussion. The authors of this paper would highly appreciate a scientific debate concerning the aforementioned issue.

The definition of sustainable development explicitly emphasizes the necessity of taking into account the needs of both, current and future generations (intergenerational justice). However,

whenever economic performance aspects are assessed as part of a sustainability assessment, usually the position and perspective of the current generation is assumed. Inter alia, this circumstance is reflected in / expressed through the discounting of future cash flows. If and to what extent the (economic) interests of future generations can also be taken into account requires further examination and scientific debate. Possible approaches to allow for such considerations are: diminishing discount rates; a discount rate of zero (or even a negative discount rate); the full Visualization of Financial Implications (VoFI); proof of unindebtedness at a given due date; proof of sufficient capital reserves for maintenance, modernization and deconstruction; or the avoidance of external costs within the scope of a subsequent deconstruction including disposal.

Apparently but at a first glance only, the assessment of economic performance aspects within the context of sustainability assessments of buildings involves a contradiction or a loop/circular argument. On the one hand, and due to the reasons explained above, economic considerations shall be directly integrated into sustainability assessments of buildings. On the other hand, however, a connection is often made between the sustainability of buildings and market participants' willingness to pay, which, in turn, is reflected in the buildings' economic value. The apparent contradiction may be resolved as follows: Besides certain exceptions, sustainability assessments of buildings usually do not involve valuations (in the sense of market valuations) or specific/individual economic efficiency calculations. What can be described and assessed as part of a sustainability assessment is – in the sense of a partial (economic) indicator – the *building-induced contribution to financial risk* (see Chapter 4.4 below). Thereby, the actual property valuation – which considers several further aspects (such as overall market conditions) in addition to sustainability-related value relevant building features – still remains outside of sustainability assessments.

The discussion and agreement on appropriate areas and goals of protection as well as the positioning relating to fundamental issues and questions form the basis for the development of appropriate assessment criteria.

4. Discussion of possible assessment criteria and indicators

4.1 Construction / investment costs

In connection with energy efficient and/or sustainable buildings the construction / investment costs (in the sense of purchase payments) are often at the centre of discussion as the misconception of significantly higher costs in comparison to standard or "conventional" buildings still prevails. But this also automatically reveals a key problem because in order to be able to disclose (additional) costs for sustainable construction in comparison to "conventional" construction there needs to be a baseline or benchmark to define "conventional".
In the case of new buildings, the benchmark or baseline usually is the current state of construction technique or the current state of national legislation and standardization. However, such a baseline or benchmark does not automatically define/specify a particular building or constructive solution but leads to a wide variety of construction variants with quite different construction costs. As such, the choice and determination of the actual reference value for "conventional" construction costs remains problematic. Therefore, an exact definition of what has been (or what shall be) included in the construction / investment cots is required (e.g. selected groups of construction costs, costs for planning/design costs, management, and the plot of land, value added tax, etc.). The respective system boundary depends on the intended usage / scope of the analysis and the applied benchmark (see also section 4.3). It is either common to focus on mere construction costs for the building, equipment and appliances or to disclose all investment costs including costs for the management and the plot of land.

Within some assessment systems and subsidy programs (e.g. in Austria and Switzerland) additional costs for energy efficient/sustainable buildings of up to 10% are being accepted (the difficulty of determining the baseline or benchmark has already been mentioned above). But based on an analysis of completed construction projects it can be argued that, for example, in France and

Germany, energy efficient/sustainable buildings can be realized with relatively low additional construction costs between 5% and 0%. The reason for this lies in the already high level of required performance of “conventional” new buildings in these countries.

As a result of experiences in Germany the authors of this paper favour another approach than debating “additional” costs for sustainable buildings: For many building types and usages an “average budget” can be specified based on past experiences and/or specifications set by public authorities. If such a “budget” is given, it can then be shown that by applying the principles of integral planning, energy efficient / sustainable buildings can be realised within this budget (as the case may be at the upper limit of the budget). An important issue is also the comparability of the specifications of the building under investigation as well as of the budget (base year, system boundaries, region, etc.); if applicable, conversions and validations may be necessary. In any case, following this approach diverts the attention from the level of “additional” costs for sustainable buildings to the compliance with a given budget.

From the authors‘ point of view, mere construction / investment costs cannot be recommended as an appropriate criterion for assessing the economic performance of buildings within the scope of sustainability assessments. Instead, it would be possible to consider *maximum additional costs* or demand *compliance with a given budget* as an additional requirement – e.g. within the scope of assessing life cycle costs.
By all means, the authors’ recommend paying attention to a clear, transparent and traceable depiction of construction / investment costs (in the sense of “additional information” accompanying an assessment results) whenever energy efficient / sustainable building projects are to be presented / showcased. Depicting mere construction costs (i.e. costs of the building without, for example, costs for purchasing the plot of land) has proven useful in this context.

4.2 Life cycle costs / selected costs within the building life cycle

In connection with the description and assessment of the sustainability of buildings and construction works there is widespread consensus that life cycle costs have to be considered at first in order to describe and assess economic performance. An international standard (which is currently under revision) for calculating life cycle costs is available: ISO 15686-5. However, the current structure of the standard is more or less a checklist to declare included cost categories. As such, the existing standard only partially answers currently unsolved questions.

The results of a life cycle cost analysis are influenced, among other issues, through the following parameters:

a) Type and scope of included cost categories
b) Measures and time frame under observation
c) Applied discount rate for calculating net present value / net present cost
d) Assumed inflation rates
e) Price level for utilities supplies
f) Assumed scenarios for maintenance, modernization and end of life

The results of a life cycle cost analysis can only be interpreted / judged (by third parties) in a meaningful manner if the aforementioned parameters are disclosed. Selected parameters will be dealt with in more detail in the following:

a) Type and scope of included cost categories
There are various forms of describing and structuring different cost categories which could be included within a life cycle cost analysis. Basically, a distinction has to be made between a life cycle cost analysis in a strict sense (i.e. only payments-out / costs are considered - LCC) and a life cycle cost analysis in a wider sense (i.e. in addition to costs also income / payments-in are taken

into account – WLC). For describing and assessing the economic performance within the scope of sustainability assessments, a life cycle costs analysis in a strict sense is usually drawn upon. But this approach also bears some problems / open questions; particularly if income arises due to electricity generation by buildings equipped with photovoltaic-systems. If applicable, this income could be treated as “negative” costs.
The life cycle costs of a building are usually comprised of construction costs (DIN 276 in Germany) and operating costs (DIN 18960 in Germany). Up until now, usually not all costs / cost categories according to DIN 18960 are being considered within the scope of life cycle cost analyses in the context of sustainability assessments in Germany. Instead, a selection is made in order to consider building-induced costs only, since only these costs can directly be influenced through decisions made during the planning / design phase (e.g. energy costs, maintenance costs, cleaning costs). But it is still open for discussion whether or not also insurance and financing costs are to be taken into account in order to achieve a better representation of real-life circumstances; this particularly applies in market environments within which favorable lending and insurance conditions are offered for sustainable buildings by banks and insurance companies.
A further area of discussion is whether external costs should be considered within the scope of life cycle costs analyses in the future or if these costs should be accounted for separately. In any case, a consideration of external costs does make sense from the authors’ point of view – particularly when construction projects of public authorities are to be analyzed; in such cases, for example additional fees on energy prices could be a possible approach.

b) Measures and time frame under observation (study period)
To date, the most common practice in portraying building-induced costs along the building life cycle is calculating the net present cost. Building-induced costs occur at different points in the life cycle of a building; also building-induced costs (e.g. for modernization) can be seen as investments into highly illiquid assets. As a consequence, they cannot be compared or summed up directly due to the *time value of money* and the *value of liquidity*. (The last mentioned issue (i.e. how to account for the value of liquidity) has not yet gained much attention and debate within the sustainability assessment related literature.)
The mechanism to account for the time value of money and the value of liquidity is discounting. Costs are discounted back (i.e. converted) to their present value. Net present cost can be defined as the total cost of a building after the time value of money (and the value of liquidity) have been taken into account.
If a life cycle cost analysis in a wider sense is carried out (i.e. if also income / payments-in are considered), then the result of the calculations is the net present value which can be defined as the present value of the payments-in minus the present value of the payments-out.
In either case, it is required to specify an appropriate time frame under observation. And this involves finding a compromise between the growing uncertainty of cost and income projections during the future life cycle (which would call for a preferably short time frame) and the implied goal of taking a long-term view (e.g. in order not to disregard future generations). From a methodological point of view, sustainability assessments of buildings favor taking an identical time frame (as well as an identical building model) for both, life cycle analysis (LCA) as well as life cycle cost analysis. In Germany, for example, the time frame (or reference study period) for both aspects of the assessment is 50 years.
However, the interest in an appropriate assessment of buildings with varying life spans leads to further questions and calls for alternative ways for portraying buildings’ (whole) life cycle costs. Amongst other issues, the concept of equivalent annual cost is being discussed which can be defined as the cost per year of owning and operating an asset over its entire lifespan (see: Davis Langdon, 2007).

c) Choice of the discount rate
The choice of the applied discount rate significantly impacts on both, the resulting net present cost or net present value respectively as well as on the relationship between initial construction / investment costs and follow-up costs. The choice of the discount rate (and also the selection of the

applied discounting model; e.g. exponential or hyperbolic discounting) can be made from a number of different perspectives.
For example, the consideration of interests of future generations requires a preferably low discount rate (usually 0% - 2% are mentioned in the literature). High, or too high, discount rates reduce the relative importance of follow-up costs and of possible future cost-saving effects. This has an adverse impact on the assessment of (additional) measures for improving a building's energy efficiency and degree of sustainability.
The European Commission currently recommends a discount rate of 3% and, in addition, the application of a discount rate which is in line with "market conditions".
Within the context of sustainability assessments, the choice of an appropriate discount rate and the selection of an adequate discounting model are (and shall be) intensely discussed within the literature (e.g. Quiggi, 1997; Evans and Sezer, 2005; Gollier, 2011). From the authors' point of view, this is due to the circumstance that there may be no absolute, objective, or "right" answer to this problem since discount rates for sustainability assessments cannot be deduced mathematically or evidenced empirically. Rather, their selection depends on the context of the assessment (assessment purpose; assessment perspective, type of client, e.g. public authority or industry/business; etc.). As such, the choice of the discount rate needs to be adequately described and justified.

4.3 Cost-Value Ratio

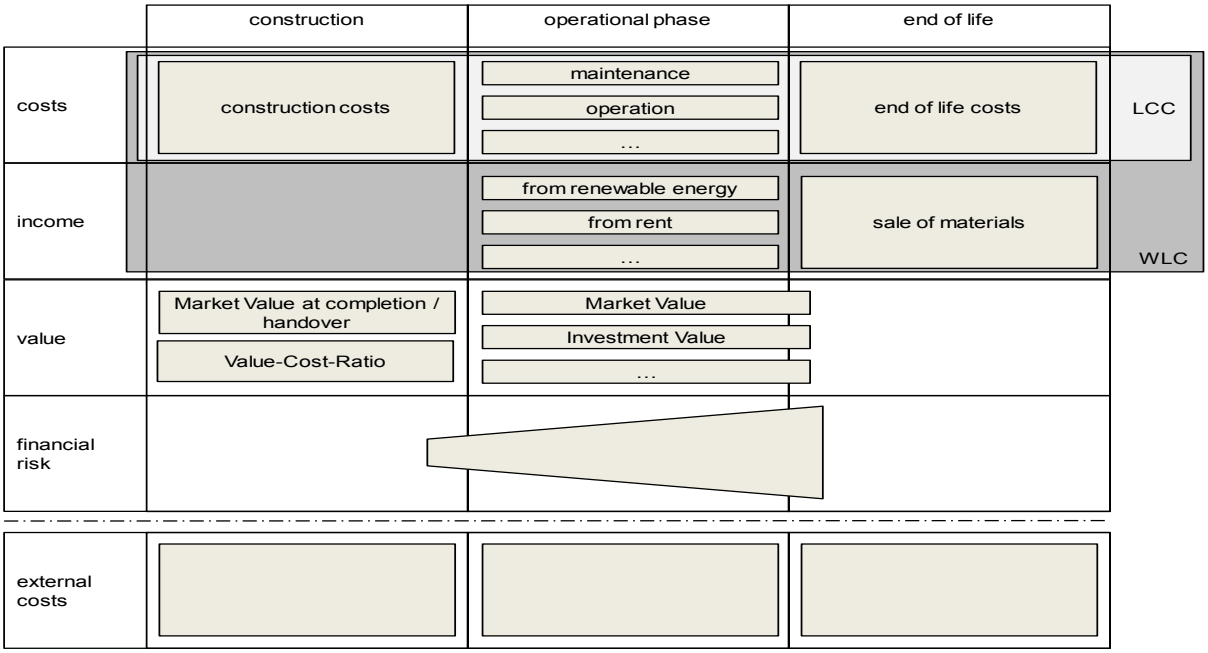
Often the question arises whether or not the economic value created through a construction and/or building project "justifies" the capital invested into this project. Or expressed in other words: investors as well as owner occupiers have an interest in ensuring that the economic value of the building at point of completion is not less than the capital cost of it.
An approach for assessing this worthwhileness of an investment at the date of handover has been developed in Germany (with the collaboration of one of the authors of this paper, Thomas Lützkendorf) within a project concerned with the development of a sustainability assessment and certification system for residential buildings called NaWoh (Nachhaltiger Wohnungsbau – Sustainable Housing). The approach pursued in this project relates the total cost needed to bring a project to a commercially operable status (e.g. purchase of land, buildings, construction and equipment, an investor's profit margin, etc.) to the completed building's Market Value (estimated by applying the income/investment method of valuation) at the date of handover. This *Cost-Value ratio* at point of handover illustrates how worthwhile the investment into a project is at the point of completing the project since it reveals whether or not the capital costs are appropriately related to the current market situation.
This approach particularly lends itself for the assessment of buildings which shall be fully rented right after completion. A further area of application is in the context of modernization/refurbishment projects in order to assess if the capital invested is appropriately related to the potential value increase associated with the modernization/refurbishment measures.
As a side issue, it can be discussed if and to what extent the quality of a sustainable building is already reflected in rent levels and thus, in the current Market Value of the building. This also leads to the general question if and to what extent the property valuation profession and valuation practice already take into account sustainable building issues (see also Chapter 5 below).

By introduction a Cost-Value ratio as an additional indicator into the sustainability assessment of buildings, the market valuation of properties (the traditional domain of the property valuation profession) becomes a basis for calculating this ratio. And this inevitably leads to further questions; notably the question whether or not non-valuation specialists are actually able to accurately assesses a building's Market Value? Property valuation is a complex professional activity backed-up by professional codes, extensive standards and guidelines and usually, carrying out valuations in practice requires extensive expertise and appropriate education and training.
Advocates of a Cost-Value ratio might argue that a detailed property valuation is not really necessary in this context and that simplified valuation methods could be applied by laymen since finding out whether the capital costs are *significantly* higher (or lower) than the Market Value at the

date of handover is sufficient. However, the counterargument here is that several past real estate and financial crises have painfully demonstrated that even experienced valuation professionals occasionally *significantly* under- or overestimate a building's Market Value. Consequently, it needs to be discussed if external expertise (in the form of trained valuation professionals) is necessary whenever sustainability assessments of buildings aim to also assess the worthwhileness of an investment.

4.4 Long-term stability of value and value development / contribution to financial risk

The desire of assessing the long-term stability of value and value development of buildings is closely connected to the goods/commodities and goals of protection as discussed above. In addition, taking a long-term view particularly reflects the perspective and goals of sustainable development. Nonetheless, a medium- to long-term perspective on the economic value of buildings is extremely difficult and associated with various uncertainties. This is due to various reasons: first of all, assessments of the economic value of buildings are *snapshots in time*, they are usually valid only for the specified date of valuation. The concept of a long-term perspective on a building's economic value is termed *mortgage lending value* within the valuation profession; and this concept is controversially discussed since parts of the valuation profession simply deny (for good reasons) that a long-term assessment of economic value can even exist.
In any case, forecasting the future value development of buildings is hardly ever possible. In addition, the value development of buildings depends on many factors (e.g. market conditions) other than building-related characteristics and attributes. Furthermore, integrating the long-term stability of value into sustainability assessments of buildings would mean taking the current Market Value as a starting point for the analysis; and this, in turn, would lead to the very same problems and open questions as discussed in the context of a cost-value ratio above.



At the moment the German sustainability assessment systems of BNB and DGNB take into account a building's value stability through replacement-indicators which are based on an assessment of the building's usability by third parties and of additional technical-functional building characteristics. As such, not the building's value stability and value development (in a strict sense) are captured through these assessment systems but the building-induced contribution to a (potential/likely) value stability and value development. An additional problem is that assessing a building's usability by third parties and other technical-functional characteristics within the context of evaluating economic performance aspects is somewhat like a repetition (since these characteristics are also assessed within other assessment categories); as a consequence, the multiple impact of these characteristics is often confused with double-counting.

For these reasons the authors of this paper suggest assessing the medium- to long-term *building-induced contribution to financial risk*. In practice, this could be done along the lines of so called property and market rating systems (the rating category "property" is of particular relevance in this context) which are applied by the valuation and financial industry since several years in order to measure and portray the financial risk of property investments and of loans secured by real estate assets (for a further explanation of such rating systems see: TEGoVA, 2012, p. 207-220; Lützkendorf and Lorenz, 2007).

Assessing the building-induced medium- to long-term contribution to financial risk (or to its reduction) allows for both, reflecting the high degree of uncertainty involved and concentrating on building-related characteristics and attributes. However, the approach of assessing building-induced contributions to financial risk within the scope of sustainability assessment systems is currently under discussion and, as a start, needs to be tested in practice.

The following Figure 1 summarizes possible criteria/indicators which have been discussed in Chapter 4 and which could be used for evaluating economic performance aspects of buildings within the context of sustainability assessments.

Figure 1: *Economic performance criteria / indicators along the building life cycle*

5. Sustainability and property valuation – state of theory and practice

Within some sub-markets and in some countries property pricing is increasingly distinguishing between buildings that exhibit different sustainability-related building features and associated physical or operational performance. There is recognition that buildings which are not resource efficient, low carbon in terms of operation and location and which are not equipped to flex to changing occupier needs will not be future proofed in market value terms. As a result, the academic valuation community but also practitioners are discussing the issue of integrating sustainability considerations into the valuation process since more than a decade. More recently, the topic was also taken up and advanced by the large professional organizations and valuation standard setting bodies such as the UK-based Royal Institution of Chartered Surveyors (RICS), the Appraisal Institute in the USA and The European Group of Valuers' Associations (TEGoVA). To date, these organizations have published respective guidance and encourage valuation professionals to consider sustainability issues when undertaking property valuations.

For example, in 2009, the RICS published a global Valuation Information Paper (VIP13) on this topic which was the first attempt of a valuation standard setting body to advice professionals on how to cope with the issue of sustainability in commercial valuation practice. In 2011, the RICS published an Information Paper (IP 22) for UK-application only on how to deal with the issue within the scope of residential valuations. In this paper the RICS also encourages valuers to expand their basic data collection procedures to include a record of any sustainability features, even if they do not currently have an impact on value. Similar advice and associated recommendations have now also been produced by other professional organisations but also by groups of individual practitioners and researchers. An example for the latter case is the NUWEL-guideline for professionals operating in the German, Austrian and Swiss property markets (see: Meins et al., 2012). The following Table 1 provides an overview on existing guidance and guidelines for valuers.

Table 1: *Existing sustainability related guidance, guidelines and requirements for valuers (Lorenz et al., 2013)*

Title / Description	VIP 13	IP 22	VIP 13 (Australia)	EVS 2012 (Information paper on sustainability and valuation)	ImmoWertV	NUWEL	RICS Draft Guidance Note
Publisher	RICS	RICS	RICS Oceania	TEGoVA	BMVBS	CCSR	RICS
Year of Publication	2009	2011	2011	2012	2011	2011	2013 (planned)
Application: Property type	Commercial Property	Residential Property	Commercial Property	All	All	All	Commercial Property
Application: country / region	Global	UK	Australia	Europe	Germany	Germany, Austria, Switzerland	Global
Coverage of sustainability issues	broad	broad	broad (but focus on energy)	broad	Energetic quality	broad (detailed listing of issues)	broad (detailed listing of issues)
Degree of compul-sion / bindingness	informative	informative	informative	informative	mandatory	informative	recommended good practice
Character: generic requirements / detailed recommen-dations	generic	generic	detailed	generic	-	detailed	detailed
Recommendations for valuation reports	-	-	X	-	-	X	X
Recommendations on the extension of the data collection process	-	X	X	-	-	X	X

The topic of integrating sustainability issues into property valuation has a theoretical, methodological, practical and ethical dimension. As such, discussing the issue in detail would lead far beyond the scope of the present paper. Therefore, only selected aspects are briefly discussed below.

Towards a "long-list" of value-relevant factors

Traditionally, valuation professionals have considered a range factors in order to derive an opinion of value. These factors include, for example, national and local market conditions, rent level, functional quality of the building, usability by third parties, letting situation, etc. etc. With the advent of the sustainable development discourse within the valuation profession, "sustainability" has been treated as a somewhat separate category of value-relevant factors. However, recently the perception has emerged that this does not make a lot of sense for a number of different reasons. First of all, traditional valuation methods and practices do take (and have always taken) into account building characteristics which are now termed 'sustainability issue' or 'sustainability aspect'. One example for this is the building's functionality. Consequently, any valuation approach that separates sustainability considerations from the other value-influencing factors is likely to be methodologically incorrect. The methodological separation of sustainability considerations from traditional factors creates the possibility of double counting and does not provide a clear process for evaluating and pricing the sustainability factors. As a result, the valuation profession has started to embed sustainability issues into the traditional "canon" of value-relevant factors and is moving towards a "long-list". An example for such a list can be found in Lützkendorf and Lorenz (2011) and in the already mentioned NUWEL-guideline.

Towards mandatory sustainability related requirements for valuers

Most of the existing sustainability related advice and recommended practices for valuers (as shown

in Table 1 above) are as yet not mandatory requirements enforced by professional organisations but are of informative character only. It is therefore likely to assume that most valuers would hesitate to modify their practices as well as to extend their data collection procedures as this could be seen as an unpaid extra-work. Nonetheless, there are two exceptions to this:
(1) In Germany valuation standards are not developed and enforced by professional organisations but by the state in the form of so-called valuation orders. And in 2011 a revised version of the German valuation order (Immobilienwertermittlungsverordnung, ImmoWertV) came into force. And within this valuation order, the subject property's energetic qualities are listed as a value influencing factor that has to be taken into account within the valuation process. The explicit recognition of the relationship between a building's energetic qualities and its market value can be considered as a very good step into the right direction.
(2) The RICS is currently in the process of adopting a respective guidance note on the issue of sustainability and commercial property valuation (see Table 1 above) to be included in an updated version of the RICS Red Book (i.e. their internationally recognised valuation standards). The content of a guidance note is defined as "recommended good practice" for valuation professionals; deviations from the prescriptions of a guidance note within a valuation assignment have to be explained in writing with the valuation report. As such, a guidance note can be seen as a quasi-mandatory requirement for professional members of the RICS. Since the publication of the guidance note on sustainability and commercial valuation is scheduled for this year (2013) it can be expected that sustainability will now become an integral part of future valuation assignments carried out be members of the RICS.

Towards improved data and empirical evidence
A key concern in connection with the issue of sustainability and valuation is the lack of both, data and information on the sustainability credentials of the property to be valued and, an appropriate empirical evidence base to support / back up an individual valuer's decision on how to price the subject property's sustainability credentials (or their absence) within a given local market environment. Both aspects are currently being addressed by individual valuers, professional valuation organisations and other third parties.
On the one hand, effective mechanisms are being sought and developed to link sales prices (and other financial information such as rental bids) with information on the respective properties' sustainability credentials (e.g. through the increased usage of information contained in energy performance certificate and sustainability assessments). Good examples for this are (1) efforts undertaken by individual German valuation expert bodies who have started to extend their comparable sales databases to include sustainability related information in addtiona to "traditional" variables; and (2) efforts undertaken by the Investment Property Databank (IPD, a globally operating commercial real estate index provider) to integrate envornmental performance information in their real estate indixes (see the IPD EcoPAS initiative).
On the other hand, valuation professionals are either explicitly encouraged (e.g. by TEGoVA) to seek expert advice (i.e. from sustainability assessment experts) and/or to rely on relevant certification results as to a property's sustainability rather than to assess the sustainability of subject property personally because valuers must act within the limits of their professional skills (see: TEGoVA, 2012). Or valuers are encouraged (e.g. by the RICS) to expand their basic data collection procedures to include a record of any sustainability features (if possible), even if they do not currently have an impact on value in order to improve the information available in the marketplace. The last mentioned approach involves the question if and to what extent valuation professionals actually have the knowledge and skills to gather (or even produce) such information personally. This question has been elegantly solved by the RICS: within the already mentioned RICS draft guidance note on sustainability and commercial property valuation it is stated that valuation professinals should personally gathter/generate sustainability related information only if this is in line with their professinal skills (e.g. valuers can analyse an energy bill or asses whether or not the subject property exhibits the potential for solar energy usage, etc.); in all other cases, valuers are encouraged to *ask their clients* (i.e. in most cases the building owners) to provide information on the subject property's sustainability credentials. And if clients cannot deliver this information, then either external (sustainability) experts have to be involved, or, valuers may treat this lack of information as an additional risk factor that can impact on the overall valuation result. In either case, it is likely that the demand for sustainability assessments and/or building performance evaluation and reporting will signifcantly increase due to the aforementioned developments within the valuation profession.

6. Summary and outlook

The present paper has shown that any attempt to evaluate economic performance aspects of buildings within the scope of sustainability assessments reveals a range of unsolved questions and problems which have not yet been sufficiently discussed within national and international research communities. The authors' attempt was not to solve these questions and problems but to highlight them in order to stimulate scientific discussion and debate on these important issues.

The paper has also revealed that two formerly distinct disciplines (i.e. sustainability assessment of buildings and property valuation) are now converging and rely heavily on each other. On the one hand, sustainability assessments of buildings increasingly rely on concepts (Market Value) and methods (income/investment valuation method) originally developed by the valuation profession in order to be able to appropriately describe and asses the economic performance of buildings. On the other hand, the valuation profession increasingly relies on sustainability related information in order to be able to appropriately estimate the economic value of buildings. As such, it appears advisable for both disciplines not to attempt to "reinvent the wheel" but to rely on and make clear reference to the terminology, standards, norms, and definitions which have already been developed and applied within the respective other discipline. This requires dialogue and cooperation between the key representatives and professional bodies of these disciplines.

The interaction between sustainability and quality in building – systemic approach and case study buildings

Annette Hafner
researcher
Chair of timber structures and building construction
Technische Universität München
Germany
a.hafner@tum.de

Summary

Today sustainability gains a growing acceptance in the building sector and is seen as a trendsetting part for buildings. On the other hand building processes up to date are still only evaluated through price competition and marked by the handling of failures and insufficiencies in the construction and erection of buildings. Positive effects of better building quality are not identified widely.
Therefore this paper examines the interaction and impacts between aspects of sustainability and the criteria of quality in buildings. The analysis is carried out through a sensitivity model and evaluation of results through case studies. Cybernetic modelling is introduced to highlight interactions and their influences on each other.

Firstly the elastic terms of quality in the building context and sustainability are discussed. A sensitivity analysis is made to show the interactions of the different aspects on each other and to work out the important aspects.
Therefore twenty variables are deduced from the firm establishment of the terms, which matter most for this topic. They constitute the set of variables for a sensitivity analysis from Vester. With the sensitivity analysis an impact matrix and an effect system are elaborated to emphasise the critical variables for the processes and variables which matter most.
On these results and for closer inspection of the correlations, sustainable buildings, which are recognised as exemplary representatives, are examined to identify the underlying principals. Processes behind planning and erection of each building were observed critically. The results of the building analysis are then contrasted with the results of the (previous) sensitivity analysis.

An effect system for the creation of sustainable buildings is developed as a cybernetic model. In this model it is outlined which prerequisites are required to develop sustainable buildings. Certain aspects, which generate high impact for the whole system, were emphasised and starting points for improvements elaborated.
True sustainable buildings can only evolve from stronger interactions between the separate disciplines. The first step is to understand the interdependencies and interactions between the variables and then to develop the main factors so that the system changes with the lowest input. In reaching sustainable buildings, design with its complex dependencies has to regain a central position. Client behaviour as well as quality of construction work on site are also fundamental. Motivation of planners and builders and communication between them is highly important.
More training for all parts of the building sector in these issues is necessary. A honest culture of teamwork for the best result rather than only the economic success is fundamental.

Keywords: sustainability; quality in buildings; sensitivity analysis; interaction

1. Introduction

In recent years sustainability has gained growing acceptance in the building sector and is seen as a trendsetting part of buildings. The certification of sustainability with systems like DGNB / BNB, bream etc. have introduced further requirements to building processes. Various guidelines have been developed for this gain. Newly developed calculation tools (e.g. for LCA / LCC calculation) are being used more and more.
On the other hand building processes up until now have still only been evaluated through differences in price and marked by the handling of failures and insufficiencies in the construction and erection of buildings.
Communication and exchange of data is often insufficient. Clients often only look at construction costs without concern for later operational costs.
Positive effects of better quality of buildings are not widely identified or at least not realised consistently with early quality assurance systems. Extra money is spent on sustainability criteria but not invested in obvious quality assurance.
This paper examines the interaction and impact between aspects of sustainability and the quality in buildings. Through this the main influencing factors of the building process on sustainability goals is examined through a sensitivity model and their influence is visualized by analysis of different realised buildings.

2. Main issues and their definition

Firstly the elastic terms of quality in the building context and sustainability, as well as complex interactions are discussed. Then a sensitivity analysis is produced to work out the most important aspects and to show their interaction with each other.

2.1 Quality in buildings

The term quality has a broad meaning. In the ISO standard ISO 9001 quality is defined as a “degree to which a set of inherent characteristics fulfils requirements.”[1] To bring it into practice quality for the building sector can be defined as adherence to agreed properties. According to Trost [2] quality in buildings can be divided into concrete, abstract and indirect characteristics. Technical issues and their realisation belong to the first category, aesthetics and image of the building to the abstract category and indirect issues are communication and cooperation in building sector.
Main objective for quality in buildings is the adherence of the agreed qualities. If the quality is not complied with, we speak of faults, defects / insufficiencies and damages. To the left, figure 1 shows the percentage of faults and defects in building context and how many of these end in damages [3]. To the right, figure 1 shows the reasons for such faults [4].

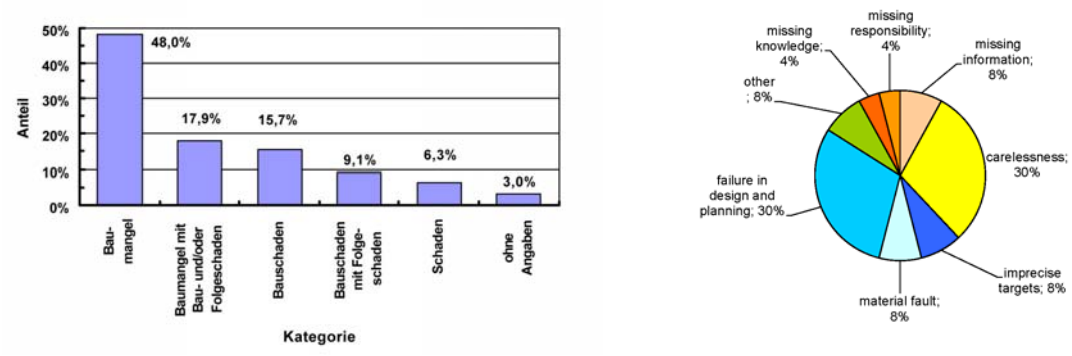

Fig. 1: categories of defects [3] and faults / defects in building sector according to [4]

By looking at these figures the conclusion can be drawn that a high percentage of faults could be avoided by accurate planning and in improvements in communication and knowledge. Knowledge here applies mainly on having sufficient information and explicit dedicated responsibilities.

2.2 Sustainability

The term of sustainability is used according to the sustainability triangular and the definitions underlying the actual certification systems of BNB and DGNB [5]. Individual criteria are included in the considerations on assessable factors for sustainability issues in the building sector. As shown in figure 2 sustainability issues are divided in columns and then subdivided in single issues.

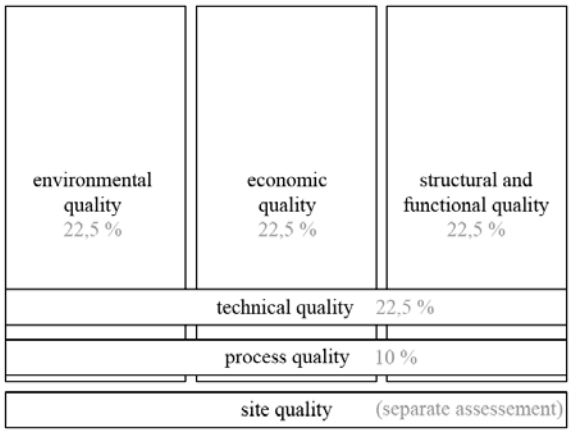

Fig. 2: subdivision of sustainability issues in compliance with sustainability certification schemes

2.3 Complex interactions – cybernetic

Interactions and dependencies have become more complex due to strong division of work, due to specialisation and also advanced communication systems. Therefore problems can often not be solved immediately and without further adjustments further down the line. The solving of one problem often generates problems with other issues. Frequently cause and effects are not easily connected. Complex systems and interactions are dynamic systems. The characteristics for these systems are that even small faults can have a major influence on the whole system.
The building sector is marked by the involvement of many participants, very diverse objectives and a new approach for every project.
In that context cybernetics is introduced to allow visualisation and handling of complex issues and interactions. Cybernetics is an interdisciplinary science to regulate and control open loop projects. It aims at identification of nature and control of complex systems. The systemic approach is introduced with this.

3. Interaction between sustainability and quality in building

To study the interactions between sustainability and quality in buildings twenty variables are deduced from the firm establishment of the terms explained above. Systematic approach is introduced to emphasise on changes of interactions. They constitute the set of variables for a sensitivity analysis from Vester. The most effective variables are filtered trough the impact matrix and effect system. Simulation of individual parts of the system help to visualize the overall effect of changes to the system. Based on these results, sustainable buildings, which are recognised as exemplary, are examined in order to identify the underlying principals and their correlation. The results of the building analysis are then matched with the results of the sensitivity analysis. An effect system for the creation of sustainable buildings is then developed as a cybernetic model.

3.1 Sensitivity model for interactions (according to Vester)

Frederic Vester developed a methodical tool for network thinking [6]. With this tool it is possible to recognise, control and self-regulate networked processes with minimal input. The individual parts of the system depend in many ways on each other and have many direct or indirect interactions. Sensitivity modelling, according to Vester’s model, shows a systematic approach to the analysis of

complex interactions. It also allows to show correlations and reactions in a transparent way. This systemic analysis is basis for the sensitivity analysis according to Vester and results in a cybernetic modelling system which is applicable to all areas of interest.
For an exact representation, three preconditions have to be complied with: right choice of the variables, definition of interactions between variables, linking variables. [6]

3.1.1 Variables and sensitivity analysis

Starting point for the sensitivity model are the variables. Variables are adjustable measurements - points in the system – from which the cybernetic of the system is identified. These variables were defined by carving out core competences for the individual issues and condensing the set to gain a manageable set of variables.
The variables consist of the components of *sustainability*, *quality in buildings* and other factors, which are important for the model. The variables are shown in figure 3. A criteria matrix in the Vester system checks the completeness of the variables. This ensures that no crucial issue is missing.

Impact categories

sustainability	**quality in buildings**	**others**
1 hight of impacts on environment	11 implementation of integral planning	20 legal ajustments
2 hight of material consumtion	12 decisivness of client	
3 hight of construction cost	13 quality control during building process	
4 hight of operational cost	14 intensity of motivation	
5 hight of end-of-life cost	15 intensity of competition	
6 durability	16 communication	
7 improvement of maintenance	17 performance of technical aspects	
8 health of occupants	18 holistic approach to design	
9 comfort of occupants	19 holistic approach to functionality	
10 consumer satisfaction		

Fig.3: variables for sensitivity analysis

3.1.2 Influence matrix

Dependencies of the variables were defined and interferences estimated with the use of the influence matrix. Each variable was examined on its conversion in regard to all the other variables. Dependencies were defined by literature studies, previous knowledge and experience in sustainability certification and quality management certification.

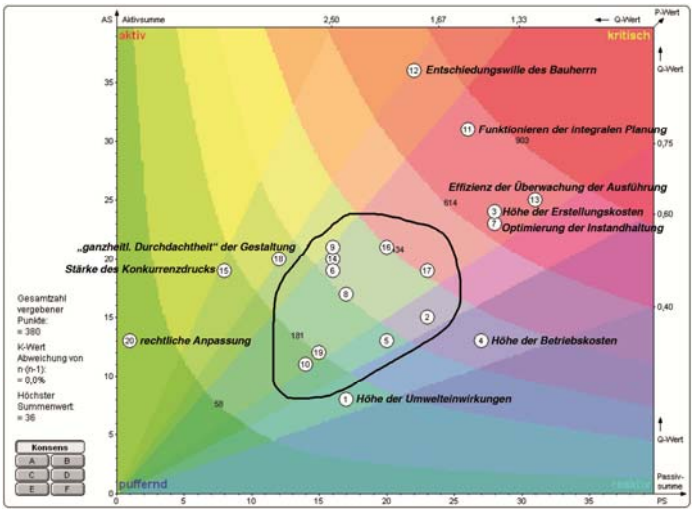

Fig. 4: influence matrix

Figure 4 shows the influence matrix with the parameters and the results. The picture shows the variables very clearly which have most effect on the system. Variables in the red area mark a high influence on others with minimal change. These are: *decisiveness of client, implementation of integral planning, quality control during building process, amount of construction cost and improvement of maintenance*. They are the most critical variables.
Variables which influence the system sparsely but steadily are *holistic approach to design and intensity of competition*. They have a slow but steady influence. Variables in the circle in the centre of figure 3 reach an equilibrium. This means that whenever changes in one variable occur all the actions and reactions of the involved system help to stabilise the system. Changes in these variables cannot influence the system in a big way. But these variables are necessary to keep the system in an equilibrium.
The influence matrix clearly shows that the above mentioned variables within the red area are of major importance to the system. They need to be a focal point in the planning and building process in order to influence sustainability and quality of buildings positively. Therefore main focus in the work was dedicated to these issues.

3.1.3 Effect system

The effect system shows the chain and their reactions. This makes the interactions visible and allows further simulation on scenarios. The effect system only shows real effects and distinguishes between rising or descending effects on the variable included. In that context a dashed line means that a rising of a starting variable results in a lowering of resulting variable. The normal line means that a change in the starting variable also results change of resulting variable in same direction. In general this system shows less interconnections than the influence matrix. Close interactions with reaction coupling can be seen e.g. for variable "*decisiveness of client*" and "*implementation of integral planning*".

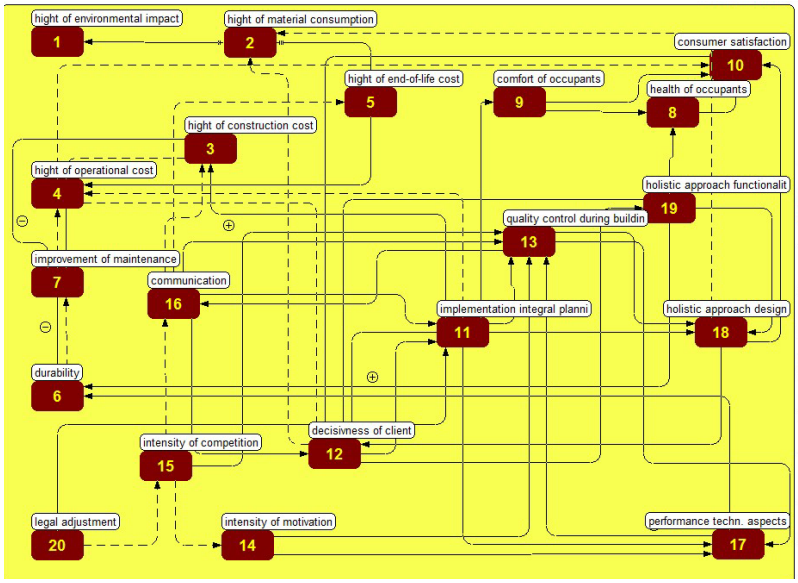

Fig. 5: effect system of interactions between sustainability and quality in buildings

3.2 Comparison of case study buildings

The results of the sensitivity analysis were contrasted with the results of building analysis. Four buildings, publicly approved as sustainable and awarded various awards for sustainable building, were analysed. Buildings serve different uses and are built from diverse materials. For all of them the underlying processes and their interactions where analysed. Analysis was done for the areas of:

- design and connection to site and localities
- planning and building processes
- influence on energy concept
- materiality and processes behind the choices
- cost, maintenance, use of building

3.2.1 Case study buildings

Each building was analysed through plans and interviews with planners. Main focus were: surrounding, design quality and the underlying process to come to these results; planning and building phase including obstacles to reach the goals; trace decision-making process; timeframe for introduction of energetic issues in planning process, material choice, cost / maintenance; user comfort.
For each project a flow-chart was developed to show dependencies of different issues. In figure 6 the chosen case study projects are shown.Analysis of buildings are shown in [7].

Case studies are:

- Hotel in an apple garden, Hohenbercha / Germany (Deppisch Architekten)
- Patchworkhouse (house for two families, Müllheim / Germany (Pfeifer Roser Kuhn

Architekten)
- Multi story dwelling, Zurich / Switzerland (Maier Hess Architekten)
- Community centre, Ludesch / Austria (Hermann Kaufmann ZT GmbH)

Fig. 6: chosen case study buildings (from left to right): Hotel Hohenbercha, Patchworkhouse, Multi-story dwelling Zurich, community centre Ludesch

3.2.2 Results of comparison

The analysis of the processes behind building development shows, that the client played a major role in defining reachable goals at the beginning of the project and helped to achieve them by supporting quality assurance in the construction process. In each project integral planning was implemented at the beginning of the projects. The energetic and technical concepts were developed right at the start with minimal extra impact, adjusted during the process and reflected on construction, cost and maintenance issues. Material choice and health issues for the users were a major task. All decisions had to be justified in regard to cost, gains and maintenance.
An effect system of all interactions was generated to highlight most important variables for case studies.

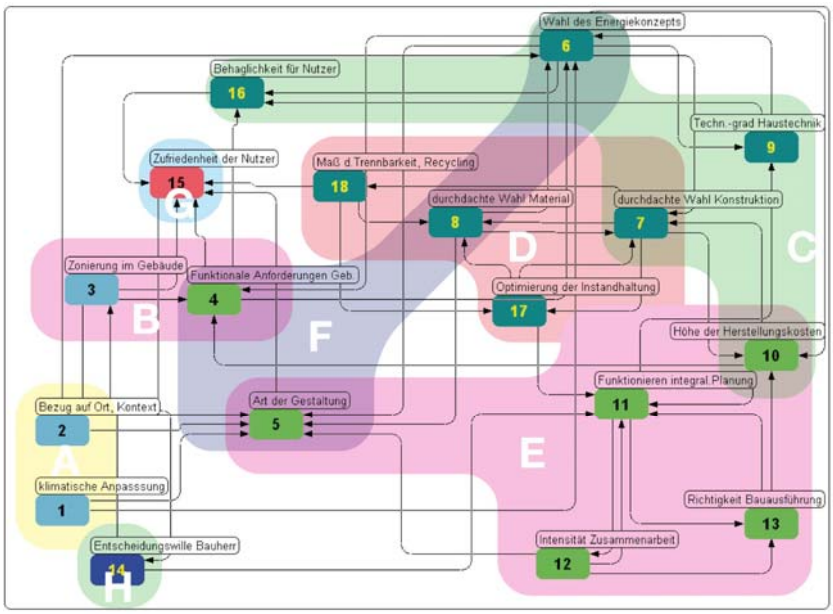

Fig. 7: effect system of interactions between sustainability and quality in buildings on case studies

In addition to important indicators in figure 5 results showed that the site and site specific issues model a different framework for each project. Complex interactions between the issues of energy concept, materiality and quality assurance, but also between design, client, integral planning are visualized.

4. Results

Theoretical effect system and effect system according to case studies were combined to an effect system for the creation of sustainable buildings was developed as a cybernetic model. The cybernetic model indicated which prerequisites are required to develop sustainable buildings.
Certain aspects, which generate high impact for the whole system, can be highlighted and starting points for improvements elaborated.
In figure 8 the interactions of the individual variables are shown. The main issues, which have a major effect on the system of interactions of sustainability and quality in buildings can be outlined. Keeping these in mind helps to strengthen results for sustainable building.
Main issues are:

Client:
The client has an important role to play at the beginning of the project with the definition of the goals for the different aspects and keeps to them throughout the whole project. Clients need to realise about the consequences of changes in goals during the planning process. Also it is important to evaluate quality on site continually in the construction phase, with consistent reparation of mistakes.

integral planning:
An integral planning team at the early stages of the project means an inclusion of all necessary specialist input right from the beginning. Questions which might arise on specialist issues (e.g. fire safety, energetic standard, use of renewable energies) can be properly integrated considering its interactions on other parts. The project coordinator needs to be able to integrate all aspects and has to be mindful of the independence of each other.

construction quality:
Improving the quality of construction can be influenced by precise communication and good motivation of employees on all levels. Constructive cooperation on site has a positive influence on the building. Extensive quality assurance on site produces extra costs but helps to integrate a level

of quality for the building. Therefore the extra cost for an external quality control is invested wisely, as it reduces damage to the building in the life cycle. Not only the actual construction costs should be given attention to in tendering. Also later maintenance and replacement should be included.

life cycle cost:
Introducing life cycle analysis on ecological and economic issues in an early planning stage helps to reach the most sustainable and economically useful solution. The earlier this happens the more interdependencies can be tackled and the fewer extra costs have to be invested in later.

design:
Design is highly dependent on the integration and performance of the interactions between the different variables. In all examined case studies, sustainable architecture is interwoven with a specific site and realised through the integration of an energy concept from design phase to detailing and material choices.

communication:
Knowledge about interactions and close relationships are the basis for explicit communication. Besides this, all parties need to be eagerly motivated in order to achieve the best results to implement sustainable buildings. Sustainability certification can help to integrate the different aspects although design is not clearly quantifiable and sustainable design is not dependent on certification.

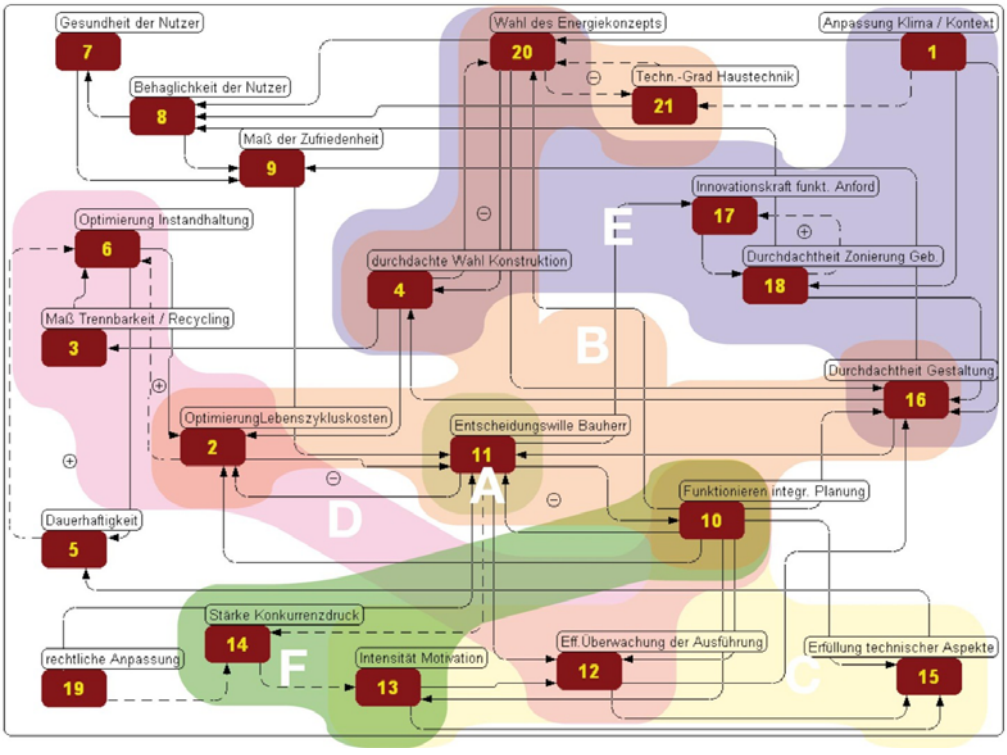

Fig. 8: cybernetic model of interactions – main focus areas

5. Conclusion

Through the cybernetic model many interactions between sustainability and quality in buildings were shown. True sustainable buildings can only evolve from stronger interactions between the separate disciplines. The first step is to understand the interdependencies and interactions between the variables and then to develop the main factors so that the system changes with the lowest input. In order to achieve sustainable buildings, design with its complex dependencies has to regain a central position in planning. The importance of client behaviour as well as quality of

construction work on site needs to come back into focus. Motivation of planners and builders and their communication is highly important.
More training for all parts of the building sector in these issues is necessary. A honest culture of teamwork for the best result rather than only the economic success is fundamental. All the shown issues help to achieve sustainable buildings through manageable processes.

Short Summary

The object of this paper is to present a method to include aspects of sustainability in the various stages of project development and in the processes involved in real estate development. To that end, the criteria for the certification of office and administrative buildings according to the Austrian Society for Sustainable Real Estate (ÖGNI) are analyzed and their influence is examined. Then an analysis of an ideal development process is carried out to see whether sustainability criteria can be implemented, and the temporal and causal correlation between sustainability certification and project development processes are described using a matrix. As a result the authors have adapted the project development process to include all aspects necessary in their opinion for the sustainability certification of office and administrative buildings according to ÖGNI / DGNB standards.

Keywords: Project development, project development process, sustainability, ÖGNI / DGNB, certification systems, real estate industry

1. Introduction

The concept of sustainability and the challenges it involves for us and future generations has become more and more important in recent years. As a result, "sustainability" has become a megatrend. Megatrends can be defined as tendencies in society and business that have an impact on the lives and the economy of future generations. Therefore it is logical that aspects of sustainability have become a big influence in the real estate industry as well. A survey by Jones Lang La Salle has revealed that sustainability will have the highest strategic priority for 83% of real estates professionals in the next ten years. The reason for this is that the real estate industry is one of the largest sectors of the economy as such and is considered one of the major agents when it comes to improving the current situation, in particular because resource consumption is considerable when constructing or running a building. Therefore the potential of the real estate industry for contributing to a sustainable economy is enormous. cf. [1, p.4]

In the opinion of the authors, aspects of sustainability can only be implemented if companies become fully aware of the concept and consider the need for sustainable buildings in an early stage of the development process.

2. Basic concepts

2.1 Project development

As we do not yet have a uniform approach to implementing aspects of sustainability when developing a real estate project, the building and real estate industry interprets the concept and the role of project development in many different ways.

Therefore it is not possible to identify or define the boundaries separating it from other professional fields cf. [2, p. 5]. As a term "project development" is used to signify different phases of time and stages of a project's implementation. According to Brauer three main periods can be identified:

- Development of a real estate project in a narrow sense
  (The period considered lasts from the idea for a project to the design phase)
- Development of a real estate project in an intermediate sense
  (The period considered lasts from the idea for a project until the end of the construction phase)
- Development of a real estate project in a broad sense
  (The period considered lasts from the idea for a project until the end of the demolition or the overall renovation or adaptation of a building) cf. [3, p. 585]

Diederich's definition of project development in general is:

"Project development (in a broad sense) has to combine the factors 'location, project idea and capital' in such a way as to create real estate projects that are competitive in micro-economic terms, that create and secure jobs, that are socially and environmentally sustainable in macro-economic terms and that are cost-efficient in their long-term use." [2, p.5]

From this we can conclude that a building resulting from a project development process has to be motivated not only by the individual requirements of the customer (owners of buildings, investors), but has to take the needs of the public affected by it into account as well cf. [2, p. 5].

2.2 Project development process

Basically there are three relevant models to describe the contents and the conceptualisation of the project development process:

- Equilibrium models: based on political economics
- Agency models: based on behavioristic concepts and administrative economics
- Event-sequence models: focusing mainly on the business-related aspects of managing the project development process as such. To this end, the project development process is subdivided into individual stages cf. [4, p.30]

In this study we have employed the event-sequence model because it is based on the processes taking place in the real world of real estate development. It uses traditional event sequences or schemes that result from the various coordinated and consecutive steps characterizing the processes involved in the production of goods and services. Furthermore, this model captures the complexity of the project development process and the dynamics necessary and allows for overlaps, parallel events and feedback effects cf. [4, p. 35].

The event-sequence model of a project development process according to Schulte / Bone-Winkel in figure 2-1 is used as a basis for creating a new, ideal development process which includes aspects of sustainability.

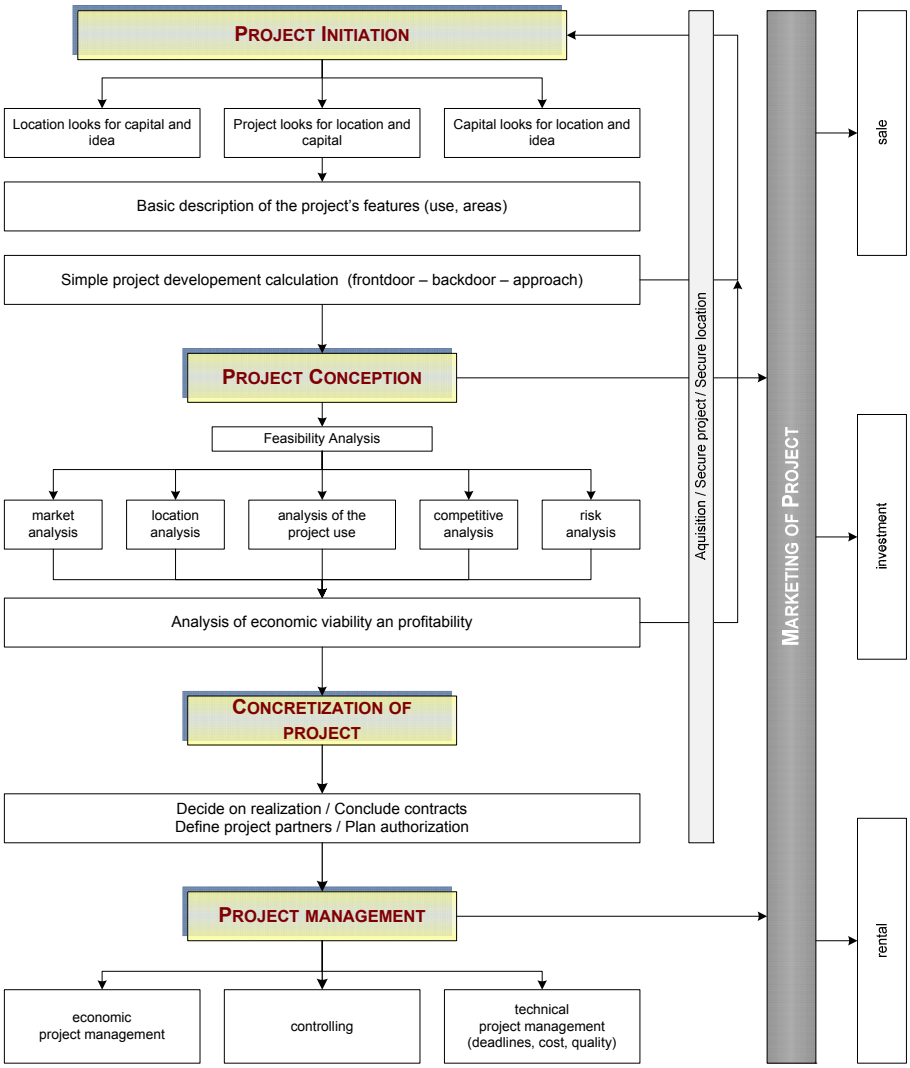

Figure 2-1: Event-sequence model of the project development process [4, p.36]

2.3 Sustainability

As a megatrend, sustainability has an influence on all aspects of our future actions. This is to say that the concept of "sustainability", which scientists started to examine only 40 years ago, is no longer just discussed in the exclusive circle of experts, but has arrived in the centre of society and in the real estate industry as well cf. [1, p.4]

The World Commission on Environment and Development (WCED), the Brundtland-Commission as it is called, contributed significantly to defining the concept and to our current understanding of the term cf. [5, p. 20]. In its report "Our Common Future (1987) sustainability was defined as follows:

"Sustainable development is development that meets the needs of the present without compromising the ability of future generations to meet their own needs" [6]

However, the concept of sustainability was not invented by our society. The idea was first developed in forestry and can be traced back to Hans Carl von Carlowitz, who invented the term in the 18th century cf. [5, p.20].

2.4 Sustainability certificates

The various sustainability certificates in existence play a central role when it comes to implementing sustainability aspects. The reason is that only a building that has obtained a certificate or quality label will be considered a sustainable building by the wider public.

Internationally there are numerous certificates and quality labels that have been adapted to meet the needs of the countries concerned. The following list of the most important sustainability certificates can serve as an example:

- Austria ÖGNI / DGNB
- Germany DGNB
- United Kingdom BREEAM
- USA LEED
- Australia Green Star
- Japan CASBEE
- Switzerland Minergie
- France HQE

to name just a few. cf. [7, pp. 90]

The following study uses the ÖGNI / DGNB certification system, because it constitutes a transparent and coherent real estate certification method suitable for the Austrian market.

2.5 ÖGNI / DGNB specifications

Basically, the ÖGNI / DGNB system is divided into six main criteria. The main criteria are composed of groups of criteria that again are made up of the individual criteria described in the specifications. Figure 2-2 shows a diagram of all main criteria groups employed by ÖGNI /DGNB. cf. [7, pp. 96]

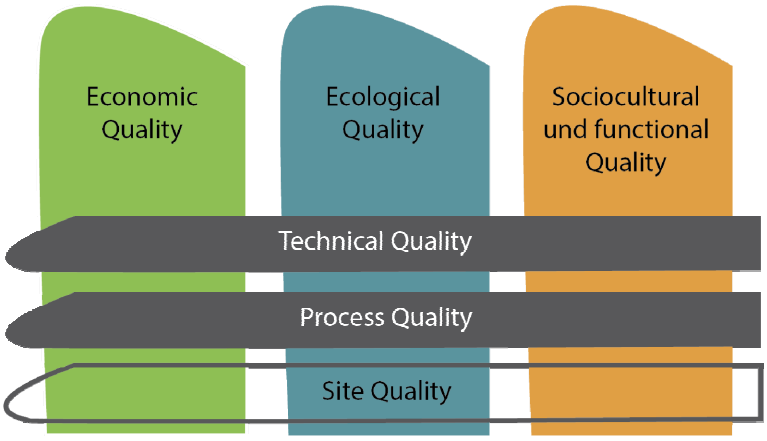

Figure 2 2: System components of ÖGNI certification [7, p.97]

In this context we have to mention that the quality of the location is currently not considered in the final assessment or certification of a building.[1]

The smallest unit in the certification process is the individual specifications containing the descriptions needed for the assessment by allocating points for each criterion. The number of specifications listed depends on the purpose of the building. For this study we have used the specifications for "new office and administrative buildings" comprising 49 individual criteria.

[1] This differs from the "certification of urban districts" according to the DGNB which attributes vital importance to the site of a project.

2.6 Impact of sustainability issues on project development

Sustainability and the certificates connected to it are becoming a significant economic factor in the real estate industry. Jones Lang LaSalle, for instance, published a survey in March 2011, showing that about 75% of all executives responsible for corporate real estate would be prepared to pay higher rents for sustainable buildings cf. [7, p. 3]. We can call real estate development sustainable when the following prerequisites are met:

- cost-efficient
- ecofriendly
- resource saving and
- optimum integration in the socio-cultural environment. cf. [1, p. 16]

Taking its entire life-cycle into account, this should guarantee that a sustainable building is of higher long-term value to communities, investors, owners and users. cf. [1, p. 16]

Figure 2-3 illustrates the main advantages of sustainable development related to the three basic principles of sustainability.

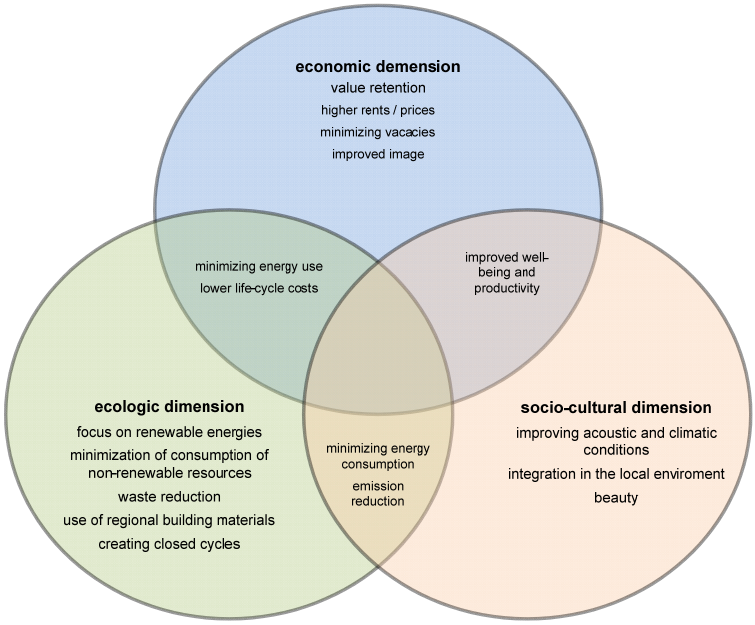

Figure 2-3: The three dimensions of sustainability [1, p. 17]

Due to the interdependence of these aspects, they must not be viewed and worked on in isolation, but have to be combined in a holistic, integrative approach to achieve the best results when developing a real estate project.
In spite of this, cost-efficiency will always be at the centre of investors' attention; ideally, however, sustainable development will lead to more cost-efficiency. cf. [7, p. 81]

3. Adapted project development stages and processes

The steps to be taken to adapt or re-write project development processes are illustrated below:

3.1 Analysis of existing project development processes

Our analysis of project development processes goes to show that they do not include the implementation of sustainability criteria in the individual stages of the process or only deal with them cursorily. Therefore it is easily possible that real estate projects fail to meet sustainability objectives.

According to 2.2 it is necessary to formulate a new, ideal project development process on the basis of Schulte / Bone-Winkel's project development process which includes and guarantees the criteria the authors believe to be necessary to obtain a sustainability certificate.

Figure 3-1 shows a new process resulting from the considerations above, the "accompanying process of sustainability management" for all stages of project development in an intermediate sense. The important element here is that "information" is condensed during the individual stages, which then has to be analyzed and assessed several times with regard to sustainability to obtain a certificate.

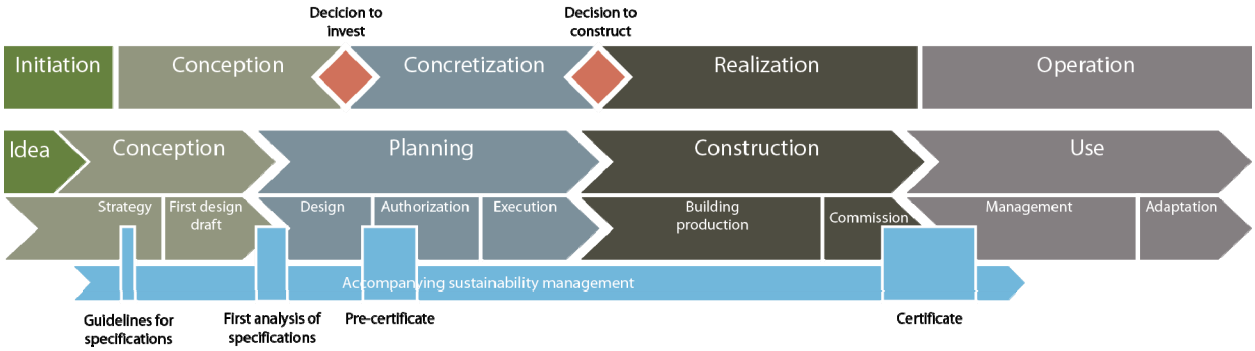

Figure 3-1: Accompanying process of sustainability management during the stages of project development cf. [7, p. 106]

3.2 Analysis of ÖGNI / DGNB specifications:

Our analysis of ÖGNI / DGNB specifications has shown that it is necessary to establish target parameters (e.g. the main ecological and economic criteria groups) and quality requirements (e.g. process quality) at an early stage of the process to obtain the desired ÖGNI /DGNB label cost-efficiently.

3.3 Generating a process matrix focussing on the project development stages as defined in the ÖGNI / DGNB specifications

We have created a matrix illustrating the interdependence and correlation between the specifications and the individual modules of the process. It shows which specifications are needed in which steps of the process to develop an office or administrative building.

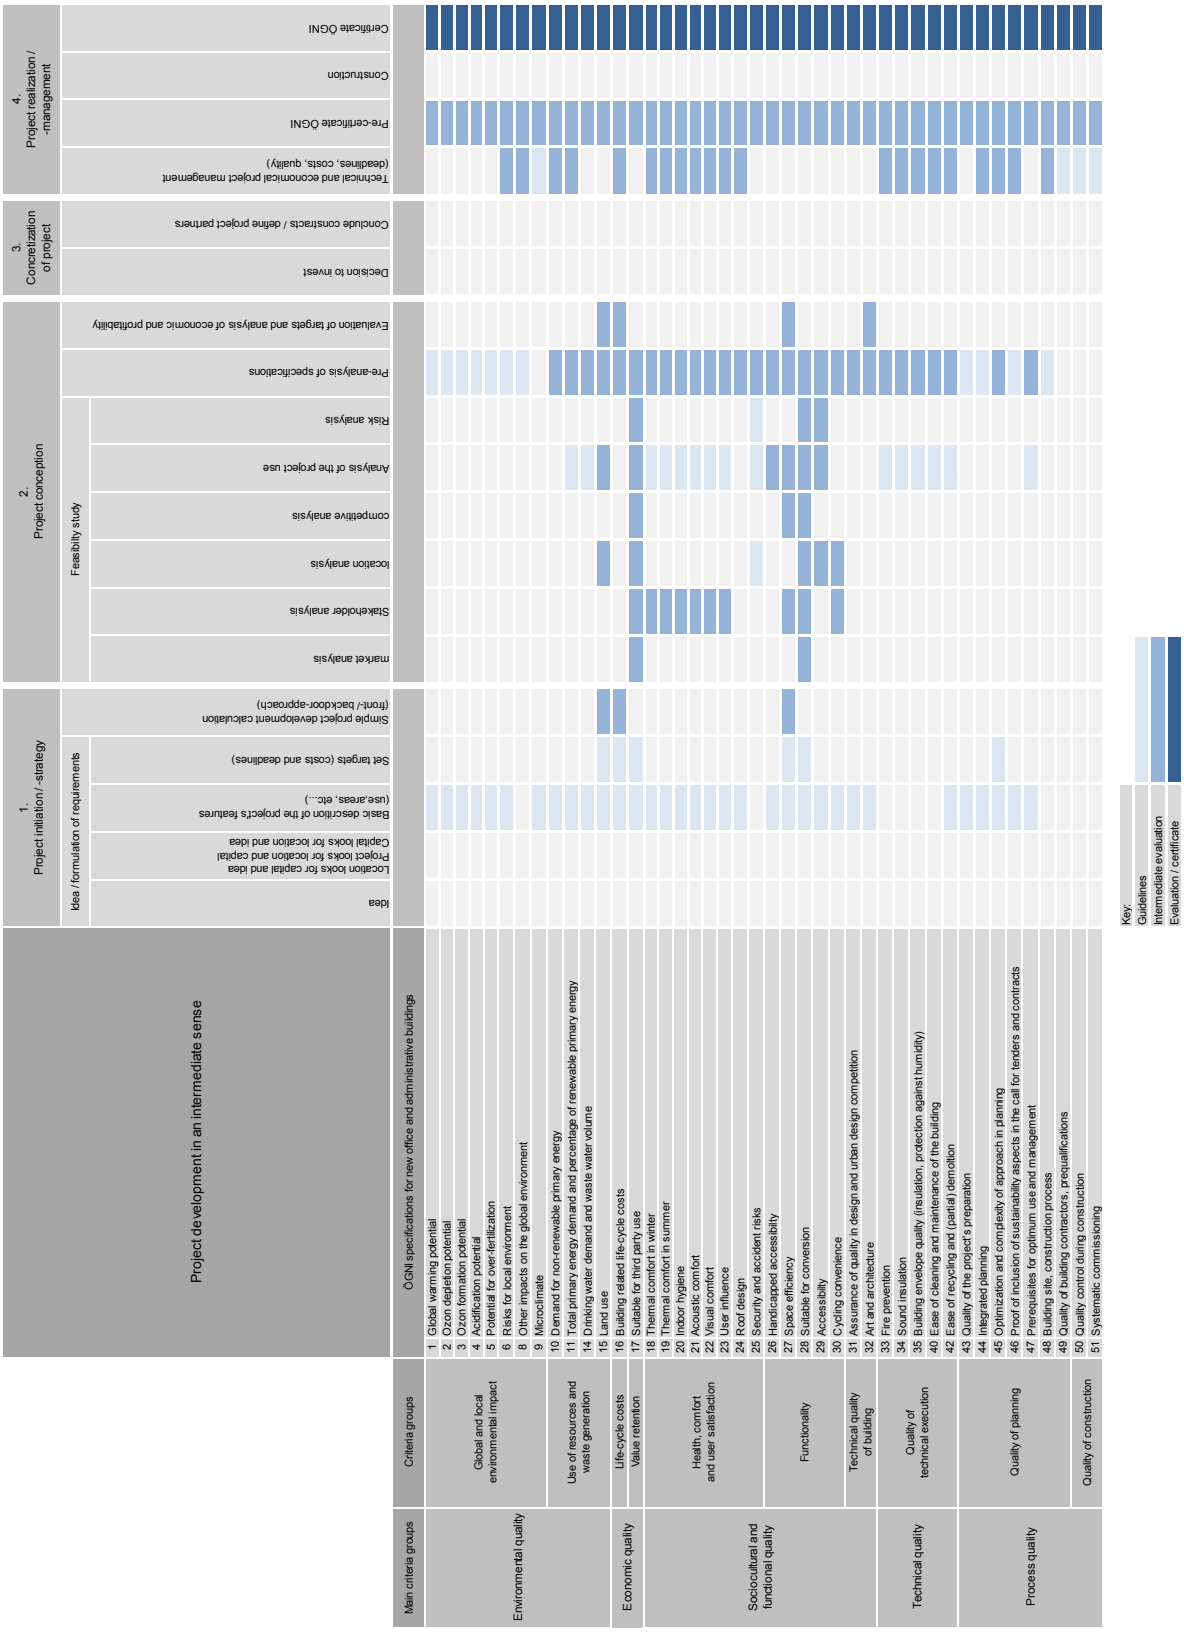

Figure 3-2: Dependence matrix for the ÖGNI /DGNB specifications and the project development process

The matrix in figure 3-2 shows how information and data are condensed during the development of the project by identifying target parameters and quality criteria. In doing so the information given is evaluated several times during the individual stages.

By considering the criteria of sustainability early on during the conception stage, a goal-oriented approach to real estate project development becomes possible. In this way the needs of customers concerning deadlines, cost and public perception can be influenced.

3.4 Implementing the results in a real estate development process

Figure 3-3 shows an adapted real estate development process based on the event-sequence model by Schulte / Bone-Winkel which utilizes the matrix created in point 3.3.

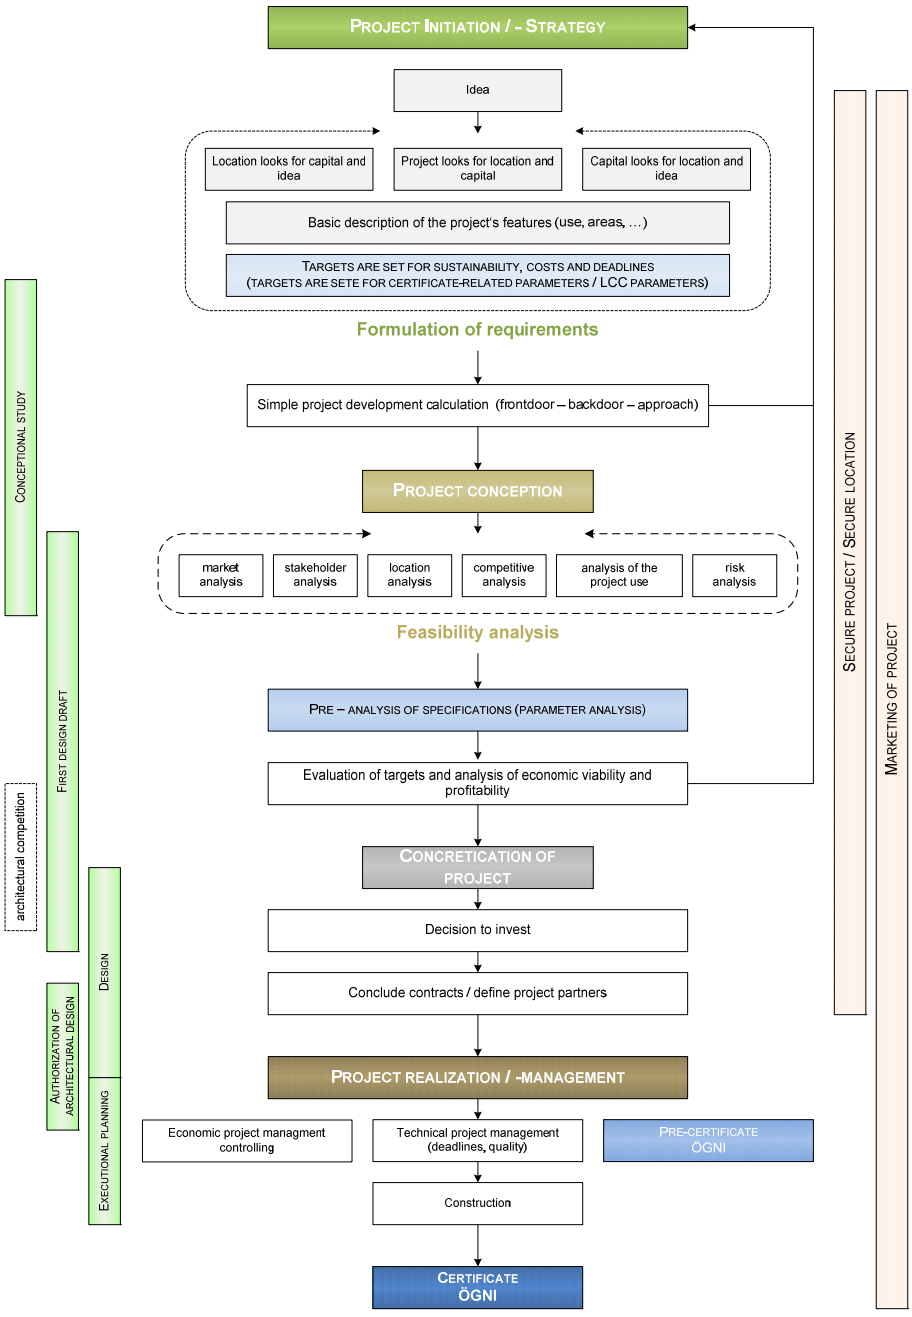

Figure 3-3: Adapted project development process cf. [4, p. 36]

It is essential here that a first set of guidelines for the desired ÖGNI / DGNB label is established when the need for the project is formulated or when the project is initiated and the strategy is developed; the corresponding target parameters and quality objectives have to be set at this early stage.

During the stage of a project's conception a first intermediate evaluation of the target parameters must follow the feasibility study to recognize potential deficiencies at an early stage, so that measures can be taken to control them.

In the end an ÖGNI / DGNB pre-certificate is obtained during the stage of the project's realization and management, which then serves as a basis for the sustainable realization of the project and the final ÖGNI / DGNB certification with the desired ÖGNI / DGNB label.

4. Future perspectives in research

The authors have no doubts that sustainability certification influences real estate development processes. The effects our adapted process has on the structure and operational organization of real estate companies will now be the object of further scientific research employing empirical methods in order to guarantee that the project development process formulated can be managed in the best way possible. Therefore idealtypical forms of organizations are formulated. Further, the results regarding optimum operational or structural organization, including all impacts of sustainability, should be verified on sample projects.

The prerequisites for the accompanying sustainability management as shown in figure 3-1 should be worked out as soon as possible and should be widely discussed with potential project partners and public officials.

5. Conclusions

Studies about implementing ÖGNI / DGNB specifications and criteria in the real estate development process have made it clear that it is easy to consider them at an early stage. This is necessary if projects are to be developed continually and functional and economic targets are to be met. To this purpose, the authors have defined a new process, the accompanying process of sustainability management, which needs organizational support when implementing it.
A detailed dependence matrix was created to show the correlation between ÖGNI / DGNB specifications and the project development process.

This approach contributes to implementing a holistic view of project development to prevent that the sustainability requirements of a building are not only considered in the limited fields of planning, construction and operation.

Short Summary

The paper in the beginning clarifies what the nearly Zero Energy Building (nZEB) means and what the advantages of an Integration Energy Design (IED) process are. Afterwards, it shows two local experiences about nearly zero energy target integration in two different public design tenders procedures. The first experience regards a restricted design competition which aims at finding the best design proposal within a restricted number of projects. While the second experience regards a negotiated design tender which just aims at selecting the design team will design the new public building. Results show how to integrate, require and evaluate the results of different tender procedures, advantages to use IED process.

Keywords: nZEB, IED, public design tender.

1. Introduction

The Directive 2010/31/EU [1] invited public authorities to develop plans to increase the number of nearly Zero Energy Buildings (nZEBs). This paper proposes a way to increase the number of nZEBs including the zero energy balance target within the public design tender for new buildings (or for building renovation) and to push the design teams to follow an Integrated Energy Design (IED) process. The goal was to define the most effective rules and points of attention that municipalities or public administrations must consider in the tender elaboration phase. The paper shows the approach applied to two real experiences with two different public administrations. In both cases close collaborations between EURAC team and municipalities were necessary to fix energy performance indicators, establish a method to calculate the energy balance, the award score criteria and the evaluation commission members.

2. Integrated Energy Design process (IED)

The project Affirmative Integrated Design Action (AIDA), supported by the Intelligent Energy Europe (IEE) programme, aims at setting up strategies to support local authorities in pursuing nZEB target for new buildings and building renovations. One of the key approaches suggested is to enhance the decision making process through an Integrated Energy Design. The IED is a multidisciplinary, collaborative process that analyses the whole building process and integrates different aspects and knowledge during all phases of development of the

building.
The ultimate goal is the achievement of the performance targets defined by the customer (e.g. null energy balance, high internal comfort, economy, functionality, aesthetic impact, etc.) through a collaborative process for determining the most advantageous solution [2]. The IED work team consists of individual figures (i.e. contractor, architect, engineer, constructor, sponsor and users), whose specific expertise, if effectively integrated allows to define, analyse and evaluate different design solutions and their possible interactions. The choices are taken from a work team through a participatory decision making process. Thanks to the IED process qualitative, economic, functional and aesthetical aspects of a wide range of design solutions can be taken into consideration to find the optimal solution [3]. Generally, IED is an iterative process with a feedback loops mechanism [4].

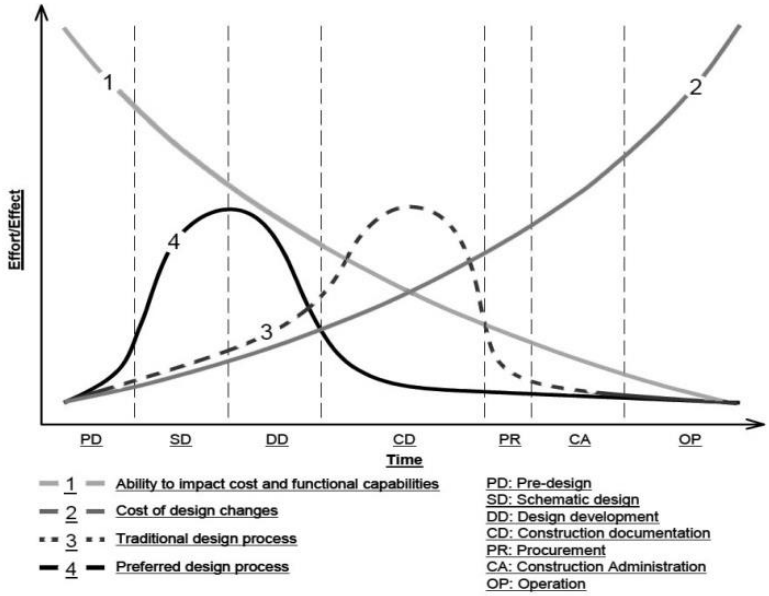

Figure 1: Difference between traditional design process and integrated design process. [14]

Figure 1 shows the difference between a traditional approach and an integrated design process. The main advantage of the IED is, that design decisions are taken at a time, when the cost does influence only design changes and not the overall construction cost. Therefore the design effort is higher during the early design phases than in the construction phase.
For this reason a close collaboration between public administrative figures, engaged to draw up public tenders and to untangle legislative procedures, and nZEB expert figures, is a key to success, which should be included into the rules of design competition procedures.

3. Nearly Zero Energy Buildings

The EPBD recast 2010 introduced the concept of nearly zero energy buildings stating that "*nearly zero energy building means a building that has a very high energy performance*" and that "*the nearly zero or very low amount of energy required should to a very significant extent be covered by energy from renewable sources, including renewable energy produced on-site or nearby*". Member States should ensure that by December 2018 all new buildings owned or occupied by public authorities are nearly ZEBs; public authorities are in charge of promoting and setting up strategies to pursue the nearly ZEB target.
The lack of a precise definition of nZEB [5], has led several member countries of the International Energy Agency to launch the research project "IEA SHC Task 40 – ECBCS Annex 52: Towards Net Zero Energy Solar Buildings". The project aims at clarifying the precise meaning of Net ZEB, translating it in calculation methodologies, and showing the implications of the latter on design solution sets. EURAC is participating in the project and is collaborating, with the Province of Bolzano to transfer the gained knowledge at local level.
The nZEB requirements part included in design tenders are the results of Task 40 project, and consists of energy performance indicators (energy balance, heating/cooling/electric demand, IEQ level, etc.), energy calculation methods (tools and methods) and evaluation

methods (ranking procedures through assignment of points and weighted sum).
In addition to this guide lines, in the tenders should be reported the national/local laws that fixes the energy performance indexes. In the Province of Bolzano, CasaClima Agency is the public authority in charge of establishing the energy performance requirements, and verifying them, for new and existing buildings through an energy certification performance (ECP) procedure. The CasaClima certification defines energy performance classes based on envelope performance during the heating season.
The new legislative decree DP 362/2013, in force from the 4th March 2013, introduces other energy performance requirements such as CO_2 emission, heating load and minimum energy production by renewable energy (see Table 1).

Table 1: Energy requirements for new buildings. Source: DP 362 of 4th March 2013.

Measures	Energy efficiency	RES
New buildings	CasaClima B (Heating Load<50kWh/(m²year))	40% of the total primary energy produced by RES
	CO_2 emission < 20kg/(m²year) (for non residential buildings CO_2<100kg/(m2year))	60% of the DHW load covered by RES
	minimum periodic thermal transmittance (Y_{ie}) for summer season	minimum of 20W (of for each square meter covered) of electric production system from RES

The following sections describe the nZEB definition applied to the two case studies in terms of metrics and calculation boundaries.

4. Alpine huts design competition

In November 2011 the Bolzano Provincial Committee has announced a design tender restricted to 8 selected design teams. The tender concerns the design of three alpine huts located at an altitude of 2000 - 3000 m [6].
The new alpine huts would serve two important purposes: to provide alpinists and hikers protection from the elements and a comfortable place to rest, to be an arrival point for families. The activity period is from July to September, except for a small part of the huts used as winter bivouacs. The huts are not connected to the public power and water supply grids and cannot be reached by vehicles. Actually victuals and supplies are delivered by helicopter or by walk. The construction process cannot be accomplished with traditional methods. So the designers had to contend with the challenge of building the new huts in isolated sites.
The Provincial Committee challenged further the designers by requiring the nZEB target and involved EURAC as energy consultant to support the energy concept design. The first version of the tender just mentioned some general requirements as energy production from renewable energy and sustainable construction mode. EURAC worked with the Provincial Committee to include energy guidelines in the second version of the tender and provided two simplified tools to estimate the energy performance indicators.
As this tender is a first attempt of IED introduction in the common procedures, the Provincial Committee did not include the energy concept in the ranking list and the nZEB target was not mandatory.
EURAC, according to the Provincial Committee and the hut manager's needs, established the following energy targets:

- energy efficiency of the building envelope with heating load ≤ 50 kWh/m²y (CasaClima B);
- 50% of domestic hot water consumption and 20% of the sum of heating and domestic hot water consumption have to be produced by thermal systems driven by renewable energy sources;
- 20% of electric energy demand has to be covered by electric energy produced by renewable supply systems.

The energy autarchy would require a wide area of solar collectors and PV panels with

resulting big storage volumes. Besides the lack of space, we also considered the plant transportation costs both in economic and environmental terms and the fuel transportation which would occur if we do not rely exclusively on renewable plants. We also considered that helicopter flights needed to deliver victuals could also be exploited for fuel transportation.
Another important requirement fixed by the huts manager is the low maintenance need of the systems. High reliability has the priority on high efficiency.

4.1 Simplified tools to assess energy performance

EURAC provided two simplified tools to prove the accomplishment of the fixed target. We modified the existing energy performance calculation tool (CasaClima version 2.3) adding weather data measured by local weather station, adjusting the load profiles according to huts manager descriptions and changing the heating period from winter to summer.
The resulting heating load is needed to calculate the share of energy consumption covered by renewable energy production. We developed an excel tool that enables designers to verify these energy targets accomplishments (Figure 2).

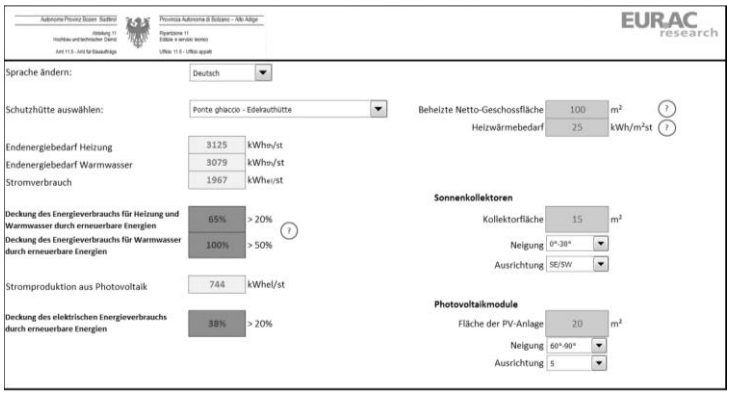

Figure 2: Excel tool to verify target accomplishment.

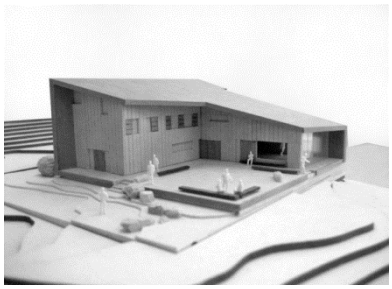
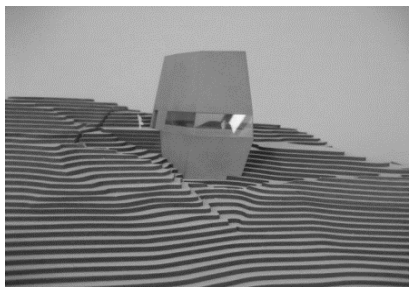


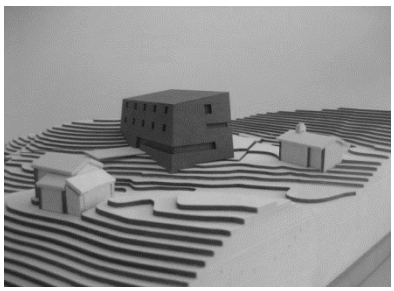
The tool requires as input the following data: net conditioned area, heating load during the activity period, total area, tilt angle and orientation of solar thermal collectors and PV panels.
We estimated Domestic Hot Water (DHW) consumption on the base of the total overnights during the hut opening season and by referring to the standard UNI TS 11300-2. Hut managers gave us indication about the kitchen electric energy consumption. Regarding lighting, we considered a power of 8 W/m² per 5 hours per day. We estimated the auxiliaries' consumption as 2% of the final energy demand of heating and DHW system.
We calculated the solar fraction of the solar thermal system by the f-chart method [7]. Solar thermal collector efficiency and losses are referred to a standard flat plate collector. We advised against evacuated tube solar collector application at high altitudes because they are more frail and need more maintenance compared to the flat plate ones.
We assessed the electric energy production of a standard mono-crystalline PV panel with 14% efficiency in the three location by means of the software PVsol [8] and using the global radiation on surfaces with different inclination and orientation calculated by Meteonorm [9]. We advise against thin film technology at high altitude applications because it is more subject to wear compared to the crystalline technology.
The energy concept guidelines recommend a combination of the following thermal system: gas micro-turbine for cogeneration, wooden boiler or solar thermal collectors with storage.
Gas micro-turbine are recommended for a decentralized use because of their almost constant efficiency in a wide range of load. Considering that the system requires fuel transportation by helicopter and produces exhaust gas emission, the turbine has to be activated only as backup.
For the electric energy production the guidelines recommend a combination of the following electric system: photovoltaic system, wind turbine, hydro turbine or cogeneration.
Due to the lack of wind data collected on site, the wind turbine feasibility and production cannot be assessed at this stage of the project.
The tender also suggests the area needed for storage tanks and batteries.

4.2 Evaluation criteria



Besides the accomplishment of the tender requirements, the evaluation criteria consists of architectural quality and landscape integration (50 points), functional quality and general standard and law accomplishment (35 points), construction, maintenance and operating costs (15 points).
Even though the ranking list does not include criteria to assign points to the energy concept, EURAC evaluated each project from the energy point of view and presented the results to the Provincial Committee.
Besides the accomplishment of energy target, we evaluated the building shape and the facade layout. Big roof surfaces and solar optimized orientation are preferred. Due to the low outdoor temperature even during the summer season, compact volumes can reduce heat losses.
The position of technical services should be advantageous in order to have a good energy savings potential. The restaurant zone has the higher internal loads due to large window surfaces, the presence of visitors and the kitchen. This zone could be exploited to heat passively the night zones, if the heat losses are limited.

4.3 Results



Since the design concept phase the design teams have considered energy efficiency issues. Most of the projects had a compact building shape to reduce heat losses. The design teams defined the thermal and electric energy generation systems and size the technical rooms properly in order to contain storage, batteries and system equipment.
As the huts are located at high altitudes, the landscape integration plays an essential role. Solar optimized orientation of envelope surfaces and high integration of solar systems are important design characteristics to be evaluated. Figure 3 reports the winner project models.

Pio XI / Weisskugelhütte
Arch. Höller & Klotzner

Figure 3: Winner project models.

Main mistakes found from the energy point of view concern the building orientation and the compact shape. Some designers separated into two or more volumes the building isolating the restaurant zone from the rest of the spaces.
The energy concept development was no mandatory and there were no award criteria for energy requirements achieved. Therefore some design proposals had no energy concept description.
In some cases the energy requirements seemed to influence the architectural project in a not advantageous way. In some projects the restaurant zone is oriented towards the afternoon sun to have high solar loads, neglecting that a panoramic view is a high priority requirement too.

5. Negotiated tender to design a new elementary school

The municipality of Merano accepted to join the AIDA project and EURAC supported them in setting up the public design tender for a new elementary school. When the collaboration started, the public administration had already determined which kind of administrative

procedure to adopt for the design tender. The municipality decided to select the design team through a public tender for design service, also called “Negotiated tender”.
This kind of tendering process was chosen to reduce tender time and costs.
The negotiated tender rules the relation between public authorities and private companies as regard design and/or construction services and supply costs. The winner is determined by the most economically advantageous offer and by its experience (curriculum). Design teams participate at the tender without any design proposals. The winning team will deal with the preliminary, definitive and executive project and will direct the construction phase too.
Despite the tender does not demand for a design proposal, the development of an energy strategy was set as obligatory requirement. To support the design teams in this task, energy guidelines were included into the tender documents.
Therefore, the public tender is based on:

- a ‘Preliminary document for design phases’, including national and local laws (fire, acoustic, energy and structural regulation laws...), functional and dimensional requirements, energy performance targets (fixed to nZEB), budget and technical rules (for design teams) to participate in the design competition;
- energy concept guidelines to support design teams in developing energy strategies;
- evaluation criteria.

5.1 Energy concept guidelines

The energy concept guidelines consist of two parts.
The first part fixes the energy design targets and the energy performance requirements. This part explains what nZEB is meant to be, by defining the energy balance calculation method, the balance metric and weighting factors and the physical boundaries of building system [10].
The second part of the guidelines defines the rules of participation and gives instructions about the implementation mode of the required energy strategy. The tender requires an IED process and introduces the design team to this design approach.
The target, for the new elementary school of Sinigo, is the nearly zero energy one. The tender constrains the design team to follow an IED process during the design development.
The Municipality of Merano requires more restrictive energy performance requirements than the local law DP 362/2013 (see Table 1), which adopts the EPBD recast:

- energy efficiency of the building envelope with heating load lower than 30kWh/m²y (CasaClima A);
- nearly zero energy balance, using the calculation method developed within IEA SHC Task 40 project, and described in the energy guidelines of the tender.

The CasaClima certification protocol requires the proof of building envelope air tightness through a Blower Door Test and the on-site inspection of the building site by a CasaClima Agent to prove the correct realization of the execution, the absence of thermal bridges and the thickness of insulation layers. For these reasons, these actions are not mentioned in the energy section of the public design tender.
We define the nearly Zero Energy Building as a building, fulfilling CasaClima A requirements of the local EPC system and any national (DPR59/09 e s.m.i., DLgs 28/2011 e s.m.i.)/local (DP 362/2013) energy efficiency requirements, which offsets the yearly balance between generation and load (Equation 1), weighted in terms of equivalent carbon emissions. [10]
The balance has to be checked in the design phase by means of dynamic simulations.
All the energy uses of the building are considered as negative balance items: heating, domestic hot water, cooling, lighting, auxiliaries, ventilation and every kind of plug loads.
As positive balance item, only the on-site generation from on- or off-site sources can be considered, as long as the generation systems are architecturally and/or urban integrated inside the physical boundary. The physical boundary identifies so called ‘on-site’ generation systems and energy use. If a system is within the boundary it is considered ‘on-site’, otherwise it is ‘off-site’. If an energy use is within the boundary, it is included in the balance, otherwise it is not considered. The physical boundary in this case is defined as the perimeter of the urban lot, also delimited by the point of connection to the energy grid.

In order to guarantee a high aesthetic building value, the integration of energy generation systems is an important aspect which has to be taken into account from the beginning of the project. These systems can be integrated into the architectural elements of the building or in others elements located within the boundary system limits (e.g. integrated into the bus shelter of the parking area).
Weighting factors to translate final energy in equivalent carbon emissions are defined by DP 362 of 4th March 2013.

$$\sum_i g_i * w_{e,i} - \sum_i l_i * w_{d,i} = G - L \geq 0 \quad (1)$$

where:
i = energy carrier
g_i = generation of the i-th energy carrier
l_i = load of the i-th energy carrier
$w_{e,i}$ = weighting factor for exported i-th energy carrier
$w_{d,i}$ = weighting factor for delivered i-th energy carrier
G = weighted generation
L = weighted load

The design team is also committed to follow an integrated energy design (IED) process.
Thanks to the AIDA project EURAC team will support the design team during the preliminary and definitive design phases. Specific meetings and workshops will be organized to actively support the evaluation of energy performance and indoor comfort through energy simulations.
Design teams have to present the energy concept in a report, their experiences and abilities in applying energy efficient solutions through a list of references. The school contains spaces with different functions, use patterns and comfort requirements: classrooms, gym and library. Therefore the energy concept can consider more than one conditioning system typology and/or different management systems. For this reason the tender requires the presence of an Energy Adviser/Certifier in the design team, with experience in energy efficient planning..

5.2 Evaluation criteria

The evaluation criteria consist of design architectural proposal, dimension, cost, urban integration, innovation, quality, functional aspects and daylight of connections areas (30 points), and law accomplishment construction, maintenance and operating costs, criteria to achieve nZEB target, experience of the Energy Adviser/Certifier and design team curriculums (30 points). The design team has to deliver a description of the energy strategy (passive and active solution), planned to reach the fixed energy targets through a technical report (6 points).
The tender deadline is the 22nd of May 2013. Thanks to AIDA project, we will join the jury to evaluate the energy strategy reports.

6. Conclusions

The paper shows two local experiences about energy performance requirements integration into public tenders. The legislative procedures of the tenders are totally different. The first experience (mountain huts) regards a restricted design tender which aims at finding the best design proposal within a restricted number of projects. While the second experience regards a negotiated tender (elementary school) which only aims at selecting the design team. This difference has influenced the way energy performance requirements are included into the tender. In the first case (mountain huts) energy guidelines and supporting tools are integrated in the tender and the design team has to demonstrate that the fixed targets are

reached. In the second case the energy guidelines are part of the tender to define the method that the winning design team has to use to reach the fixed targets.
In both cases the IED process is considered a necessary approach to increase the quality of the design proposal, from aesthetic, functional, energy efficiency and economic point of view. The IED main advantage is the achievement of the performance targets defined in the tender (e.g. nearly zero or zero energy balance, high level of indoor comfort, economy, functionality, aesthetic impact, etc.). The management of an IED is not always easy, because it involves different professionals that have to communicate with each other. For this reason it is necessary to identify a figure able to manage the design process and facilitate the design team meetings.
Results of the mountain huts case, show how the buildings have been shaped to allow the climate potential exploitation and to optimise renewable energy production. The design support activities and the collaboration with municipalities are still ongoing to follow the whole Integrated Energy Design Process.

7. Acknowledgements

This work was financially supported by AIDA, an Intelligent Energy Europe project, and by the Province of Bolzano within the “Verso NZEB” project. The authors wish to express their gratitude for these financial supports.

Realising Blue Buildings?- Life Cycle Management as an integrated management philosophy for blue building projects

FH-Prof. Dipl.-Ing. Dr.
Rainer Stempkowski
Chief executive officer of
Stempkowski Baumanagement &
Bauwirtschaft Consulting GmbH

www.stempkowski.at

FH-Prof. Dipl.-Ing. Dr. Rainer Stempkowski, Stempkowski Baumanagement & Bauwirtschaft Consulting GmbH, Austria, office@stempkowski.at

1. A new focus for Blue Buildings

The core question to be discussed seems to be rather basic but difficult: What is a sustainable success of a building? Green buildings reached already a high standard of ecological and technical know-how integrated. Blue buildings suffer from a missing common understanding. They are assimilated with the optimized life cycle costs. Every company would not be satisfied if its economic success was only measured at the expenditure. You have to take the earnings into account too. In future a holistic statement on the long-term success of a building needs to integrate life cycle costing on the one hand which covers the total investments and earnings out of rental income and sale proceeds over the life cycle on the other hand. Sustainable success can then be defined as the optimized mix of minimizing the (life cycle) costs and maximizing the value of the building.

Keywords: Life Cycle Management; integrated design; Blue buildings; value and earnings, controlling of sustainablity.

2. Requirements of Blue Buildings

In construction project management the main goal was to realize the project in the shortest time, at minimum (investment) costs and in the best quality. Today buildings demand to be “green” and “blue” what means to be ecological and economical sustainable. Already the project development faces these new challenges and the change of behaviour of investors and users which occur out of a rising consciousness on the relevance of the operation phase and its costs.

The main question is how to realise the ideas of blue building. What are the main aspects and criteria of blue buildings and what management issues do we have to focus on?
The management philosophy Life Cycle Management in construction is the sustainable way to cope with these new requirements. The core skills of professional construction project management have to be extended with expert knowledge of life cycle oriented design and build.

3. Efficient ways to Blue Buildings

Out of the practical experience there are five main Life Cycle Management aspects which lead to blue buildings and which are presented in more detail:

(1) Focus on life cycle costs instead of investment costs and additionally have the value and the earnings in mind as basis for all relevant decisions

(2) Use systematically experiences out of the operation phase during project development and design and integrate the learnings in the organisation and in design & construction contracts.

(3) Develop a maintenance program for the 2nd and 3rd life cycle in early project phases to enlarge the lifespan and integrate the requirements in the building concept and design.

(4) Apply (long-term) Opportunity and Risk Management in the whole project development process for a continuous project optimization.

(5) Controlling Systems for sustainability to ensure, that the concept of blue building is realized effectively

3.1 Focus on life cycle costs instead of investment costs and additionally have the value and the earnings/income in mind as basis for all relevant decisions

A deeper view on the economic approach of sustainability shows that with the determination of life cycle costs already the impact of the whole life cycle is taken into account. That seems to be sufficient. But sustainability should lead us further to a holistic approach which includes the perspective of investment and earning out of the recovery of the property. There might be economic advantages, if an investor invests more investment costs and even more life cycle costs, if the earnings increase bigger. It will be discussed which investments make sense in a long term examination.

The ISO 15686-5 [1] defines the whole-life cost. They cover the life-cycle cost (LCC) as well as externalities and income. The LCC are divided into the main cost groups construction, operation, maintenance and end-of-life. A sharp demarcation between externalities and environment cost is hard to line in practise. (Find out more at [2])

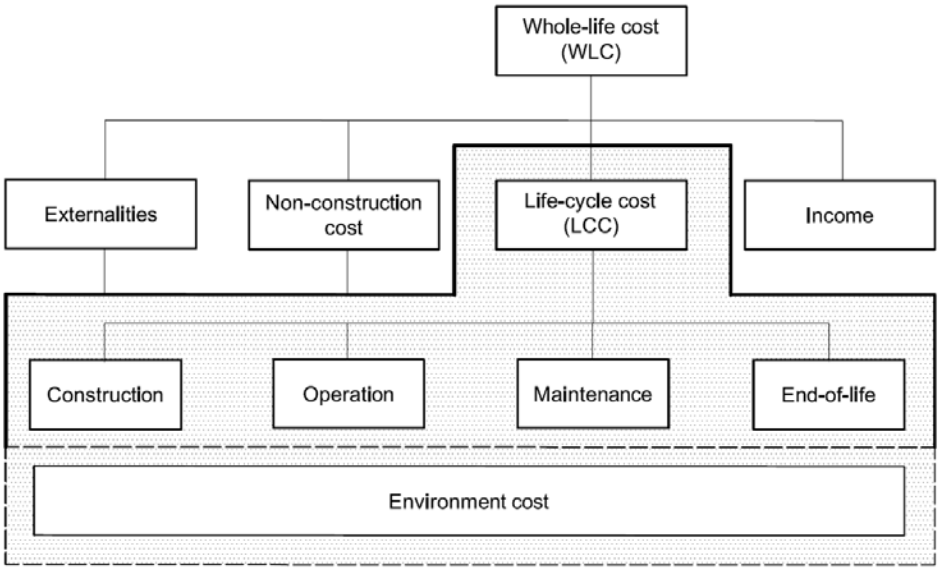

Fig. 1 Whole-life cost - ISO 15686-5 [1]

Focus on life cycle costs

An essentiell decision indicator for realising building projects remains the question of the real arising costs. The consideration only of the investment cost represents just a short-term truth of cost. An actual truth of costs over the entire life cycle can only be reached under the consideration of follow-up costs.

Various analysis of life cycle costs show that investment costs make up only a small proportion of the total life cycle costs (around 15 to 50 per cent depending on the type of object, use and estimated lifetime regarded). Therefore, the total cost planning needs a specific focus on the follow-up costs. The structure of the follow-up costs is detailled in the new Austrian Standard B 1801-2 [3] and can be used as the default for all life cycle cost determinations.

1 administration	administration and management / fees and taxes / space management
2 technical operation	technical building management / inspections, maintenance / small repairs / commissioning, decommissioning
3 supply and disposal	energy (heat, cooling, electricity) / water and sewage / waste disposal
4 cleaning and care	maintenance cleaning / window and glass surface cleaning / facade cleaning / special cleaning / winter service / cleaning public spaces / gardener service
5 security	security services / fire protection services
6 building services	house post / communications and information technology / removals / reception, internal office services / catering
7 repair, modification	major repair / improve, conversion
8 other	other
9 object removal / demolition	planning and organization / demolition and disposal, building the contract state (construction law, easement)

Fig. 2 structure of follow-up costs [3]

Due to the authors' point of view this overview has to be expanded towards financing costs, if the LCC-calculation is meant to determine e.g. the requirement of finances, a liquidity plan or an economic (respectively for tax purposes) result over a specific period.

For an effective cost steering using the life cycle costs it is absolutely necessary to identify the real cost drivers early. Only with this consciousness an ongoing project optimization can start from the very beginning.

A central influence on the determined life cycle costs is the assumed lifetime of the building. The following picture shows an example that makes this influence on the magnitude of the different cost groups pretty obvious.

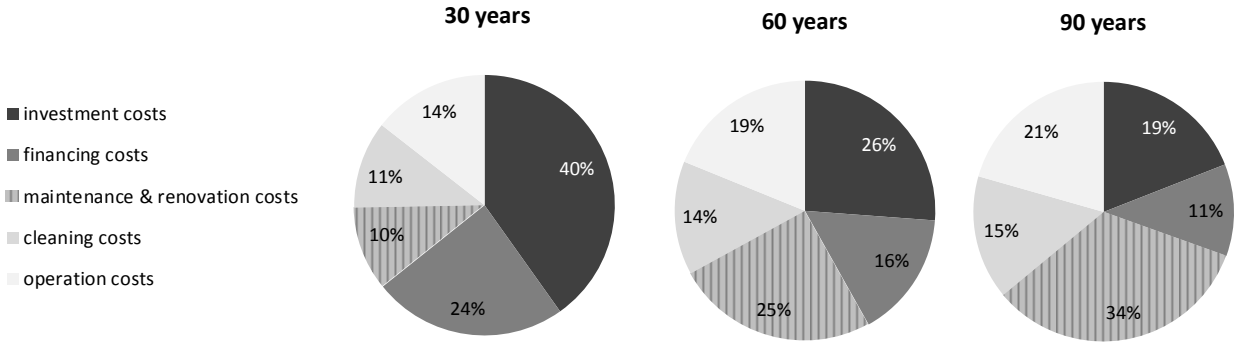

Fig. 33 Makeup of the essential cost parts of the LCC depending on the assumed lifetime [6]

The longer the lifetime is assumed for the cost planning, the higher the time-dependent cost parts like operation and cleaning carry weight. The repair and modification costs rise proportional to the number of operation phases. While in the 30 years consideration virtually maintenance costs are minimal and no modification costs arise, there are extensive repair and renovation / alteration costs for one modification in the 60 years consideration and for two modifications in the 90 years consideration.

So it is simply apparent, which cost components are crucial for a sustainable project success. One of the logical consequences is the focus of all project planning at this cost factors, with the following questions toanswer:

- How can the object be cleaned with minimal effort? (e.g. surfaces inside, facade)
- How can the object be adapted with minimal effort to new user requirements? (eg flexible structures, interchangeable surfaces, upgrading your building services and electric)
- How can the individual components are repaired with minimal effort, bearing in mind that repair work must be carried out at the same time? (Exchange of detailed planning account)
- How can the costs for the technical operation of the building are minimized, especially the staff costs for maintenance and repairs? (Low tech building, simple controls, flexible interfaces)

Consideration of value and earnings / income of the building

The economic success of buildings usually doesn't depend only on the life cycle costs, but also on the earnings from rent, a possible sale or the value of a property. Especially if real estate should be used economically by the owner, the mere consideration of the cost perspective is not enough.

Therefore, the total cost planning should involve the earnings as well including the estimation of possible income or sales proceeds (at different times). Because it can bring quite an economic benefit to invest more in certain parts of the life cycle costs when the earnings can be raised. Successful project developer and operator know exactly which investment in operating affects an increased income and which one will only increase the cost side.

An example will make this theory obvious. The economic lifetime of the surfaces in hotels is getting shorter and shorter; the level of quality is not a warranty for very much longer lifetimes. The best way seems to be to plan simple and cheap measures with a long-term focus, realize them with only a short interruption of the operation and reach the illusion of a true renewal. Than the demand can be increased again which improves the economic results.

In conclusion the author recommends a long-term prognosis that goes over several operation phases and at least 60 years. It compares the life cycle costs including the financing costs to all

possible earnings (taking into account the tax aspects). On this database solid decisions with a holistic life cycle aspect can be made.

3.2 Use systematically experiences out of the operation phase during project development and design and integrate the learnings in the organisation and in design & construction contracts.

While construction project management concentrates mainly on the phases project development, design and build, Life Cycle Management means focusing on all project phases. The whole life cycle of a building - from the start of project development to construction and operation, if necessary alteration and finally demolition respectively recycling of the building - is taken into account. Furthermore a first operating phase (lifetime e.g. 20-30 years) is followed by a second one (till the end of the life cycle) after alteration or altered utilization. Therefore the experiences and knowledge from these phases (operating, alteration and subsequent use) should be used in early project phases.

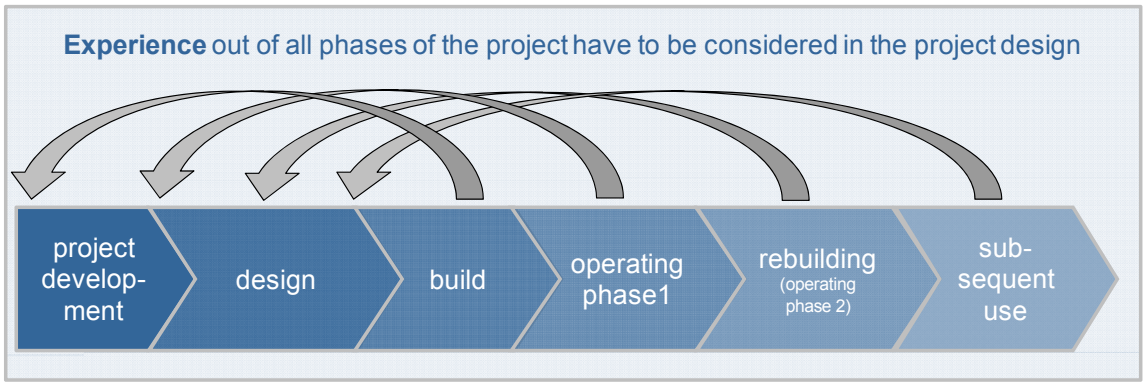

Fig. 4 Experience out of all project phases have to be considered in the early project design [10]

The basically clear demand for optimal use of experience from later phases turns out to be a real organizational challenge in regard to its actual implementation. Depending on the respective form of organization, in many cases the specific operator of the construction project may not be known at the planning phase. Therefore most often an architect whose draft has already set the relevant course is entrusted with the design and further planning process. Subsequent designers and consultants of different special fields can only develop a suitable solution according to these basic conditions.

The Integrated planning team offers a solution-oriented approach. There at a very early stage (project development, pre-draft phase) the entire planning (design) is carried out by a team that involves not only an architect and a structural engineer, but in particular also consultants in the areas of building services engineering, electrical engineering, energy technology, building physics, acoustics, façade construction and depending on the type of project further specialists (e.g. company organization, kitchen designer,).

A key role is transferred to the Facility Management Consultant who provides the experience from the building operation and within the range of facility planning can ensure that the building functions are economically in operation.

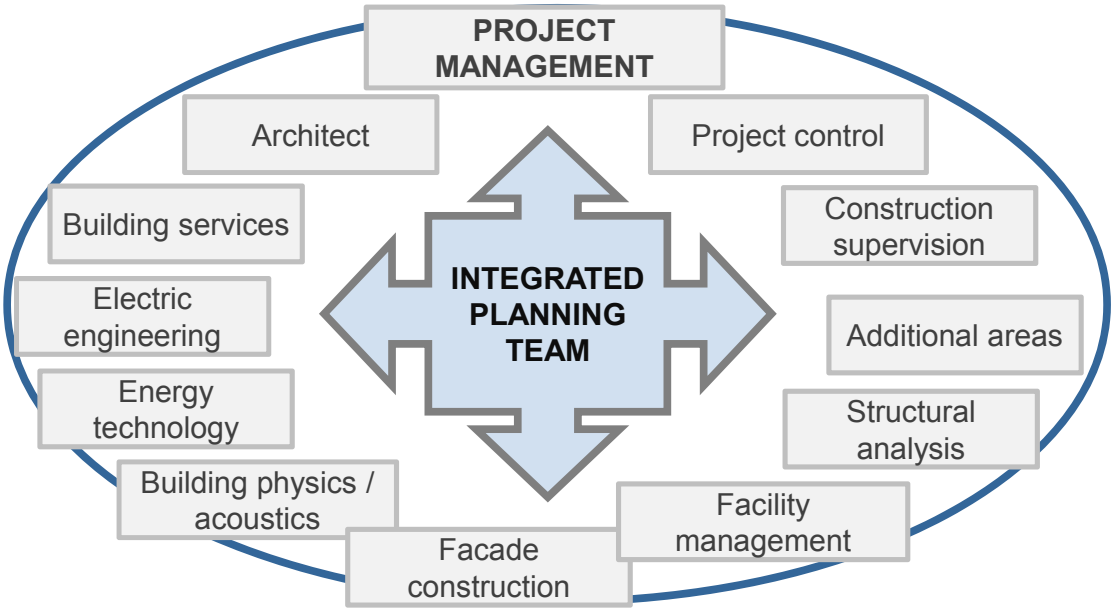

Fig. 5 Integrated planning team [4]

In order to be able to consider relevant experience from the construction phase during the planning phase, in particular concerning the realization of building contracts (e.g. accounting or deviations from specifications), the construction supervision should take an active part already in the phase of preparation, when the specifications and the bill of quantities get established.

An optimal involvement requires the development of a structured process for the progressive introduction of the individual specialists. “At the earliest stage possible” does not necessarily mean that all participants have to meet immediately. Since some specialists need first drafts or the preliminary design before being able to evaluate functionality and profitability, they have to get integrated step by step.

Furthermore, an intensive coordination among consultants and any additional tasks in the course of the joint project optimization have to be taken into account in the scope of work and determination of fees of service agreements.

Another challenge is the development of contracts for all participants, which support the ideas of Life Cycle Management and motivates all participants for project optimization during the whole planning process.

3.3 Develop a maintenance program for the 2nd and 3rd life cycle in early project phases to enlarge the lifespan and integrate the requirements in the building concept and design.

A maintenance program is an important tool to optimize the investments for maintenance, repair, overhauling and services. If the focus is on a 2nd and 3rd life Cycle (that means 60-90 years) and not only on 20-30 years, the importance of maintenance - including alteration - is evident. The experience shows that with this new view the design process and the questions to be answered have to be modified.

Maintenance Program

A Maintenance Program summarizes all measures in a long-term activity plan which are essentiell for the building conservation. In particular, the regular servicing and scheduled maintenance can

significantly affect the life cycle cost. Regular servicing can prevent minor defects to become larger (and thus more expensive to remedy) ones. Out of this thinking it can be derived that a higher investment in the servicing reduces the maintenance costs allocated over the lifetime of the induvidual elements. However, attention should be paid to the interaction between cost and lifespan. Higher servicing costs can extend the maintenance cycles, higher repair investments can prolong the lifetime. The requirement for this is to consider the conditions (market, use options) for the economic lifetime.

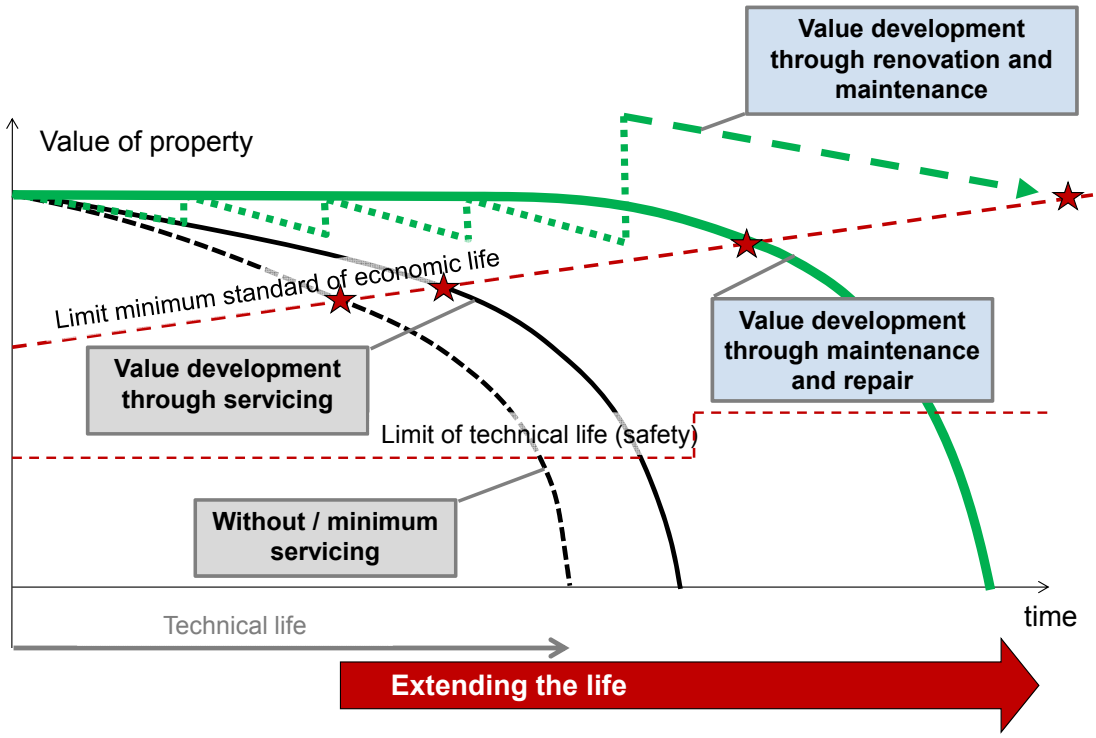

Fig. 6 Dependences between servicing, maintenance and lifetime [11]

The figure 6 shows very clearly that the economic success of a property depends heavily on the extent, kind and timing of appropriate maintenance and repair measures. The best property is always the one that enables the existing substance, the maximum useful service life.

As discussed in chapter 3.1 the maintenance costs are the biggest cost part when based on a long lifetime of the property. In future designers also has to answer these critical questions:

- How can measures for maintenance and repair be implemented?
- How could the building services & electrical engineering be extended and adapted to new user requirements?
- How can the cleaning be done effectively?
- How simple could building functions be adapted to new user requirements?
- What are the options for a conversion?
- How would certain reconstruction scenarios implementable?
- How could a deconstruction of individual components take place?

3.4 Apply (long-term) Opportunity and Risk Management in the whole project development process for a continuous project optimization.

Active Risk Management allows identifying risks early and ensures in the implementation of measures to avoid and reduce risks in sufficient time. Life Cycle Management considers not only risks during design and construction but also during operation and alteration.
Active Opportunity Management ensures that optimization and cost-reducing potentials are efficiently utilized.

Risk Management is a substantial tool of Life Cycle Management. Risk Management meets the demands and copes with the challenges of Life Cycle Management by means of suitable models, methods and responses. In order to cover an overall perspective for the statements, Risk Management simultaneously uses Opportunity Management. It works at all levels from objectives to operative implementation of building projects and integrates the results into all levels in turn. In order to achieve an application quality as high as possible, there is a need for a thorough awareness of risk philosophy and a high understanding for influences, ability to influence, sensitivity, quality of information (statements), dynamics and strategic range of the results.

Risk Management integrates practical experience, scientific research and trend analysis for the forecast to build scenarios out of different perspectives.

- It is not only about finding a right figure – for example the total investment or life cycle costs,
- it identifies the main issues,
- it shows the main aspects which have to be managed,
- it specifies measures that have to be taken,
- it creates a system for dependences and sensitivity,
- it detects time risks and uncertainties of the schedules,
- it implements opportunities and optimization potentials and
- it evaluates the knowledge from other projects.

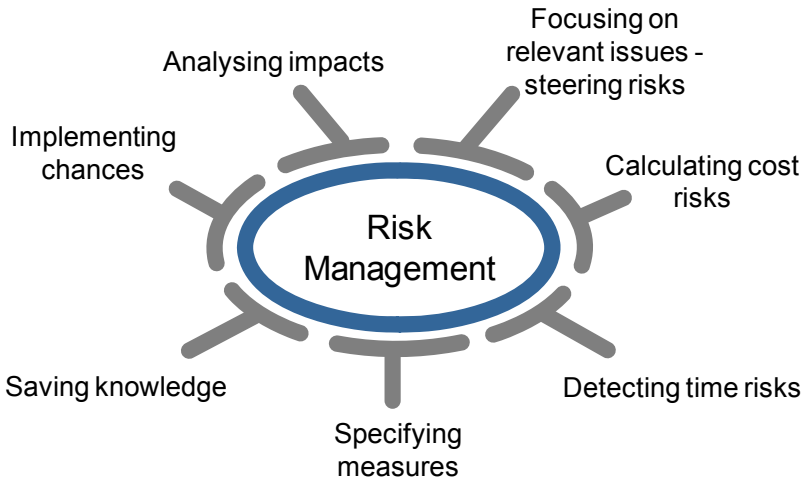

Fig. 7 Elements of Risk Management [11]

The main achievement of Risk Management is the increased reliability in design, costs and schedules. For Life Cycle Management it means an improvement of the whole design process and the output. Risk Management is the main tool to animate Life Cycle Management.

3.5 Controlling Systems for sustainability to ensure, that the concept of blue building is realized effectively

Sustainability and the blue building philosophy is part of the objectives of most real estate projects nowadays. To ensure that this is not just an add-on in the marketing brochure controlling tools are necessary. To achieve sustainable buildings the implementation of controlling tools in all project phase from the preliminary phase to the operation is essential.

Quality control from the project definition to the use

The ability to define quality is easier at the project start. It decreases from phase to phase. For a building project this quality definition should not begin with the building process but at the rather project start like all definitions of aims. In contrast, the control activity increases from phase to phase until it finds the peak of control at the project completion. Afterwards the control activities focus on the use and operation.

Integrated building certification systems represent an ideal system to develop the quality of a building in terms of sustainability (ecological, economic, social) and to examine the requirements for implementation. On one hand the comfort of the user and on the other hand the resource efficiency of the building are assessed in the life cycle. Building Passes serve clients as quality assurance and marketing tool as well as economic and ecological optimization tool. The customers get an objective assessment of housing and building quality. The application of such a principle is more relevant than the decision on a specific type of such a system. The major advantage arises only through the comprehensible definition from quality so it gets controllable and also comparable.

Practical experience from the application of certification systems as quality controlling tools

Public buildings of the province of Vorarlberg provided the analysing base for the development of a quality control system which is built up on the “Kommunalgebäudeausweis” (municipal building ID), a building certification system for sustainable properties. The quality control system deploys the options of an ongoing control and a control in particular after each project phase to compare the definitions of sustainable objectives with the implementation in real. If there are deviations countermeasures can be set in time. The documented results deliver a confirmation of the order and its specifications. The client gets more reliability of the defined quality standards. [13]

With the implementation of a quality control system for sustainability following aspects may be considered:

- Ensuring the implementation of the company's philosophy in terms of sustainability in all building projects
- Specifying the quality objectives more detailed by the definitions in the context of the certification system
- Ensuring the achievement of the quality objectives by the ongoing evaluation and early identifying deviations
- Possibly using the results for the marketing

4. Conclusions

The authors’ experience, e.g. from successfully implementing various project management and Life Cycle Management systems, provide the following success factors for developing and constructing sustainable building projects:

(1) Focus on life cycle costs instead of investment costs and additionally have the value and the earnings in mind as basis for all relevant decisions
(2) Use systematically experiences out of the operation phase during project development and design and integrate the learnings in the organisation and in design & construction contracts.
(3) Develop a maintenance program for the 2nd and 3rd life cycle in early project phases to enlarge the lifespan and integrate the requirements in the building concept and design.
(4) Apply (long-term) Opportunity and Risk Management in the whole project development process for a continuous project optimization.
(5) Controlling Systems for sustainability to ensure, that the concept of blue building is realized effectively

One does professional Life Cycle Management, if all above mentioned demands are met in a satisfactory manner.

Alexander.passer@tugraz.at

Short Summary

Since 2010 the Sustainable building certification system DGNB is in use In Austria. The Austrian Sustainable Building Council (ÖGNI) was founded in 2009, cooperates with DGNB-Gemany and adapted the German certification system for sustainable buildings to Austrian conditions [1]. This paper focuses on the results of sustainable building certifications in Austria in order to obtain benchmarks for the future development of the assessment system. The certification body of ÖGNI controls the quality of the submitted building audits. The plausibility and the conformity with the documentation guidelines and the evaluation system are verified. Meanwhile, about 50 buildings were certified by ÖGNI.

This paper presents the results of the first building certifications. Several outstanding office buildings are presented. A statistical analysis of the results of all evaluation criteria was performed and evaluated anonymously. The results show, which criteria were easy to fulfil and which were hard to meet. Conclusions concerning further development of the evaluation system are derived. Special emphasis is laid on benchmarks for ecological and technical criteria. Furthermore recommendations for a higher transparency of the results are made.

Keywords: ÖGNI; DGNB; Sustainable building certification; Benchmarking

1. Introduction

The DGNB/ÖGNI Certificate is a transparent and comprehensible rating system, which is based on the CEN/TC350 approach. It defines the performance of buildings in a comprehensive way – with 5 plus 1 topics, and enables auditors to conduct an evaluation systematically and independently. The building's performance, by reaching a defined degree of performance, is assigned a bronze, silver or gold award. Furthermore, grades are given for the total performance of the building as well as for the individual topics.

The DGNB/ÖGNI certification scheme criteria-set includes five weighted topics (main criteria groups): Ecological Quality (22.5%), Economic Quality (22.5%), Socio-functional Quality (22.5%), Technical Quality (22.5%), Quality of Process (10%) and one additionally not weighted, separately evaluated topic – Quality of the Location [2].

Each of these topics is divided into several assessment criteria. For instance, the Global Warming Potential, Total Primary Energy Demands and Proportion of Renewable Primary Energy, Thermal Comfort in Winter and Summer or Energetic and Moisture Proofing Quality of the Building's Shell are considered for the evaluation of a building. For each criterion, measurable target values are defined, and a maximum of 10 points can be assigned. The measuring methods for each criterion are clearly defined.

2. Methodology

The objective of this investigation was to learn from the first certified buildings for the development of the assessment system. Meanwhile, about 50 buildings were certified by ÖGNI and an update of the assessment system is developed currently. Therefore the results of DGNB/ÖGNI certificated buildings have been analysed in order to derive conclusions for a fine-tuning of the criteria set and the benchmarks.

The investigation includes 18 certified offices buildings that had been certified between 2010 and 2013. Data has been derived from ÖGNI and the results are presented anonymously. For each criterion the results are presented in ascending order and additionally the arithmetical mean value of all 18 buildings is shown.

3. Results

Six office buildings achieved a Gold-Certificate, eleven buildings a Silver-Certificate and one building a Bronze-Certificate.

The results (figure 1) show the percentage of the performance value. With an overall performance of more than 80 % a Gold-Certificate is achieved and with an overall performance of more than 65 % a Silver-Certificate is achieved.

The highest results in average were achieved for economical quality (89 %). The lowest results in average were achieved for process quality (65 %) which is due to the introductory phase of DGNB-Certification in Austria. For the first certified buildings the decision for certification was made in a relatively late project stage and therefore the criteria concerning earlier project stages couldn’t be influenced or improved.

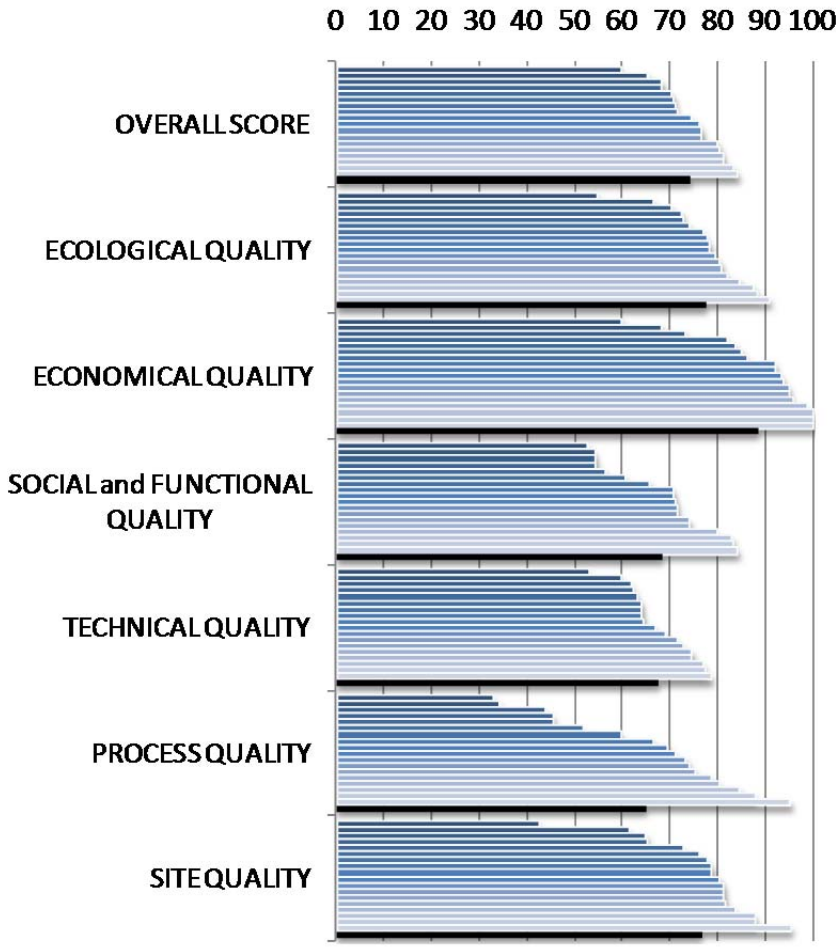

Fig 1: Overall Score and partial results of 18 selected office buildings. Single results and mean value (black bar)

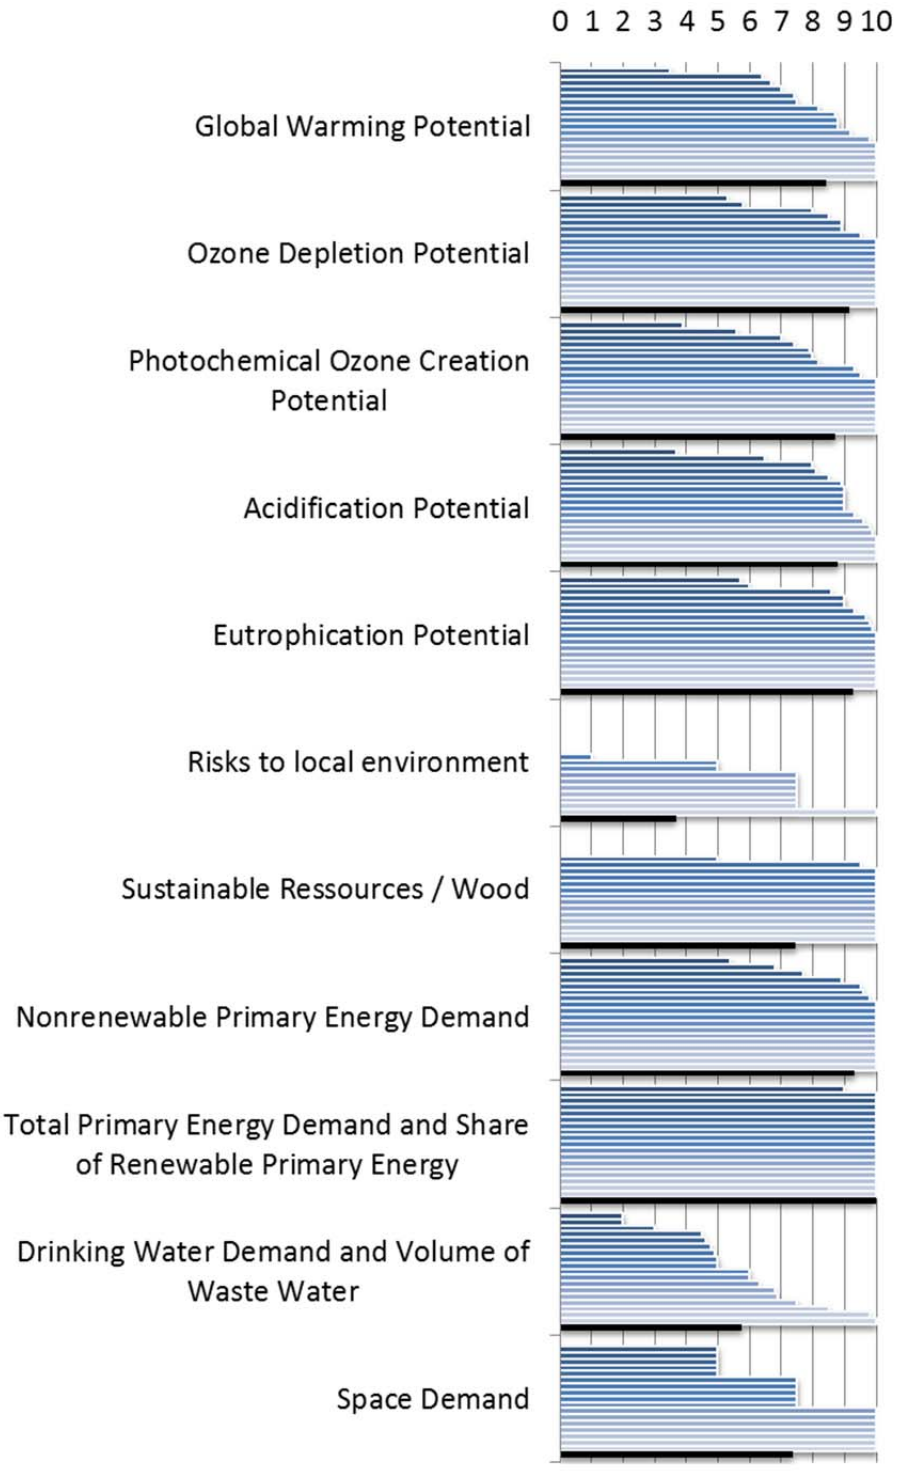

Fig 2: Results for ecological quality. Single results and mean value (black bar)

For ecological quality the highest results in average were achieved for the combined criterion “Total Primary Energy Demand and Share of Renewable Primary Energy” (9.9 assessment points of 10 possible points). The lowest results in average were achieved for “Risks to local environment” (3.7 points).

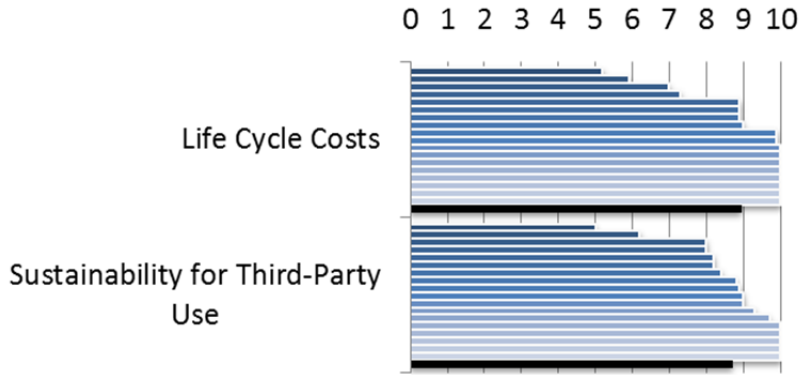

Fig 3: Results for economical quality. Single results and mean value (black bar)

For economical quality very high results in average were achieved for “Life Cycle Costs” (8.9 points).

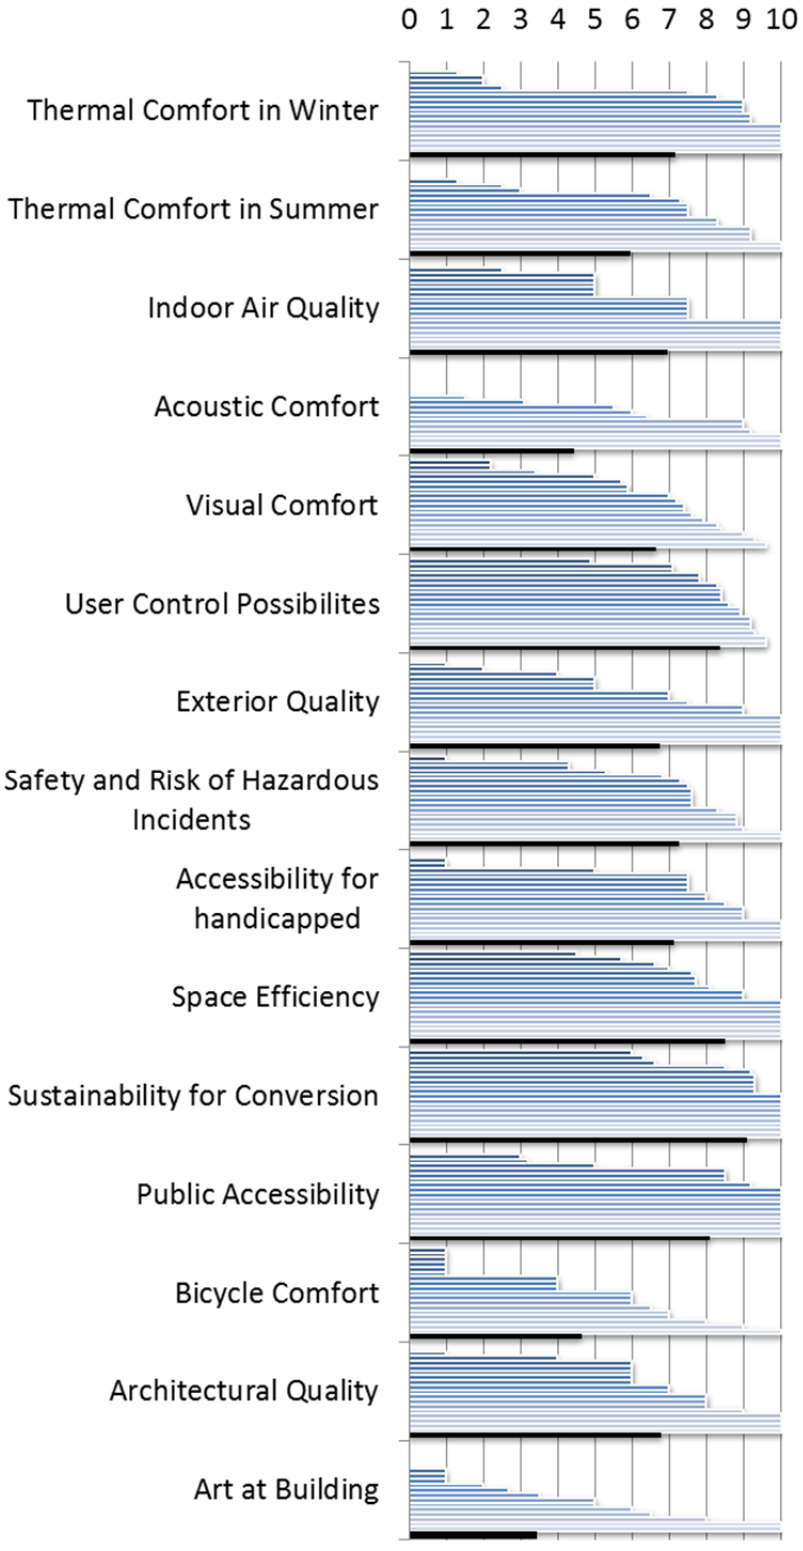

Fig 4: Results for socio-functional quality. Single results and mean value (black bar)

For socio-functional quality the highest results in average were achieved for “Sustainability for Conversion” (9.1 points), “Space Efficiency” (8.5 points) and “User Control Possibilites” (8.4 points). The lowest results in average were achieved for “Art at Building” (3.4 points), “Acoustic comfort” (4.4 points), “Bicycle comfort” (4.6 points) and “Thermal Comfort in Summer” (6.0 points).

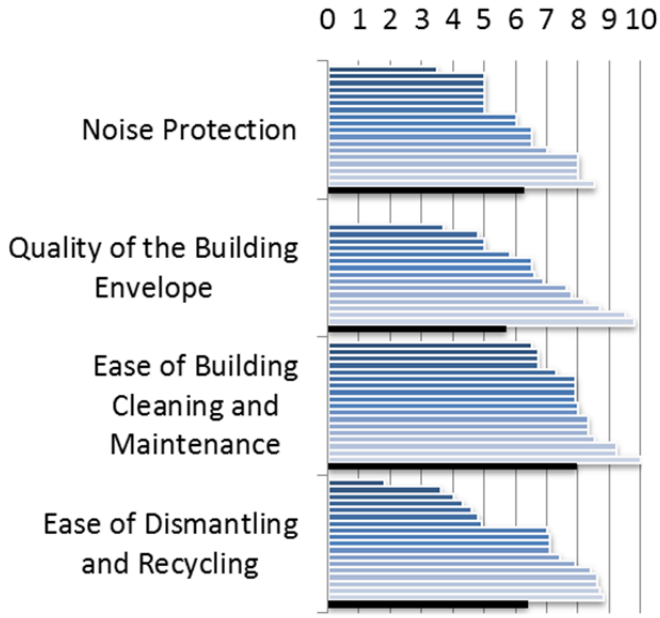

Fig 5: Results for technical quality. Single results and mean value (black bar)

For technical quality the highest results in average were achieved for “Ease of Building Cleaning and Maintenance” (8.0 points). The lowest results in average were achieved for “Quality of the Building Envelope” (5.7 points). The criterion “Fire Protection” was not investigated because it was not mandatory in the introductory phase of DGNB-Certification in Austria.

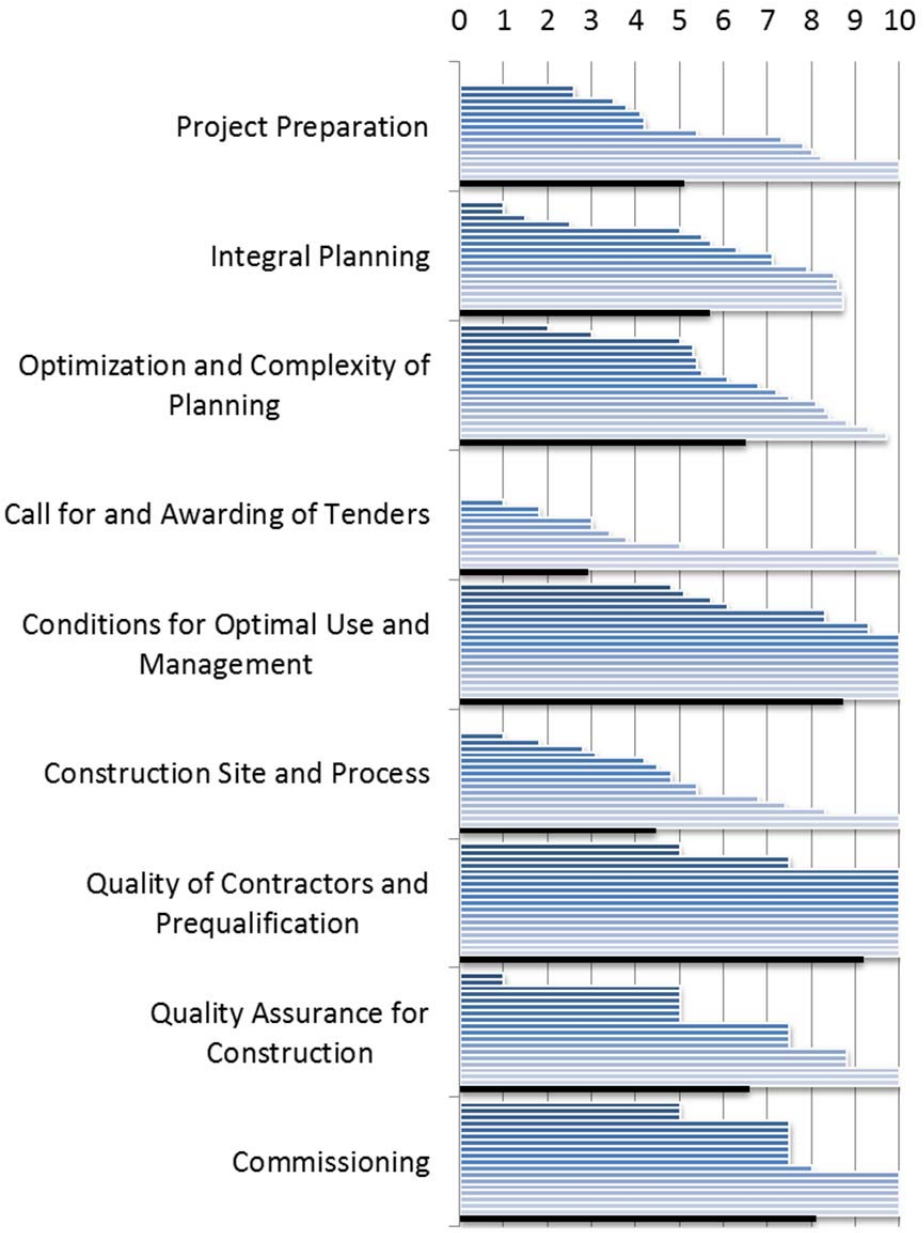

Fig 6: Results for process quality. Single results and mean value (black bar)

For process quality the highest results in average were achieved for “Quality of Contractors and Prequalification” (9.2 points) and “Conditions for Optimal Use and Management” (8.7 points). The lowest results in average were achieved for “Call for and Awarding of Tenders” (2.9 points), “Construction Site and Process” (4.5 points) and “Project Preparation” (5.1 points).

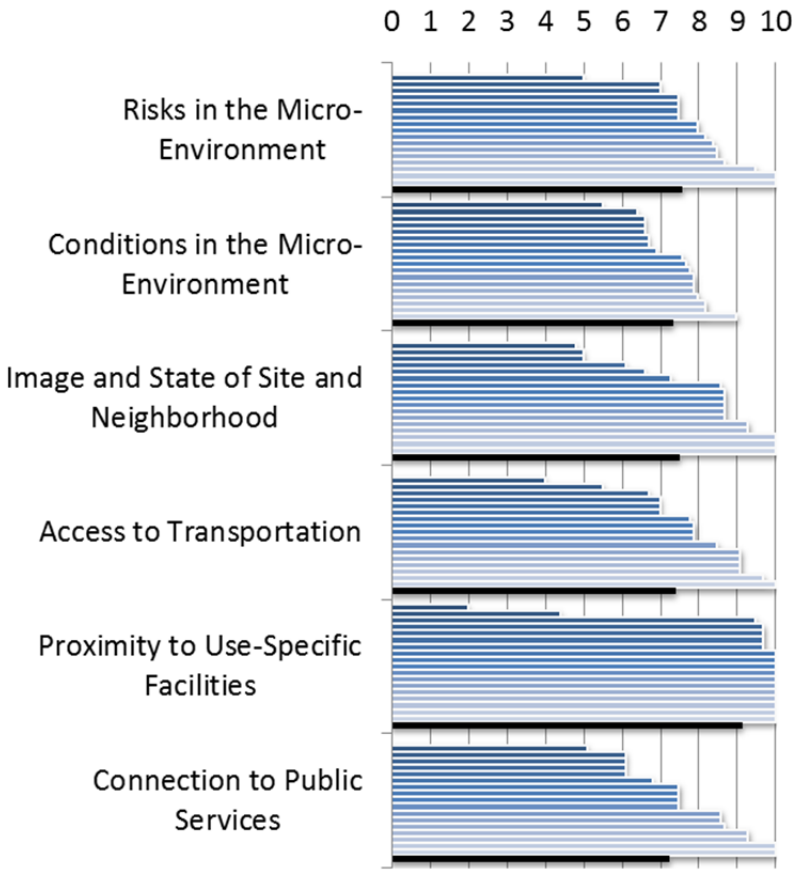

Fig 7: Results for site quality. Single results and mean value (black bar)

For site quality the highest results in average were achieved for “Proximity to Use-Specific Facilities” (9.2 points). The other criteria also achieved relatively high values in average (7.3 to 7.6 points).

4. Conclusions

In average relatively high results were achieved for most of all criteria groups and many criteria. Single results generally vary a lot for nearly all criteria and that proves that the assessment methodology is generally very suitable.

For many buildings in the introductory phase of DGNB-Certification in Austria the decision for a Certification was made relatively late in the project stage. Therefore some criteria of process quality couldn’t be influenced or improved. The results for process quality showed the biggest variations. It is assumed, that future certifications together with early decisions should show higher values for process quality.

Most of the buildings achieved relatively high results for the criteria concerning environmental life cycle assessment (LCA), especially concerning for the combined criterion “Total Primary Energy Demand and Share of Renewable Primary Energy”. Meanwhile, in the updated German DGNB system, this combined criterion is split into two separate assessments. The new structure of the German DGNB system will be adopted in Austria as well and the benchmarks for “Share of Renewable Primary Energy” will be adjusted to Austrian objectives considering the high share of renewables in the Austrian electricity mix.

For the update of the Austrian system the results of the LCA are currently analysed more in detail in order to adjust the benchmarks. Many buildings achieved better LCA results than the target

values, but the amount of this overshooting has no influences on the results. It is recommended to improve the target values or to introduce bonus points for overshooting the target values. This also concerns the criterion “Life Cycle Costs”.

Further adjustments should be investigated concerning the criteria “Quality of Contractors and Prequalification” and “Conditions for Optimal Use and Management” because these criteria of process quality showed very high results and small variations.

Overall the analysis showed that the DGNB-methodology is very suitable to point out individual properties of buildings that are significant for sustainable development. Therefore it is a very powerful tool to quantify and illustrate building characteristics. It is recommended to show the results of all criteria in order to increase the transparency and information content of the DGNB-certificate.

5. Acknowledgments

We would like to express our sincere thanks to The Austrian Sustainable Building Council (ÖGNI) for providing the necessary data and to DI Albrecht Kemmann for his contributions to the working group.

Achieve Sustainability in Laboratory Buildings on different Ways – Building, Equipment and User Behavior

Egbert Dittrich
ceo EGNATON e.V.
Germany
European Association for
Sustainable Laboratories
egbert.dittrich@egnaton.com

Short Summary

Sustainability is in the focus of many global entities and organizations. Pushed by architectural influence the majority focus on the design of buildings. In terms of life cycle, impact of laboratory process and user behavior, as well as technical equipment such as plug-in-units, seem not to be considered seriously.1

Certification systems for laboratory buildings barely are covered by design criteria usually used for office or industrial buildings. They are dominated by an outstanding use of energy no matter if electricity, gases, demineralized water or any other services. A laboratory may have inline pipe network of more than fifteen media.

The presentation will clearly show that a mix of topics only can achieve sustainability. Laboratory apparatus have a major influence and enable users to achieve sustainability on a high scale, provided it offers energy saving, safety and other sustainable design features. No matter how sustainable the building might be, energy consumption, work flow and influence by the laboratory process impressively dominate the impact in regard to sustainable aspects. Increasing number of plug-ins either multiply those effects.

The major doctrine must be furthermore: Safety beats any other category in the sustainability evaluating system, e.g. reduction of air exchange rates shall only be achieved after a proper risk assessment. The humans and their needs and wellbeing are much important for efficiency and research output. By those means lab designers have to keep an eye on comfort, communication options and individual situations of the users. Therefore lab planners need to be educated in safety strategies either. The general and major use of supply air in a lab building for dilution and evacuation of hazardous substances and gases is changing the character of the purpose of air ventilation. On the other side limitations in regard to air velocity because of comfort aspects are to be considered as well.

For sure sustainability hardly can be achieved in a non sustainable building with non sustainable equipment and instruments, but it is easy to operate a building with a high sustainability assessment in a not sustainable way. Users have the key to operate the building in accordance with the sustainable design criteria.

Once the building is occupied, daily monitoring of the bench marks by submetering, permanent control if the goal is still on the screen and sustainability strategies are aligned to short term change of the lab processes, will help to operate for long term the unity building-lab process-user on a level that is verified with a certification system.

Life cycle cost and assessment of the building is important but operators shall know that it makes sense only if the process and its LCC caused by inevitable equipment and plug-in-units are considered also. Impact of the plug-in-units must cause an own sustainability certification system in order to succeed with the paradigm shift towards more sustainability.

[1] 1 EGBERT DITTRICH “Handbuch für nachhaltige Laboratorien”. Berlin 2012,ISBN 978 3 503 13053 5

Presenter will give an overview upon the EGNATON CERT initiative including PCRs and EPDs – a certification system for laboratory apparatus and equipment.
The learning lesson is to bring the different categories of sustainability in a balance which follows a global standard in order to provide transparency and acceptance. If entities, public bodies and authorities will not agree upon consensual assessments and the meaning of sustainability differs there is no option to penetrate sustainability to private and public life. By those means sustainability must be defined in a new way for laboratory buildings and shall be understood in a holistic view. Some important issue is: Our modern society expects that the industry in general provides sustainable products, substances and processes for the future. By those means research has a clear order which can be achieved only in sustainable buildings and work environment. As a surgeon will not succeed a surgery in a grubby operation theatre, researchers need a sustainable environment to develop sustainable results.

Time Valued Life Cycle Greenhouse Gas Emissions from Buildings

Howard Darby
Research Engineer,
Technologies for
Sustainable Built
Environments,
University of
Reading,
UK
h.j.darby@
pgr.reading.ac.uk

Dr Abbas Elmualim, School of Construction Management and Engineering, University of Reading, UK, a.a.elmualim@reading.ac.uk
Dr Fergal Kelly, Peter Brett Associates, UK, fkelly@peterbrett.com

Short Summary

The UK has adopted legally binding carbon reduction targets of 34% by 2020 and 80% by 2050 (measured against the 1990 baseline). Buildings are estimated to be responsible for more than 50% of greenhouse gas (GHG) emissions in the UK. These consist of both operational, produced during use, and embodied, produced during manufacture of materials and components, and during construction, refurbishments and demolition. A brief assessment suggests that it is unlikely that UK emission reduction targets can be met without substantial reductions in both Oc and Ec. Oc occurs over the lifetime of a building whereas the bulk of Ec occurs at the start of a building's life. A time value for emissions could influence the decision making process when it comes to comparing mitigation measures which have benefits that occur at different times. An example might be the choice between building construction using low Ec construction materials versus building construction using high Ec construction materials but with lower Oc, although the use of high Ec materials does not necessarily imply a lower Oc.
Particular time related issues examined here are: the urgency of the need to achieve large emissions reductions during the next 10 to 20 years; the earlier effective action is taken, the less costly it will be; future reduction in carbon intensity of energy supply; the carbon cycle and relationship between the release of GHG's and their subsequent concentrations in the atmosphere. An equation is proposed, which weights emissions according to when they occur during the building life cycle, and which effectively increases Ec as a proportion of the total, suggesting that reducing Ec is likely to be more beneficial, in terms of climate change, for most new buildings. Thus, giving higher priority to Ec reductions is likely to result in a bigger positive impact on climate change and mitigation costs.

Keywords: Carbon, CO_2, emissions, time value, embodied, operational, discount, life cycle, weighting.

1. Introduction

Global temperatures are expected to rise by between 1.1 and 6.4^{o}C by the end of this century, depending, to a large extent, on the quantity of man-made (anthropogenic) greenhouse gases (GHG) emitted in to the atmosphere from now onwards. This warming is expected to have very negative effects on many peoples and ecosystems and, therefore, minimising our greenhouse gas emissions is a priority and is a long-term, large-scale challenge.

The UK, along with many other countries, has adopted a target limit of 2°C of warming relative to pre-industrial temperatures, which requires global greenhouse gas emissions to peak by 2020, be

cut by 50% by 2050 and approach zero before 2100. For equal worldwide per capita emissions to be achieved by 2050 (in developed and developing nations), per capita cuts in the UK of more than 80% below 1990 levels are required before 2050.

The UK has therefore adopted legally binding carbon reduction targets of 34% by 2020 and 80% by 2050 (measured against the 1990 baseline) [1], [2].

Buildings are estimated to be responsible for more than 50% of GHG emissions in the UK [3]. These consist of both operational emissions (Oc), produced during use, and embodied, emissions produced during manufacture of materials and components, and during construction, refurbishments and demolition (Ec).

To date the major effort has focused, quite rightly, on reducing operational emissions but can we reach our reduction targets by just reducing Oc without reducing Ec?

To get an indication we can assume that buildings have to contribute their share of the targets (34% and 80% of the 1990 building emissions) and that the Ec:Oc ratio is 30%:70% over a 60 year service life. Generally different building types exhibit different Ec:Oc ratios but for this purpose a fairly representative 30%:70% ratio is used [4], [5].

Figure 1 shows typical building Ec and Oc profiles for a new building constructed in 2013 and with a service life of 60 years, up to 2073, together with the UK emissions profile from the 1990 baseline through to 2100 using actual emissions up to 2012 and targets up to 2100 [6], [7]. The building emissions are based on the premise that building emissions have already reduced towards their target by 26% in line with the overall UK reduction [6].

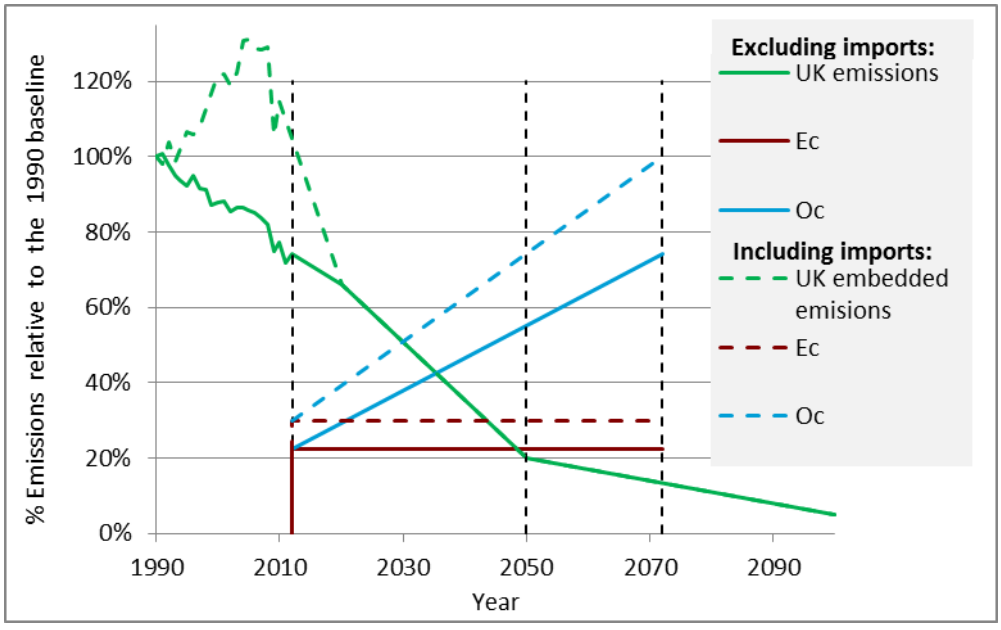

Fig.1: Typical building Ec and Oc profiles with UK emissions

The figure suggests that even if Oc is reduced to zero, Ec would need to be reduced by 10% to reach the 2050 80% target.

If we consider the current thinking for Oc reduction in terms of the 'zero carbon' definition for new homes, which applies to 'regulated' emissions only (space heating, hot water, fixed lighting and building services), and is estimated to be between half and two thirds of Oc, the required reduction in Ec rises to more than 85%. This ignores the issue of 'allowable solutions' which can effectively reduce the amount of regulated emissions which need to be included [8].

To make things worse, a recent report by the UK Committee on Climate Change [8] shows that actually, far from reducing GHG emissions since 1990, the UK has increased its emissions by more than 10% if 'embedded emissions' are considered, including imported materials and goods, with building emissions increasing by 2% over this period. This scenario is shown in dotted lines in Figure 1. If we assume that the 1990 and 2012 emissions are the same (an approximation) and we have made no effective reductions over this period, then if Oc is reduced to zero Ec would need to be reduced by around 30% to reach the 2050 80% target, or reduced to less than zero to meet the target implied by the 'zero carbon' definition.

The exact numbers used above can be debated, however, the example is sufficient to suggest that it is unlikely that emission targets can be met without substantial reductions in both Oc and Ec.

One of the main differences between the two is that Oc occurs over the lifetime of a building, for example 60years and 100years, which are commonly used metrics for the service life of buildings, whereas the bulk of Ec occurs at the start of a building's life during the production of materials and components and building construction. So the timing of building emissions, and in some cases removals as with sequestered carbon during the production of biogenic materials such as wood, varies across the building life cycle.

Therefore, an important issue that needs to be addressed is the time value of these emissions, in other words do emissions that occur now have the same impact as emissions that occur in the future. Or conversely, are emissions avoided now more beneficial than emissions avoided in the future.

A time value for emissions could influence the decision making process when it comes to comparing mitigation measures which have benefits that occur at different times. An example might be the choice between building construction using low impact construction materials but with high operational impact versus building construction using high impact construction materials but with low operational impact.

As operational emissions reduce and further reductions become more difficult and costly, consideration of early embodied GHG reductions, rather than just future operational reductions may be more beneficial, particularly in view of the short 2020 and 2050 timeframes for GHG reductions in the UK.

2. Issues affecting time value

There are a number of time related issues which lead to the idea that emissions occurring at different times during the building life cycle should perhaps be valued differently. The issues considered in this paper are:

- the urgency of the need to achieve large emissions reductions over the next 7 to 37 years (by 2020 and 2050)
- the findings of the Stern Review [9] that the earlier effective action is taken, the less costly it will be
- future decarbonisation of energy supply and more energy efficient building equipment
- the reduced time that delayed emissions are present in the atmosphere during the assessment period
- the carbon cycle and the relationship between the release of GHG's and their subsequent concentrations in the atmosphere over time

2.1 The urgency and cost savings by early effective action.

We need to achieve large emissions reductions over the next 7 to 37 years (by 2020 and 2050). If we don't achieve these reductions we will probably have missed the chance of keeping global temperature below the 2^{o}C target (with the likely extremely serious global impacts) and, because of the way emissions persist in the atmosphere and are only gradually re-absorbed, emission reductions after this date will not help to keep temperatures below this threshold. So it can be

argued that the emission savings during the early life (the earlier the better) of buildings built today should be our first priority, and are therefore more valuable.

The Stern Review [10] demonstrated in economic terms, the need for early effective action. The Review estimates that if no action is taken the costs and risks of climate change will be equivalent to losing between 5% and 20% of global GDP each year from now and into the future. However, with effective action to reduce GHG emissions over the next 10-20 years this can be limited to around 1% of global GDP per year. Although the review findings were not universally accepted at the time (2006), they have been strongly defended [11] and more recent climate data indicates that the review, if anything, underestimated the risks, and the threats to economies [12].

Due to the time lag between taking actions and the effects, the costs of climate change mitigation measures taken now are borne by the present generation but future generations get the benefits and, because of the complexity, many of the effects and consequences are uncertain. So the issue is how to evaluate the costs and the benefits occurring at different times and by different generations.

In terms of economic appraisal, discounting is the generally accepted method of dealing with time, which involves discounting a unit of cost or benefit in the future relative to that unit now. This enables costs and benefits occurring at different times to be converted into a single 'net present value' (NPV) number for decision making. In this context, Stern has suggested that discounting is a slightly misleading term as it implies disregarding benefits in the future and has suggested it may be more helpful to describe the process as 'intertemporal values and valuations' rather than discounting.

Its application in the field of climate change appears to be very controversial with much debate over whether the use of a simplistic system of discounting is appropriate for the complex issue of climate change and what might be an appropriate discount rate to use [11], [12], [13]. Nevertheless, the consensus appears to be that discounting can be a useful tool to provide guidance in the appraisal of options for mitigating climate change.

The formula for net present value can be expressed as:

$$NPV = \sum_{1}^{n} C(1+i)^{-n} \qquad (1)$$

Where C is the cost or benefit in year n at a discount rate of i.

Generally, a positive discount rate is assumed, which reduces the value of a unit of cost or a unit of benefit spent or received in the future in relation to the value of that unit today. The value reduces the further you go into the future and the level of the discount rate considered (generally between 3% and 8%) makes a big difference in assessing options with long-term effects, and therefore finding the correct discount rate for the benefits of reducing GHGs is crucial and is a complex subject giving rise to much disagreement even amongst economic experts.

It is useful to briefly consider the main justifications for discounting. These have been described as [12]:

- Future generations may be wealthier and as you get wealthier the same unit of cost becomes less significant. This leads to the difficulty of forecasting how much wealthier. The problem of climate change could be considered fairly unique in this sense, as it is partly the mitigation actions taken today which will determine the wealth of future generations, and it is by no means certain that they will be wealthier, particularly if only weak mitigation actions are taken.

- 'Pure time' discounting based on the idea that it is a natural preference to have a unit of income or benefit now rather than at some time in the future. The argument goes that we are in fact discounting the benefits to future generations just because they are in the future, which seems difficult to justify ethically. One seemingly justifiable reason for 'pure time' discounting is risk

and uncertainty about whether future generations will continue to exist due to some catastrophic global event unrelated to anthropogenic climate change such as a nuclear war or a meteorite strike. It would seem reasonable to attach slightly less value to benefits occurring in the future over say the next one hundred years to account for the probability (although very low) of such an event happening.

- The 'opportunity cost' basis for discounting looks at future costs and benefits in relation to the level of return from other investment alternatives. On this basis, the discount rate for benefits and costs of a project would be at least as high as the expected market rate of return from the best alternative.

The choice of discount rate appears to be fairly subjective and is generally based on a combination of the above. The so called 'Social discount rate' (SDR) has been described as the measure used to help guide choices about the value of social projects. It is defined as 'the appropriate discount rate to use in computing present discounted value for social investments.' [14], [15], for example to estimate the value of infrastructure projects, schools, or environmental protection schemes. The SDR is used to put a value on both future costs such as maintenance or on future benefits such as reduced pollution emissions, and places less of an emphasis on the market 'opportunity cost'.

Stern arrived at the relatively low overall value of +1.4%, which includes 0.1% 'pure time' discount rate, effectively valuing future generations equally with the current generation but assuming approximately a one in ten chance of the planet being destroyed by the end of this century.

Figure 2 shows discount factors, which can be applied to emissions occurring at different times during a building's service life. A range of discount rates are shown to demonstrate how they influence the results. Using a discount rate of +1.4%, emissions at year 0 are roughly 2.3 times as 'damaging' as emissions at year 60 and 4 times as 'damaging as emissions at year 100. Or putting it another way, emission savings in year zero are 2.3 times as 'beneficial' as those at year 60 and 4 times as 'beneficial' as those at year 100.

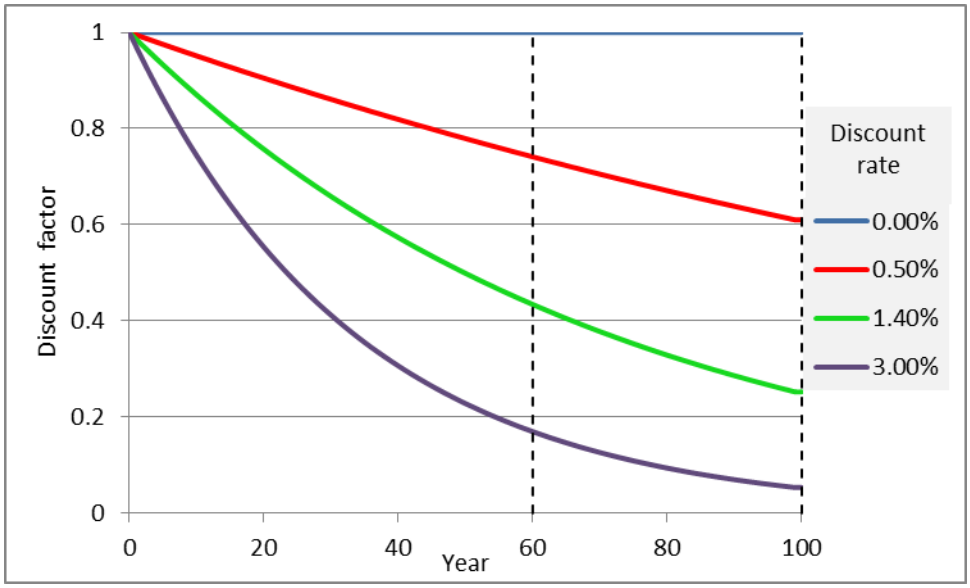

Fig.2: Discount factors for emissions occurring in the future

Assuming equal emissions per year, the NPV of all emissions for a given period is the area under the curve for that period multiplied by the annual emission. In the case of a discount rate of +1.4% and periods 0 to 60 years and 0 to 100 years, the NPVs are 68% and 54% of the non-discounted emissions.

The appropriate discount rate in relation to climate change is still a hotly debated topic amongst economists but the principle of discounting at some level appears to be generally accepted. For the purposes of this paper the methodology and rate put forward by Stern [10] are adopted which

results in a discount rate at the low end of the range discussed in the literature. Adoption of a higher rate would give an even higher value to early embodied emission savings.

2.2 Future decarbonisation of energy supply and more energy efficient building equipment

Decarbonising the electricity supply is a key part of the UK's low carbon transition plan. The ambition is to reduce carbon intensity in line with the Markal scenarios [16], all with reductions of around 90% of the 2010 intensity by 2050, albeit at different rates. The 'mean' scenario is shown in Figure 3.

In 2011 electricity comprised approximately 33% of energy consumption in UK buildings resulting in 55% of emissions [6], [17]. Carbon intensity has already reduced by 35% (2011 figures) against a 1990 baseline. However, electricity use increased resulting in a net reduction in emissions of 16%.

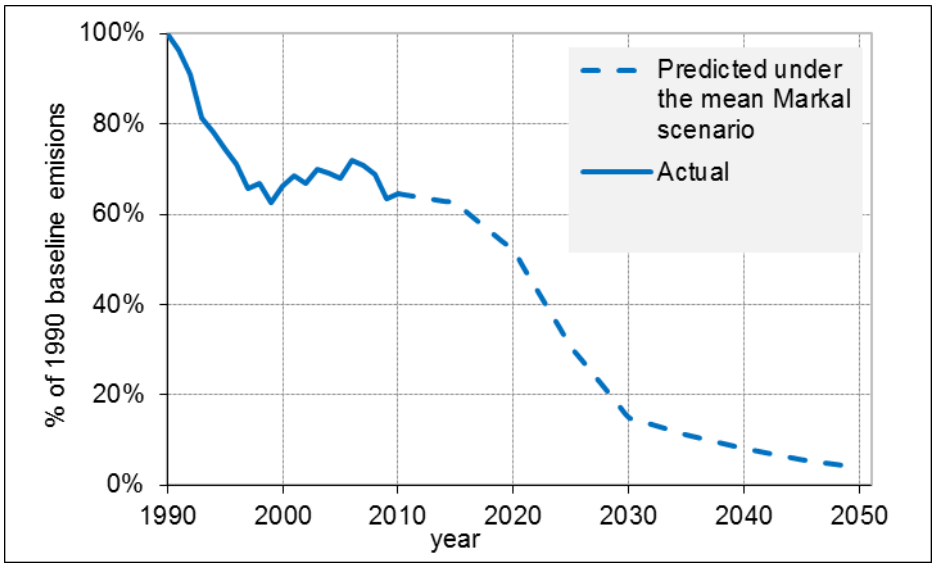

Fig.3: Carbon intensity of grid electricity – rate of reduction based on the mean of Markal scenarios

Gas comprised approximately 57% of energy consumption in UK buildings, resulting in 37% of emissions. There was particularly low gas consumption in 2011 due to a mild winter and more normal percentage emissions would perhaps be 50% from gas and 40% from electricity consumption.

Emissions from oil and solid fuel use were around 8%.

So the question is how will these emissions change in the future? Figure 4 shows emissions from the four main energy sources and the combined total from 1990 to 2011.

Crude linear trend lines have been added, together with the mean Markal profile for reduction of carbon intensity of grid electricity. The trend lines suggest that the UK will not even meet the overall 80% reduction target for all emissions by 2050, whereas, in actual fact the reduction in emissions from new buildings is required to be greater than 80% to make up for the existing building stock, of which a large proportion will still be in use in 2050, and other sectors of the economy, which will be unable to make the same level of reduction [15].

Any future increase in exploitation of shale gas is predicted to increase the carbon intensity of gas supply due to increased fugitive emissions, although the recent report from the Committee on Climate Change [9] has stated that improvements in extraction techniques could possibly maintain the current level of intensity. Overall, it seems unlikely that the carbon intensity of gas supply can be improved significantly and therefore reducing the reliance on fossil gas seems unavoidable.

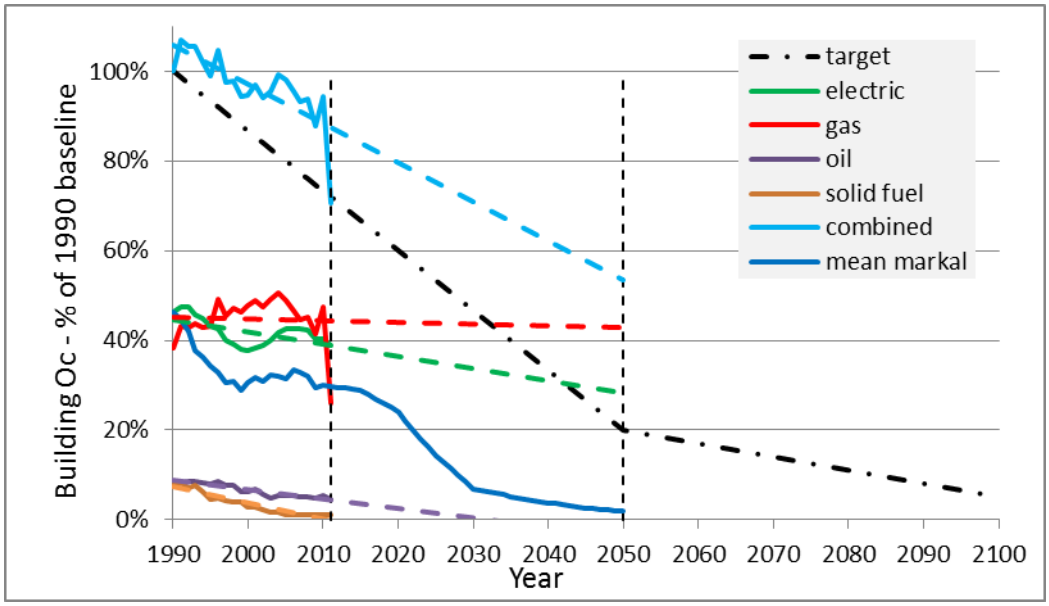

Fig.4: Building Oc- target, emissions from different energy sources, trends based on 1990-2011 emissions and mean Markal scenario for decarbonisation of grid electricity

Substantial changes in energy supply and energy use will be needed to achieve the sort of emission reductions required. These are likely to include: accelerating the reduction of carbon intensity of grid electricity in line with the Markal scenarios; reduced use of fossil gas and oil; more energy efficient replacement equipment in building upgrades and refits, increased use of biogenic fuel sources and consumer behaviour change.

For the purposes of this paper it is assumed, and some would argue we have little option, that the reduction of emissions from buildings built today will generally follow the path of the overall UK emissions, reducing by 80% from 1990 to 2050 and by 95% by 2100 [7], although predicting what reductions may be required at the end of the century can at best be described as somewhat speculative.

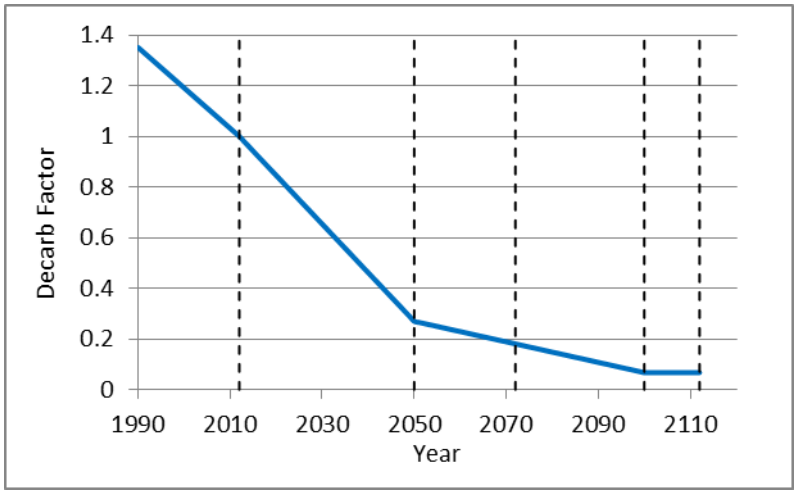

Fig.5: Factors to account for decarbonisation of energy supply

Figure 5 shows the resulting factors, adjusted in accordance with the previously stated premise that building emissions have already reduced towards their target by 26% in line with the overall UK reduction, giving a factor of 1 at the starting point of 2012/13. (1990 was the 100% level, 2012 the 74% 2050 needs to be the 20% level; this effectively means a reduction of 73% of the 2012 level by 2050).

Assuming equal emissions per year, the NPV of all emissions for a given period is again the area under the curve for that period multiplied by the annual emission. For periods 0 to 60 years and 0 to 100 years from 2012/13, the NPVs are 49% and 34% of the unfactored emissions.

2.3 Delayed emissions and the carbon cycle

British Standards Institute publication 'Publicly available specification, PAS 2050, Specification for the assessment of the life cycle greenhouse gas emissions of goods and services' [19] states 'Emissions that are released over time through long use (e.g. light bulbs) or final disposal phases cannot be treated as a single release of emissions at the start of the 100-year assessment period. Therefore, these emissions must be calculated to represent the weighted average time in the atmosphere during the assessment period.'

In addition, all carbon, including anthropogenic carbon, released into the atmosphere is redistributed during the following decades and centuries between the three main reservoirs: atmosphere, ocean, and land biosphere. It is the increase in concentrations of carbon dioxide and other GHGs in the atmosphere, which leads to a rise in global temperature. Some of the anthropogenic carbon released into the atmosphere therefore, effectively 'decays' as it is gradually re- absorbed into the other two reservoirs.

The relationship between anthropogenic carbon emissions and atmospheric CO2 concentrations over time is described by 'the revised version of the Bern Carbon cycle model' [18], which is the basis for calculations of global warming potentials by the Intergovernmental Panel on Climate Change (IPCC).

A weighting factor to account for delayed emissions and 'decay' of atmospheric carbon can be described by Equation 2.

$$Weighting\ factor = \sum_{n=1}^{100} x_n (1 - 0.0068n - (3 \times 10^{-5})n^2) \quad (2)$$

Where n is each year in which emissions occur and x is the proportion of total emissions occurring in any year n.

A simplified version is used in PAS 2050 given by Equation 3.

$$Weighting\ factor = (\sum_{n=1}^{100} x_n (100 - n))/100 \quad (3)$$

The emissions from a building are analogous with the light bulb example and therefore it appears entirely consistent to consider emissions from buildings in the same way.

Plots of the IPCC equation and the simplified PAS 2050 version are shown in Figure 6. The areas under the two curves are approximately equal and therefore for annual emissions over a 100 year assessment period both equations give approximately equal total emissions but can differ for emissions not occurring over the full period.

A limitation with both equations is that they apply only to CO_2 emissions and GHG's with different decay characteristics may not be well represented, although the consideration of CO_2 equivalence for other GHG's goes some way to addressing this issue.

Assuming equal emissions per year, the NPV of all emissions for a given period is again the area under the curve for that period multiplied by the annual emission. For periods 0 to 60 years and 0 to 100 years the NPVs are 76% and 56% of the unfactored emissions using the IPCC equation and 70% and 50% using the PAS 2050 equation.

For the purposes of this paper the IPCC equation is used.

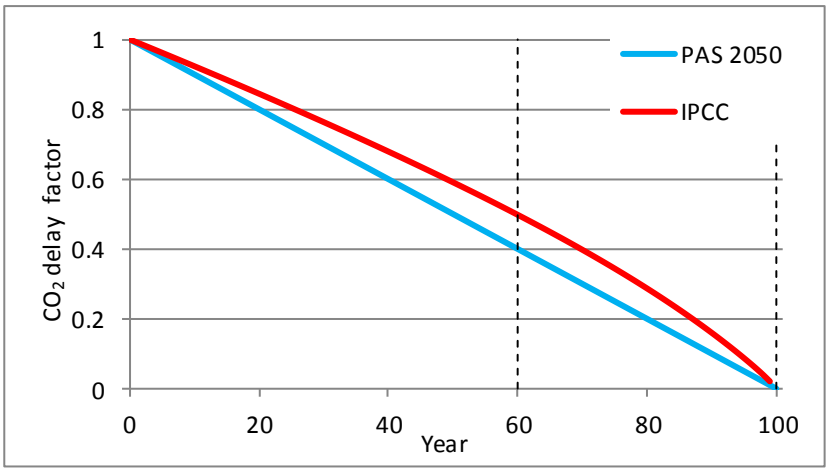

Fig.6: CO_2 delay factors

3. An overall time value of emissions

The overall time value of emissions can be calculated by first applying the decarb factor for the anticipated reductions in energy carbon intensity and energy demand due to energy efficiencies and behaviour change, followed by the decay factor allowing for the atmospheric decay of the resulting emissions, followed by the economic discount factor.

Figure 7 shows these three factors, together with the resulting combined factor and a proposed close fit curve.

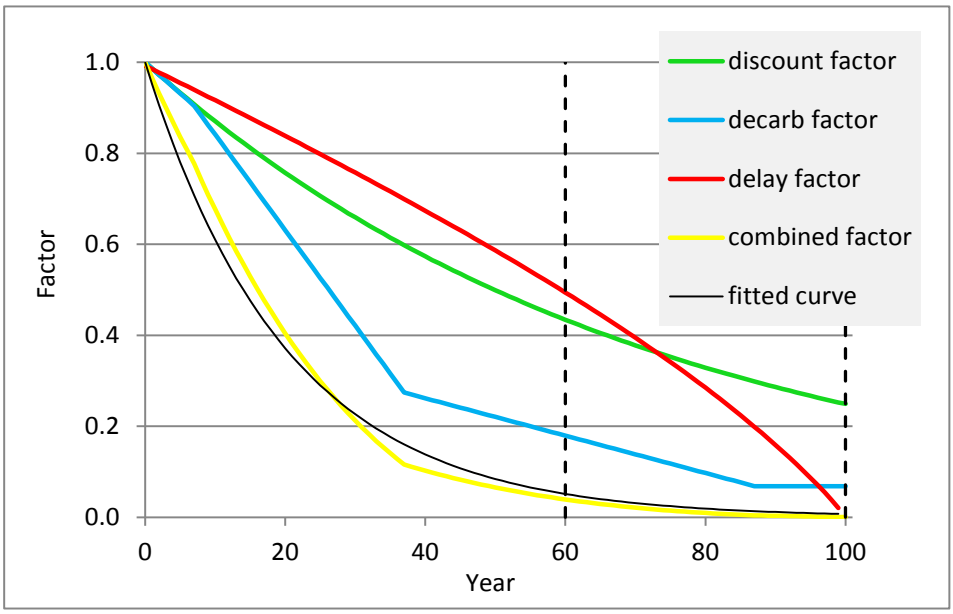

Fig.7: Combined factors for emissions occurring in the future

The close fit curve proposed here is represented by Equation 4

$$Weighting\ factor = \sum_{n=1}^{n} x_n e^{-0.0495n} \quad (4)$$

Where n is each year in which emissions occur and x is the proportion of total emissions occurring in any year n.

Assuming equal emissions per year, the overall NPV of all emissions for a given period is again the area under the combined fitted curve for that period multiplied by the annual emission. For periods 0 to 60 years and 0 to 100 years the overall NPVs are approximately 32% and 20% of the unfactored emissions.

4. Discussion

There seems a strong case for putting a time value on emissions from buildings. Reduction of carbon intensity of energy supply is a reality and there is already a precedent for the principle of delayed emissions in PAS 2050. The likely economic benefits of early reductions have been clearly stated [10], and the urgent need to make substantial early emissions cuts over the next two or three decades is now the mainstream view.

The proposed time value put forward for discussion and comment in this paper is described by Equation 4. It is suggested that a time value factor (TVF) of this type could be a useful tool for assessing and prioritising building options to achieve the most beneficial overall GHG emissions outcome to minimise climate change impacts.

Figure 8 shows a simplified building emission profile (cumulative) with and without time value factors. This is based on a 30%:70% life cycle emission ratio between unfactored Ec and Oc. Applying the combined TVF changes the ratio to 64%:36%, an almost complete reversal.

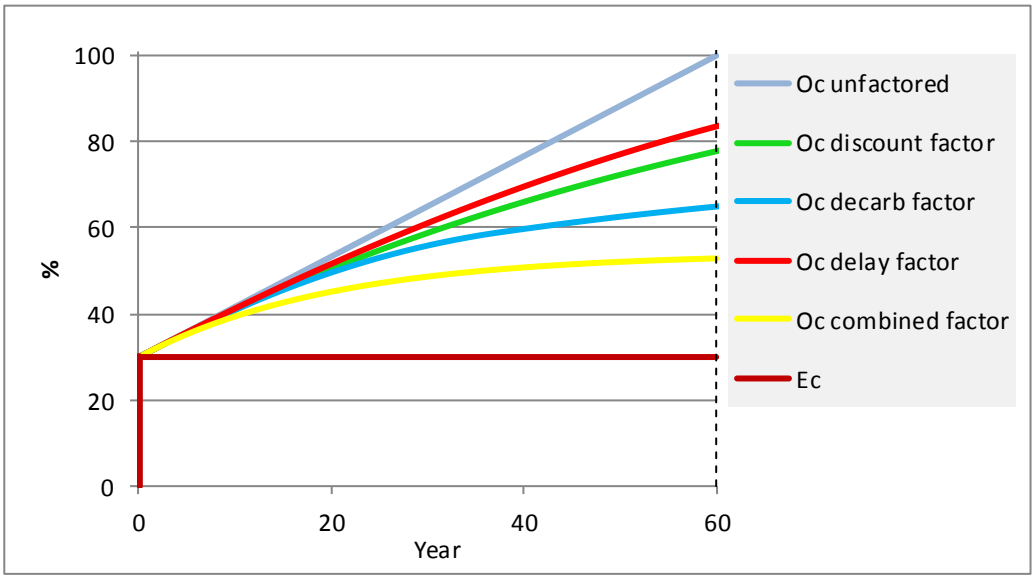

Fig.8: Typical building Ec and Oc unfactored and factored emission profiles over a 60 year service life

Table 1 shows the changes to the Ec:Oc ratio applying the separate TVFs and the final combined TVF for different unfactored ratios ranging from 10%:90% to 80%:20%.

Both the CO_2 and Decarb factors are themselves time dependant and would need to be updated over time.

The CO_2 factor is based on an atmospheric concentration of 378ppm, current at the time the Bern model was developed, but as atmospheric concentrations increase (the 400ppm level has recently been reached) up to the target maximum of 550ppm, the rate of decay may change.

The Decarb factor will need to be updated as the UK progresses down the carbon intensity curve.

Table 1: Unfactored and factored Ec:Oc ratios

Unfactored		Discount factor only		Delay factor only		Decarb factor only		Combined factor	
Ratio (%)		Ratio (%)		Ratio (%)		Ratio (%)		Ratio (%)	
Ec	Oc	Ec	Oc	*Ec*	Oc	Ec	Oc	Ec	Oc
10	90	14	86	13	87	19	81	26	74
20	80	27	73	25	75	34	66	44	56
30	70	39	61	36	64	47	53	57	43
40	60	50	50	47	53	58	42	68	32
50	50	60	40	57	43	67	33	76	24
60	40	69	31	66	34	76	24	82	18
70	30	77	23	75	25	83	17	88	12
80	20	86	14	84	16	89	11	93	7

5. Conclusions

It seems likely that substantial reductions in both Oc and Ec from new buildings will be required to meet the UK emissions targets.

The proposed time value equation could provide a useful tool for comparing different mitigation options giving benefits at different times during the building life cycle, for example when making comparisons between embodied and operational emissions.

A time value for emissions has implications for life cycle assessment methods used for evaluating embodied emissions for materials, products and complete buildings. Factored 'end of life' emissions have a much reduced influence and this suggests that 'cradle to grave' or 'cradle to cradle' assessments may give very similar results to 'cradle to site' assessments. If this is the case, embodied carbon calculations using very much simpler 'cradle to site' assessments could be justified.

When taken at face value, Oc usually appears to dominate and is the focus of reduction strategies. However, when appropriate allowances are made for future scenarios, reducing Ec is likely to be more beneficial, in terms of climate change, for most new buildings. Thus, giving higher priority to Ec reductions is likely to result in a bigger positive impact on climate change and mitigation costs.

The influence of structural design on the sustainability assessment of building constructions

Dipl.-Ing. Dr. Julia Maydl
Project assistant Sustainable Buildings
AEE – Institute for Sustainable Technologies
j.maydl@aee.at

Short Summary

The comparison of commonly used certification systems in Europe and the associated literature displays that an advanced consideration of structural design doesn't happen. Thereof the approach of implementing structural design in the assessment was defined as a main topic of this paper.

An evaluation tool was developed that is based on the structure of DGNB/ÖGNI and this allows evaluating construction details including building materials and fasteners. Content and system boundaries focus only on the technical quality of a construction. Essentially for the development of the assessment model was to ensure the applicability on a component level and to facilitate the evaluation of component layers and joining techniques. As part of the valuation of the model in practice three buildings of the Graz University of Technology have been analysed, evaluated and compared with each other. focus of the assessment have been aspects of maintenance, disassembly, separation and recycling.

The test revealed that the model allows both a detailed and a quick review. The weighting can be adjusted individually so that single component layers can be highlighted in view of their importance. The evaluation matrix can be used both as a decision support system for planers (designers), product manufactures and producers as well as implemented into the DGNB/ÖGNI certification system. For this purpose further development is still needed.

Keywords: sustainability, building evaluation, building certification, building construction, structural design

1. Introduction and background information

Recent discussions about the pros and cons of various methods of constructions are influenced by general principals of sustainable development – sustainable building. To harmonise the assessment of buildings in Europe, in 2004 the European Commission has placed an order with the mandate M350 to CEN to the "Development of horizontal standardised methods for the assessment of the integrated environmental performance of buildings". This European regulation will significantly influence the future planning, construction and operation of a building as well as its demolition. The basis for this is next to the environmental, economic and socio-cultural dimensions the consideration of technical and process-oriented levels of the entire life cycle of a building.

Political intensions led to the development of European standards and regulations regarding sustainability in the building and building material sector. At the same time certification systems all over the world were developed to react to the upcoming trend of building certifications. These systems treat different aspects and topics that make it difficult to compare them with each other. The technical evaluation of a building and/or the evaluation of the building construction are considered in none of the systems. This demand of action is responsible for the aim of this paper – the implementation of constructive design in an evaluation.

2. Objective of the project

In the last few years certification systems were developed that offer the possibility to compare buildings due to their sustainability. These systems provide however no guidance how to use them at an early stage of the planning and during planning.

The literature shows that a lot of research projects have dealt with the optimisation and the development of certification systems. The implementation of structural design is an aspect that has been avoided in the literature up to now. This is the main reason why this, especially for planning decisions, important topic is the focus of this paper.
Expected results are:

- evaluation tool that indicates and evaluates structural design due to sustainable aspects
- guidance for practical use
- to identify the need of addition of the chosen certification system
- evaluation of the assessment tool
- to identify opportunities for improvement and implementation

3. Certification systems

Since a few years a growing interest in “green buildings” and “certifications” has been existing. Nearly all member states of the European Union encourage the public to build “green”, environmentally acceptable and resource efficient buildings like passive houses or low energy houses.

Because of the recent demand a significant number of certification systems came up. These programs assess a building’s sustainability whereas certain topics like the quality of the construction are not considered. Most certification systems deal with energy consumption, emissions, life cycle costs, health and comfort. A missing transparency discourages owners and enterprises to order a certification. Common preconceptions associated with building certifications are that it is too ecological and that the effort is not related to the needs of the certification demanders.

The individual certification schemes are tailored to national standards and conditions. They differ in their complexity, their criteria for evaluation and the valuation methods used. Depending on whether it is an administrative building, a residential or industrial building, specially for different types of use developed system variants of the certification systems have to be considered. In recent years three certification systems have been established on the German real estate market (Austria, Germany, Switzerland):

- LEED
- BREEAM
- DGNB (Austria: ÖGNI)
-

The results out of a certification can be the base for future investment decisions. Following aspects determine which label is the most suitable evaluation system:

- availability and suitability of the evaluation tool
- considered criteria
- accordance of system contents with the wishes and objectives of the client
- establishment of the system on the market
- system’s adaptability
- cost for certification

If you evaluate the 3 most common certification systems, you can see that these systems differ not only in the number of their system variants but also feature different evaluation aspects. A detailed comparison of these three labels shows, that the rating categories and the assignment of criteria for each category are difficult to compare. BREEAM and LEED f.e dispose (distribute) ecological aspects to different rating categories whereas the DGNB/ÖGNI system deals with just one ecological category. Only a few aspects of the certification schemes are comparable to a certain

degree. This is another reason why it is nearly impossible to compare results of different certification systems with one another.

Table 1: Weighting of evaluation criteria for administrative and office buildings (own illustration based on [4])

evaluation aspects	BREEAM	LEED	DGNB
ecological aspects	58,5%	64,0%	22,5%
economic aspects	-	-	22,5%
social aspects	14,0%	14,5%	16,0%
functional aspects	5,0%	0,5%	6,5%
technical aspects	5,0%	-	22,5%
aspects of planning process	1,0%	2,0%	5,0%
aspects of construction process	7,0%	8,0%	3,0%
aspects of business procedures	4,0%	1,5%	2,0%
aspects of location	5,5%	9,5%	separate

The main topic in LEED deals with ecological aspects (64%), nearly the same can be seen in BREEAM (appr. 60% ecological aspects). DGNB has however a uniform weighting of evaluation criteria and considers technical aspects as well. One aspect they all have in common is their aim to develop tools to measure and evaluate the ecological quality of buildings.

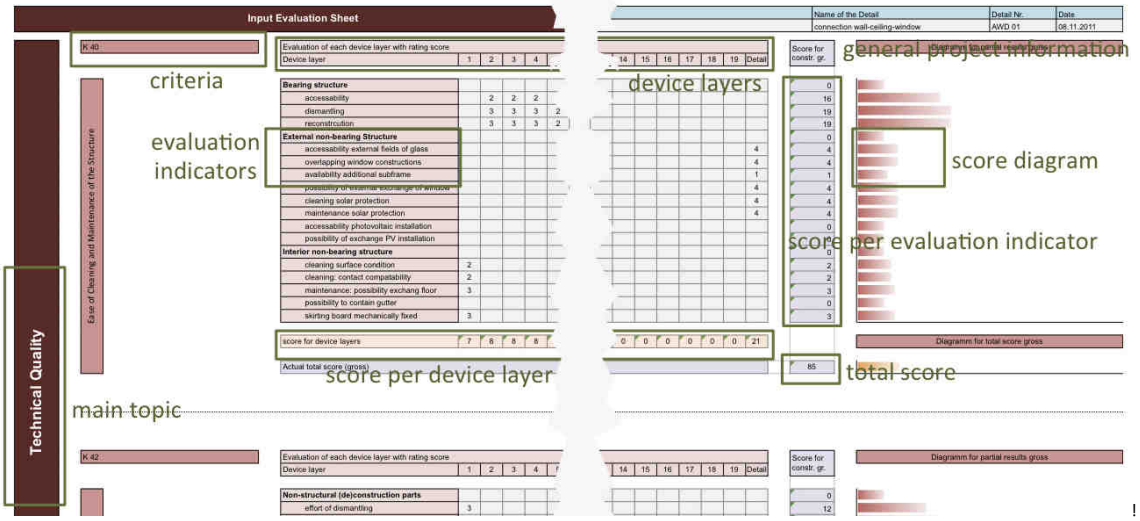
Sustainability has to be evaluated but ecological aspects are not the only topic to look at, although the main focus is apparently on this aspect. Sociocultural and functional aspects are taken into consideration, but with less intense. But there is an essential distinction between the DGNB system and other certification systems: the analyse of economic quality which is defined by the study of life cycle costs and conversion feasability. The associated conversion of value is not covered by standards yet.

Furthermore the analyse showed that the certification system DGNB is the only one out of the three considered systems which corresponds to the structure of the CEN/TC 350 and is compatible. It is a fact that – after closer examination of the 3 analysed systems LEED, BREEAM and DGNB – only the German system takes the technical features into account. Criteria such as sound insulation, fire protection and moisture are covered. The topics of maintenance, dismantling and recycling are discussed but regarding the building construction only on a superficial level. Certain indicators are only applicable to the building level, on component level other aspects have to be taken into consideration accordingly.

4. Model development

Before developing an evaluation model the most important decision was to choose a certification system that has to function as the base for the upcoming assessment tool. After the analysis of the most common certification systems on the German speaking market the German certification system DGNB was selected. On the one hand this system is the only one with an allusion to the European standard and the work of CEN/TC 350. On the other hand the chosen system deals not only with the triple bottom line, it covers also aspects regarding the technical and the process oriented quality. Furthermore there is no special emphasis on a certain topic, all categories are treated equally, with the exception of the process quality.

The development of the evaluation model needed a structured approach and started with the analysis of all 49 criteria (stand 2009), followed by the analysis of the 49 criteria regarding their relevance for building constructions. This means that their applicability on the construction itself was evaluated based on a simple yes/no-analysis. Additionally it was tried to find a definition for “relevance for building construction”, with the aim to identify new criteria for the evaluation of building constructions.



It became apparent, that it would be necessary to limit (qualify) the number of assessed criteria. During the selection of the evaluation criteria the idea was to avoid double evaluation. The attempt was to filter those criteria that are applicable on both, the component and the building level. Because they are mentioned in the general DGNB evaluation they are not taken into consideration for the upcoming evaluation matrix.

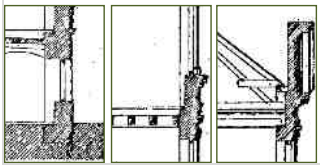
The aim of the dissertation was to evaluate building constructions on a technical level, a limitation of DGNB criteria K40 “Ease of Cleaning and Maintenance of the Structure“ and K42 “Ease of Deconstruction, Recycling, and Dismantling“ occurred. They were selected because they exhibit the closest reference to building constructions.

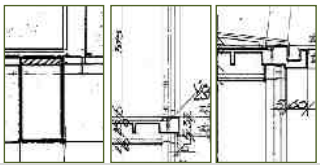
The try to define “relevance for building construction” generated new aspects that have not been considered in the actual DGNB system yet. On the one hand two new criteria emerged out of these, criterion K41a “design features” and K 41b “durability and robustness”. On the other hand the “old” criteria 40 and 42 were expanded and adapted with new evaluation indicators.

Right after the definition of the evaluation criteria the development of the evaluation matrix started. During this process it was decided to select a scoring system. The assessment and the scoring should be as simple as possible, that’s the reason for a scoring rate from 1 to 5 points. The next step was to develop the structure of the matrix, which should be as simple and clear as possible. For one criterion the matrix is exemplarily shown in table 2.

Table 2: Overview evaluation matrix criterion K40

As shown in the picture above the scoring scale varies between 1 to 5 points per evaluation indicator. The assessment is made – if possible – per each single device layer and is itemised for each layer. The weighting depends initially on the existing component layers (f.e. the construction consists of 5 device layers, therefore the criteria indicator get a weighting of 1/5). Basically there is the possibility to distinguish and weight individual component layers additionally in consideration of their importance. Using this assessment model to extend a certification system the weighting normally has to be predefined.





After the formal description of the model some starting points have to be described. Initially considerations about different maintenance scenarios regarding building constructions have been made. Certain reconstruction measures cannot be prevented and have to be scheduled and budgeted during the life cycle of a building. Thereby the existing joining technology in the construction has an enormous influence on the maintenance and is responsible for possible maintenance scenarios. Reacting to the entire life cycle of a building means not only considering the construction- and utilisation phase but to take a gander at the demolition (removal) and dismantling.

In the course of work the influence of structural design and class of age was reflected on the recycling management. For the pilot phase of the evaluation model it made sense to select demonstration buildings from different time periods. Additional considerations regarded following aspects: type of use of the building, building age, comparison and criteria and the needed documentation

5. Practical application

The developed evaluation system was tested due to its practicability on three existing buildings of the Graz University of Technology (see table 3). The three objects should be from different building periods and differ in their way of construction and their building materials. The thing they had to have in common was their utilisation: they are all administrative buildings mainly with office use. With relation to the DGNB system “office and administration buildings” it seemed useful to choose administrative alike buildings.

Table 3: Overview evaluated buildings of the Graz University of Technology

Main Building (AT)	Hydraulic Engineering Lab	Frank Stronach Institute
		
year of construction: 1884-1888 materials: bricks, natural stone, timber Building in Wilhelminian style typical: high ceilings, stukko	year of construction: 1960 materials: many different materials, prefabricated concrete elements typical: skeleton structure, flat roof, sandwich construction	year of construction: 2006 materials: reinforced concrete, steel, dry walls, many different materials, new technologies typical: open coverage type, glass facades
		

5.1 Building analysis

Before starting the evaluation with the developed assessment matrix certain preinvestigations on the buildings had to be done:

- Bill of quantities: a separation between the construction elements wall, ceiling, windows, doors and stairs and landing occurred. For each single device layer the mass was indicated and allocated to the shell construction or the fitout, whereby the relation is stated in %. This proportion should give information on the influence of a building period or construction design on the relation shell-construction and fitout.
- Detailed analysis: for each building three details were chosen for an detailed analysis: foundation and/or base, connection between exterior wall and ceiling including an existing window and roof
- detailed analysis I: each construction detail was analysed due to the building devices’ classification into a substance group (mineral, inorganic and metallic)
- detailed analysis II: the component layers of each construction detail were assessed due to their separability and recyclability. Additionally the disposal costs incurred were mentioned.

5.2 Evaluation of the model

The selected details mentioned before were evaluated and analysed based on the developed evaluation matrix. Therefore each detail with its component layers was recorded in the evaluation tool. After that it was possible to evaluate and assess each layer regarding the determined criteria, whereby the award of points took place on the basis of the new and reworked criteria lists with the defined scoring rate. Likewise the weighting was filled in, so that a sum of points is the result of the evaluation. For a better comparison and understanding a final summary of the results with the help of color-coded list was prepared for each detail. Afterwards the comparison of the buildings and their details occurred.

5.3 Comparison of the buildings

The three rated buildings were compared regarding the results obtained from the evaluation model. Besides a detailed analysis of the buildings a critical evaluation of the model should take place, in which the pros and cons are exposed and further development needs are determined.

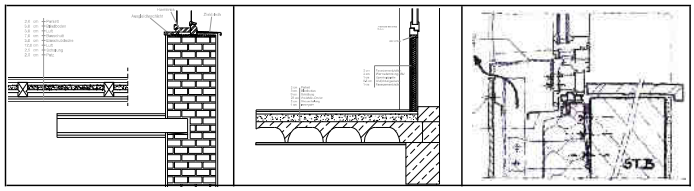
The assessment of individual structures should show that sustainability should not be limited to the building itself but must be considered in the construction details as well. Sustainability on a component level does not mean considering the building material is the only aspect, it requires the consideration of technical aspects in the same way. Recyclability and life cycle analysis is not only valid on the building level, but should also be at a detailed level.

Sustainability in the construction detail is in interaction with the sustainability of a building. Often detailed designs have to have certain aspects of sustainability so that the building itself can be classified as sustainable.
The evaluation was made due to two different aspects:

- comparison of the details
- comparison of the costs

5.3.1 Comparison of the details

The evaluation model was tested on three buildings by analysing three different detailed constructions with the assessment matrix. The comparison of the structural designs for each building is constituted by comparing the individual details for each building. This automatically leads to an assessment of the practicability of the evaluation model.



Possible fields of application are:

- useful addition to the German system DGNB
- comparison of alternatives for planning
- comparison of alternatives for system manufacturer

Table 4 shows exemplarily the comparison of the detail “connection exterior wall with the ceiling including a window”. The comparison is illustrated with a simplified color-code rating that shows the weakness in a construction.

In the present detail the accessibility f.e.– regarding the criteria – is not always possible. The disassembly of the construction requires in the detail of the AT less effort than the other constructions. One reason for this is the floor structure. The AT has a wooden beam ceiling where the component layers have been installed either by nails, plugs or loose connections. The solubility of the compounds makes the disassembly easy to perform. In the hydraulic engineering laboratory are even mainly nail joints, but less loosely installed component layers, which is responsible for the different scaling. The FSI however shows not releasable compounds whose removal is only possible through the destruction of the device layer.

Table 4: Comparison of the 3 buildings for a detail (connection ceiling-wall-window)

explanation total score

	24 - 19	points
	18 - 13	points
	12 - 7	points
	6 - 0	points

This comparison was done for all details, where the individual details of the “detail group” were compared to each other.

5.3.2 Comparison of costs

A holistic contemplation over the entire life cycle of a building means to cover also aspects about the recyclability and dismantling. Because of the fact, that a calculation for a demolition is quite difficult to undertake and mostly a cost estimation, it was decided not look at the whole demolition cost but to have a look at the disposal costs. Unfortunately there are no specific costs for simple dismantling steps available.

Therefore the disposal costs after the demolition were determined for each building. Already done measures regarding the mass and the individual component layers of each building simplified the listing of all existing building materials with their cubature and mass. That made it possible to calculate the disposal costs per m^3.

As assumed in the run-up the joining techniques, material diversity and building material selection have major influence on the disposal costs.

6. Critical evaluation of the model

The comparison of the buildings was not only meant as a comparative analysis, but also as a practical trial of the model. Pros and cons should get visible to think about further development.

A full and independent assessment regarding all aspects of sustainability is not possible with the developed model. It is considered as an additional tool to the German DGNB system. The focus in this work was the consideration of the technical quality on the component level, especially building constructions. Criteria that are part of the DGNB system and are relevant for a building construction were not considered, because a double evaluation of certain criteria should be avoided. But the tool was programmed in a way that the other qualities are linked and just have to be activated.

Following aspects can be pointed out as strengths:

- a deepened and detailed analysis is possible: all existing criteria, if relevant for the construction, can be evaluated
- rapid evaluation: it is possible, but not obligatory to assess all criteria, because
- no fixed maximum of points exists
- weighting is adaptable individually
- division in gross (without weighting) and netto points (with weighting)
- because of the programming in Excel a graphical display of the points is visible
- decision guidance for planers
- decision guidance for system manufacturer
- implementation into the DGNB system is basically possible, because it was the foundation of the evaluation model

In the course of evaluation it was possible to recognise concurrently some weaknesses:

- because of the programming in Excel a submission of criteria, points and weighting by hand is necessary
- the points to be awarded are not implemented in the tool, therefore the list with the criteria and their points is needed during the submission
- the submission by hand seems to afford a lot of effort at the first sight
- amount of sheets when printing the file
- bad definition for the German terminus “Tragkonstruktion” (supporting structure) in criteria K40

For a safe and more objective evaluation following points would need further development:

- eventually a new rating scale
- more specific explanations for the award for points for each criteria and
- eventually adding more criteria
- eventually adding the aspect “fitout” to criterion K40 with the same evaluation indicators as the aspect “supporting elements” in the same criterion
- implementation of criterion K41b “durability and robustness” into the tool
- implementation into the DGNB system

7. Conclusion

Out of the summarised view following conclusions regarding both the evaluation model as well as general aspects came up.

Use of the tool: the main field of application are these:

- additional tool for the German DGNB system
- decision aid for planers
- decision aid for system manufacturer

Basically the model can be used parallel to the planning stage for new buildings as well as during the renovation of existing buildings like f.e. for the comparison of alternatives. An advantage of the model is its flexibility – both a detailed and a rapid evaluation can be done. Now it is important to

develop tools for planers to implement sustainability in the building construction.

Content of the evaluation tool: device layers have different life spans – that is the reason why it is important to consider the different life ties in future planning and maintenance projects.

Dismantling: the demolition of a building is very difficult to calculate and often the announced costs are just estimation. In the future dismantling friendly constructions should make it possible to dismantle building components disposal-oriented and separate them varietal, whereby a dramatically increased added value out of the construction waste disposal can be earned. Basic requirement 7 of the upcoming Construction Product Regulation, after the transposition into national law, will force planers to consider the demolition and material disposal during the design. It has to be part of future planning.

Finally, it should be noted that the ultimate goal of sustainable building despite the highest demands on the assessment procedures should not be lost of sight: to leave a liveable built environment that can be returned to its original state at any time or that can be adapted to future requirement with the help of new technologies.

Short Summary

In this study, we develop an integrated endpoint-type LCA tool for the initial stage of housing design. In this part of the study, we adopt the Japanese version of Life-cycle Impact assessment based on Endpoint modeling (LIME2) and examine the associated assessment framework for the case of a detached house.

Keywords: life-cycle assessment; based on endpoint modeling; housing; initial stage of design; human health

1. Introduction

Life-cycle assessment (LCA) tools for buildings can be classified into two categories. In the first, the potential effects on a specific region of the global environment and on human health are assessed. For example, CO_2 emissions or NO_2/SO_2 emissions can be assessed through a life-cycle assessment. We define this as a characterization LCA tool. Characterization method was proposed in the early 1990's by a publication of Code of Practice (Consoli et al. 1993) by SETAC (The Society of Environmental Toxicology and Chemistry) and etc. There are previous characterization LCA tools for detached house in Japan which are "LCA tool for building that added assessment of resource circulation" by Architectural Institute of Japan and "Building Environment Assessment Tool (BEAT)-house" by Building Research Institute Incorporated Administrative Agency.

The other type combines the effects on a number of regions and yields a single overall index. We define this as an integrated LCA tool. The integrated LCA tool can be further classified into two categories: the problem comparison type, in which the importance of each region is represented by a weighting factor; and the endpoint type, in which the assessments of each region are consolidated at the endpoint level. Integrated method was proposed in the early 1990's by Eco-scarcity (Ahbe et al. 1990) in Switzerland and etc. The endpoint type was adopted by improved version of Eco-indicator (Goedkoop et al. 1999) in the late 1990s. Previous integrated problem-comparison-type LCA tool is "Comprehensive Assessment System for built Environment Efficiency (CASBEE)" developed by Japan Sustainable Building Consortium. However, there is no previous integrated endpoint-type LCA tool in Japan.

Characterization and integrated LCA tools have been previously developed for detached houses in Japan; however, there is a need for an integrated endpoint -type LCA tool , that could comprehensively assess the direct influence of building safety and comfort on residents, as well as the cost-effectiveness of buildings at a local or personal level. Such a tool has the potential to be used as a communication tool for architects and their clients to determine the direction of housing design in the initial stages. In this study, we develop an integrated endpoint-type LCA tool for the initial stage of housing design. In this part of the study, we adopt the Japanese version of Life-cycle Impact assessment based on Endpoint modeling (LIME2) and examine the associated assessment framework for a detached house.

2. Assessment framework

2.1 Protected objects

LIME2 is designed to reflect environmental ethics, and as such “Human Health,” “Biodiversity,” “Social Assets,” and “Primary Production” are defined as protected objects. Human Health and Biodi-versity are defined as the rights of human society and ecosystems to exist. Social Assets and Pri-mary Production are defined as essential items needed to maintain human society and ecosystems. Since users of this tool are residents, Primary Production is excluded as a protected object because it is considered to have a negligible influence on decision-making in housing specification. Since the required cost of housing (internal cost) is considered to have the greatest influence on decision-making in housing specification, “Intraregional Residual Cost,” which is the contribution to the local economy from the cost of the project, is defined as a protected object. Based on LIME2, the assessment elements for Human Health are death or non-lethal handicap and disease. Similarly, the assessment element for Biodiversity is extinction of a species. The assessment elements for Social Assets are limited elements that might have a direct influence on the housing site, ambient environment, and local society.

This proposed LCA tool considers existing earthquake risk management and human health risk assessment methods, such as disability-adjusted life years (DALY) proposed by the World Health Organization (WHO), and a function to estimate this is embedded in the method. DALY can estimate the decrease in lifespan resulting from harm to human health. However, it cannot estimate the increase in lifespan caused by improvements in human health. Incorporating improvements in human health into this tool will remain a challenge for the future.

2.2 Category endpoint

In this tool, it was assumed that the house and surrounding environment fulfils the Building Standards Act and other environmental standards. Thus, category endpoints are set for each protected object. The category endpoint for Biodiversity is terrestrial species because they are considered to be relatively strongly influenced by housing.

In accordance with the reasoning described in 2.1, the category endpoints for Social Assets are crops and marine products, as well as user cost and the carbon offset from CO_2 emissions trading. The user cost reflects that resources cannot be extracted in the future because they have already been used. The category endpoint for Intraregional Residual Cost is the rate of local production for local consumption. This evaluation method will be addressed in future studies and would analyze characteristics of the region, such as population size and the distribution of different industries, to yield the correct internal cost.

Among the many environmental elements and agents, the elements that influence buildings are sound, noise, vibration, sunshine, daylight, color, heat, air, humidity, water, radiation, fire, and force. Noise, sunshine, daylight, and fire are not included because of the assumptions made about the usage of housing in this tool. At this time, vibration, humidity, and water are also not included owing to insufficient evidence about their influence. Radiation is not included because it represents a highly special case. In regard to sound and color, there are established solutions and these fac-

tors are routinely considered by almost every architect in the initial stage of housing design. For these reasons, heat, air, and force are the selected elements considered in the initial design stage that affect human health and cost in the long term. The category endpoint for Human Health are symptoms and events related to these elements. In the future, evaluation of symptoms and events caused by the other elements will be added to the assessment framework.

2.3 Influence region

The influence region is set based on the category endpoint. Damage to Biodiversity is divided into chemical effects and physical effects: chemical effects are caused by exposure to harmful substances; physical effects are caused by physical changes to the habitat, which affect the ecosystem. In this tool, the influence regions considered for Biodiversity are land use, fossil-fuel consumption, consumption of forest resources, and waste, because they correspond to physical effects that directly arise from buildings.

The influence regions for Social Assets are additional fossil-fuel consumption and consumption of forest resources. Also, acidification is considered, which represents the deposition of acidifying materials that can affect forest and marine resources, and photochemical oxidants affecting the production of crops. Based on LIME2, the loss of social assets caused by landfill of waste is also included. Since CO_2 emissions trading is currently being practiced, financial profits and losses are also taken into consideration.

The influence regions for Human Health are thermal stress, heat shock, urban air pollution, photochemical oxidants, indoor air contamination, building movements, and domestic accidents. The assessment framework is shown in figure 1.

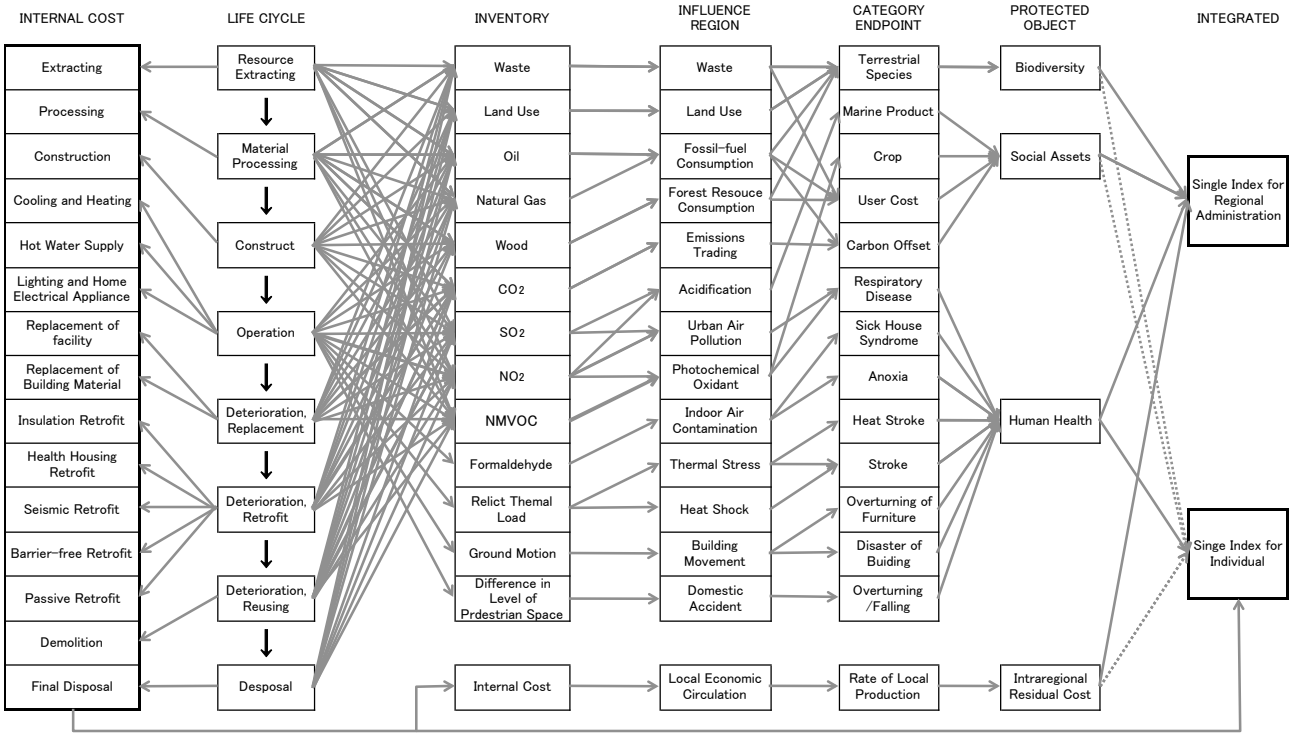

Figure 1: Assessment framework used in this study

3. Evaluation of assessment framework by case study

The cost was calculated for a case study using the assessment framework of LIME2 and the results were analyzed to examine the efficacy of the assessment framework.

3.1 Calculation model

The subject land is Akita city, Akita prefecture. With respect to land use, it was assumed that rice fields are transformed to land for buildings. The target families are a family of four with a husband, wife, and their daughter and their son (H1), and a family of two with an elderly husband and wife (H2). Both wives are full-time housewives. The average male and female life expectancies used were 79.59 years and 86.44 years, respectively. The assessment period was thirty years. The changes in household composition over thirty years are shown in table 1. The household incomes of the two families are taken from previous research and are based on the age of the husband (Ministry of Health, Labour and Welfare, 2010). The simulated housing types were C1, referred to as "Standard problem for house" (Utagawa, 1985), C2, which has thicker insulation than C1, and C3, which is an entirely air-conditioned house. The insulation efficiencies of C2 and C3 are the same. Specifications for each case and heights of furniture are shown in table 2. The heat source was heating oil and the heat source for hot water was city gas.

Table 1: Resident information

	H1	H2
Number of baths and showers	7 times/ person・week	7 times/ person・week
First year of assessment	Husband: 25 years old, Wife: 23 years old	Husband : 55 years old, Wife: 53 years old
Changes in household composition	A girl is born in the sixth year. A boy is born in the eighth year. The girl leaves the house in tthe 24th year. The boy leaves the house in tthe 26th year	Husband dies In the 26th year.

Table 2: Housing information for type of house

		C1	C2	C3
Insulation (thickness)	Ceiling	Glass wool 10K (65mm)	Glass wool 10K (200mm)	Glass wool 10K (200mm)

3.2 Assessments of ecosystem and social assets

3.2.1 Calculation method

Using LIME2, the amount of damage to the influence regions of the ecosystem and social assets were calculated. Each influence region and inventory is shown in table 2. With respect to mineral resource consumption, eco-toxicity, and eutrophication, it was difficult to acquire data on benzene, dioxin, copper, lead, nitrogen, and phosphorus, and it was decided that these could be safely ignored for normal housing. Therefore, mineral resource consumption, eco-toxicity, and eutrophication were not calculated in this study.

Table 3: Assessment framework of ecosystem and social assets

Influence region	Waste, Land Use, Forest Resouce Consumption, Fossil-fuel Consumption, Ozone Depletion, Global Warming, Acidification
Inventory	Waste, Land Use, Wood, Oil, Natural Gas, CFC, CO_2, SO_2, NO_2

1) Damage to ecosystem and social assets

Oil consumption was calculated from the heating load using a transient systems simulation program (TRNSYS). Schedules of cooling and heating were set using an automatic program for lifestyle scheduling (SCHEDULE). Natural gas consumption was estimated from the consumption of hot water using a previously reported formula (Sawachi, 1994). All natural gas was assumed to be composed of city gas, and the unit calorific value of city gas was taken as54.5MJ/kg. The unit calorific value of heating oil was45.9MJ/kg. The correspondence of heating oil to crude oil was 0.9L/L. The inventory quantities for waste (CFC, CO_2, NO_2, and $SO_{2)}$ were calculated using the detached house version of the LCA tool for buildings from the Architectural Institute of Japan. The quantities of material used for the foundations and building frame were calculated using a regression formula (Takayama, 2010); material quantities were estimated based on the "JUTAKUTOKUSYU" architectural magazine, and the regression formulae were derived based on this. The regression formulae are shown below.

Concrete: $y_c = 0.2073x_1 + 2.6164$ (1)
Reinforcing bar: $y_r = 6.5011\ x_1 - 153.47$ (2)
Lumber: $y_w = 0.0464x_2 - 0.1596$ (3)
y_c is concrete quantity, $y_{r\ i}$s reinforcing bar quantity, y_w is lumber quantity, x_1 is the ground floor space, x_2 is total floor space.

In LIME2, the inventory of land use is the product of the occupation time and occupation space. The occupation space was taken to be160.4 m^2,which is the average area of a detached house in Akita (Statistics Bureau, 2010). A formula for the amount of damage is shown below. The values of the damage coefficients were those from LIME2.

(Damage quantity) = (Damage coefficient) × (Inventory quantity) (4)

2) Internal cost

Costs of cooling and heating were converted from the cooling load and heating load calculated using TRNSYS. To determine the costs of hot-water supply and lighting, the energy consumption was calculated using a previously reported formula (Sawachi, 1994), and these were converted to costs. The costs of city gas and heating oil were three yen/MJ and 22 yen/kWh for electrical power. The costs associated with materials manufacturing, construction, and disposal were calculated using the detached house version of the LCA tool for buildings from the Architectural Institute of Japan.

3.2.2 Results and discussion

Figure 2 shows that the costs of ozone depletion and global warming were small in the ecosystem and social assets. Since the costs of acidification waste, land use, fossil-fuel consumption, and consumption of forest resources are measurable values, it is important that they be included in the assessment framework.

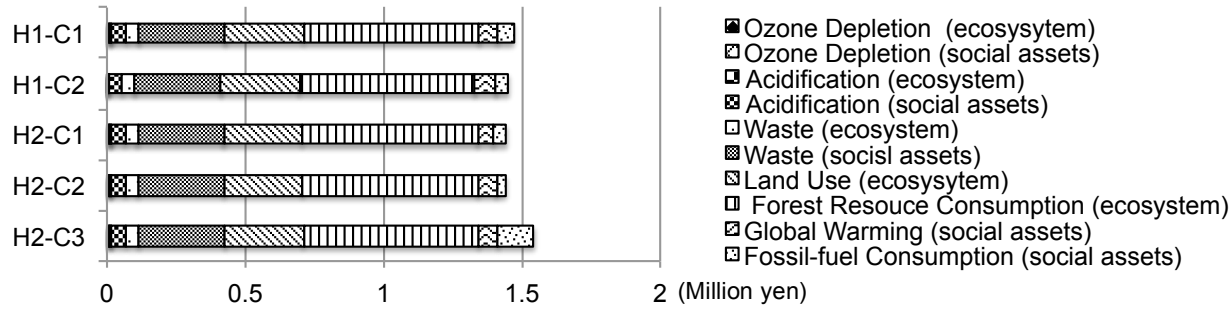

Figure 2: Cost of damage to ecosystem and social assets

3.3 Assessments of human health

3.3.1 Calculation method

Based on LIME2, the amount of damage to the influence regions of human health were calculated. Each influence region and each inventory is shown in table 3. As it is difficult to calculate the damage associated with heat shock, it was not calculated in this study. Similarly, it is difficult to calculate the amount of damage caused by heat stroke and stroke. In this study, these were replaced with heat stress and cold stress, and the amount of damage associated with these was calculated. The calculation of damage arising from heat stroke and stroke will be addressed in the future. With regard to damage caused by building moving, this is calculated as the amount of human suffering caused by toppling furniture. The methods for calculating damage caused by disasters and domestic accidents is discussed, but these damages were not calculated in this study.

Table 4: Assessment framework of human health

Influence region	Ozone Depleting, Global Warming,Urban Air Pollution, Indoor Air Contamination, Thermal Stress, Building Movement
Inventory	CO_2, CFC, NO_2, SO_2, Formaldehyde, Relict Themal Load, Ground Motion

As in LIME2, the conversion of DALY to yen was 14.7 million yen/DALY, which represents the cost of a reduction in life expectancy. This value does not include medical costs, and this will be addressed in future studies.

1) Damage quantities caused by indoor air contamination and thermal stress

The cost of sick house syndrome was calculated using a previously reported formula (Narita, et al., 2005). The release rate of formaldehyde from floors is 20 $\mu g/m^2h$ and from walls/ceilings is 5 $\mu g/m^2h$. The thermal load was calculated using TRNSYS. The annual indoor temperature was calculated, and the DALY resulting from heat stress and cold stress was calculated using a previously reported formula (Honda, et al., 1998), in which the dependent variable is outdoor temperature. The indoor temperature was modified to reflect improvements in the indoor temperature; the modified formula is shown below.

(Modified daily maximum temperature) =
(Daily maximum temperature) × (Mean indoor temperature of measured house) / (Mean indoor temperature of standard house) (5)

2) Damage caused by building moving

This damage was estimated by earthquake intensity and indoor condition. DALY was calculated according to the damage level, as shown below.

DALY = YLL + YDL (6)
YLL = N × L (7)
YDL = I × DW × L' (8)

YLL is the number of years lost by premature death, YDL is the number of healthy years lost by disability, N is the number of deaths, L is the average life expectancy at the age of death, I is the number of accidents, DW is the injury weight, L' is the average number of years until being cured or until death.
In this study, the formula for calculating the damage caused by toppling furniture is shown below.

YLL' = N × L ×(Mortality rate) × (Earthquake occurrence probability) (9)
YDL' = I × DW × L' × (Injury rate) × (Earthquake occurrence probability) (10)

YLL' is the number of years lost by premature death caused by toppling furniture, YDL' is the number of healthy years lost by disability caused by toppling furniture.

The mortality rate and injury rate were calculated using previously reported formulae (Midorikawa, et al., 1995;Okada, et al., 2003). The injury weight of DALY is taken from the Abbreviated Injury Scale (AIS). Median values of injury weights were used as representative values.

A long-term assessment published by the Headquarters for Earthquake Research Promotion was consulted to estimate the probability of furniture toppling. The potential earthquake is off the coast of Akita prefecture (magnitude of 7.5) on the eastern margin of the Japan Sea. It was assumed that the earthquake occurrence probability is the Poisson distribution for which the average occurrence interval is over a thousand years. The expected earthquake intensity is a seismic intensity of six or lower (Akita prefecture disaster prevention council, 2011). The annual earthquake occurrence probability is 0.1%, and accumulates annually. The amount of damage accounts for the household composition in the year it is calculated The most damage is the result of toppling furniture.

3.3.2 Results and discussion

Figure 3 shows that the amount of damage associated with toppling furniture is highest in the case of H1. A high probability of deadly wounding and a 100% toppling rate of furniture was used. In the future, this method must be reviewed. Since the damage associated with ozone depletion and global warning were small, we believe that the assessment framework for human health in this tool is effective.

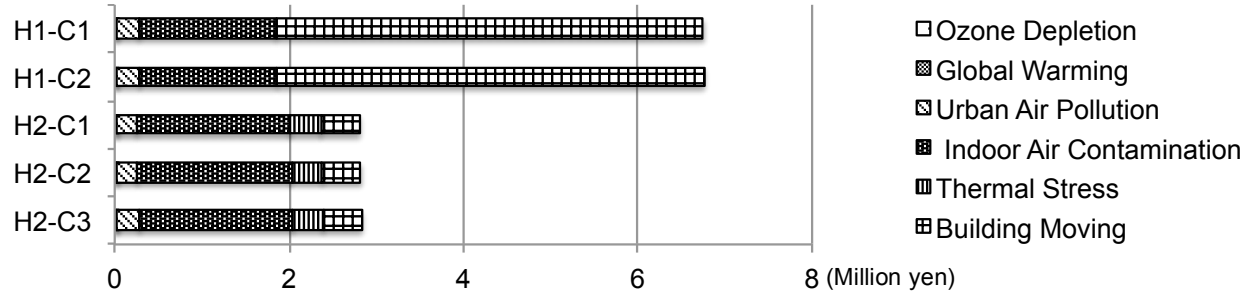

Figure 3: Cost of damage to human health

3.4 Full-cost assessment

A result of the full-cost assessment is shown in figure 4. Before the basic design, multiple housing types can be considered to decide on the best option. This figure shows that operational costs are highest. It is thought that a full-cost assessment would encourage the client to choose housing using the cost-effectiveness estimate from the LCA.

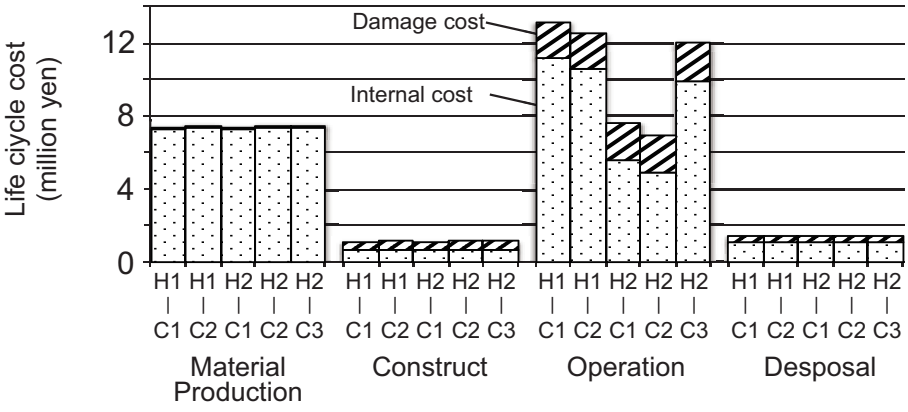

Figure 4: Full-cost assessment

4. Conclusion

In this part of the study, we have proposed a new housing LCA tool that can comprehensively assess potential damage to residents, and we have tested the assessment framework in this tool. We carried out a case study to confirm the utility of this tool. According to the case study, the overall trend of the results showed that operational costs were the highest costs.

Aspects of the study that should be improved further include the methods used to calculate toppling furniture and medical costs. Based on the results presented here, we will develop a prototype of this tool and assess its applicability.

Dr. Sabine Lindner
Manager, Consumer & Environmental Affairs
PlasticsEurope Germany
sabine.lindner@
plasticseurope.org

Summary

The contribution of plastic materials and plastic products towards more sustainable buildings is covered from a full life cycle perspective, taking into account the three pillars of sustainable development.

Environmental impacts of plastics manufacturing are weighed against contributions of plastic products in saving scarce resources (energy, water, etc.). Economic aspects are discussed in terms of cost effectiveness, based on the “Total Cost of Ownership”, i.e. life cycle costs borne by the owner/user. Last but not least, a few social considerations are developed, such as health and safety of workers and users, convenience afforded to the user, and the possibilities of creating innovative products.

Keywords: Plastic; life-cycle; eco-profile; insulation; windows; piping

1. Introduction

Buildings are responsible for roughly 40% of the EU’s energy consumption and greenhouse gas emissions [1]. Improving the energy efficiency of new and old buildings is therefore one of the keys to tackling climate change and saving resources. Around 70% of the energy used in buildings is due to space heating and cooling. With new legislation on the energy performance of buildings adopted in 2010, the European Union has set targets for all new buildings to be “nearly zero energy” by 2021 (2019 for new public buildings). However, even in 2050 most buildings will have been built before 2010. An ambitious programme of energy-efficient renovation of existing buildings is therefore needed as well. This will require a huge effort, in which all construction materials and products will have a role to play.

Energy is only one aspect of sustainability, albeit a paramount one. Both the construction of new buildings and the renovation and operation of existing ones must take into account all aspects of sustainability, i.e. energy and raw materials consumption or savings during all phases of the life cycle of the building, as well as other environmental impacts; cost effectiveness; health and safety of the workers involved throughout the value chain and of the users; the convenience afforded to the user, to name only a few.

This paper will present the contribution plastic products can bring to this array of goals.

2. Applications of plastics in buildings

Building and construction is the second largest market for plastic products in the EU, after packaging. More than 20 % of the plastics raw materials go into these long life applications, a yearly amount close to 10 million tonnes. The average working life of all plastics applications in construction is 35 years [2]. Use of plastics in construction has been growing rapidly: in 2002, it represented less than 7 million tonnes. Compared to other materials the total weight of plastics used is still small, but they make a significant contribution to a large variety of applications.

Plastics are widely used in thermal insulation products, window frames, shutters, piping systems, electric and telecommunication cables and cable ducts, roofing membranes, floor coverings, interior decoration, fitted furniture, fencing and decking. Photovoltaic cells and solar panels also rely on plastics.

3. Environmental benefits and impacts

3.1 Life cycle perspective and data availability

PlasticsEurope was the first industry organisation publishing detailed environmental data, and Life Cycle Thinking (LCT) remains a guiding principle of advocacy. By means of a comprehensive view on production systems and product life cycles, the LCT approach enhances the understanding of product benefits and burdens. Under its former APME name, PlasticsEurope first launched the Eco-profile Programme almost 20 years ago. Today, there are more than 70 Eco-profile reports available for free, covering all major plastic materials as well as monomers. Eco-profiles are detailed reports on product or material specific environmental impacts. Based on European industry averages of the respective polymer production technologies, those published by PlasticsEurope include detailed environmental datasets – the so-called life cycle inventory (LCI) – and environmental key performance indicators. Their scope is from cradle (extraction of raw materials) to gate (un-compounded precursors or resins) [3]

By providing publicly available data about the environmental performance of plastics production, the Eco-profile programme not only responds to stakeholder needs but also fosters continuous improvement, innovation and competitiveness among plastic manufacturers. Downstream users, such as plastics converters and brand owners, employ eco-profiles as an invaluable data resource

because they are reliable building blocks for LCA studies. In line with current trends and the standards developed by CEN TC 350, Environmental Product Declarations are now being derived from these eco-profiles, and are also made freely available.

3.2 Energy

Efficient heat insulation of roofs, walls, cellars and windows is a key element for reducing energy consumption. In addition, solar panels and cells further reduce energy use. Plastic products contribute to the solutions in all these applications. Combining thermal insulation with triple glazed windows can for example reduce energy consumption by up to 80%. Each year over 80 million new windows are needed in Europe. If high standard window frames were installed all over Europe tomorrow, this would eliminate the need for five large power stations [4]

All insulation materials, including plastics, have strong and weaker features; no material is best in all building applications and hence one should always choose the one best adapted to a specific need. Any insulation level can be achieved with the appropriate product thickness; it is therefore more useful to assess the respective merits of various materials on their other properties, some of which described later. At this stage, the discussion can focus merely on the energy saved over the life time of a product compared to the energy used for its production. In the case of plastic insulation, the ratio exceeds 200:1 [5].

3.3 Efficiency in the use of other resources

Raw materials, water and land use have to be considered. The plastic materials used to produce insulation products and windows are still to a very large extent based on non-renewable raw materials. Ethylene, the chemical feedstock most plastics derive from, can however be produced from natural sources. This route is not developed yet for economic reasons as well as because doing so with the current technology would hugely strain land resources. It will benefit from technology progress as production of bio-fuels and chemical building blocks is shifting to natural sources which do not compete with food production.

The current production route of plastic insulation already uses 83 % less water and 99 % less land than the production of stone wool, for example. [6]

Many plastics are very good insulators, affording the desired insulation performance with thinner products than most competing materials (fig. 3). This allows optimum use of space, an essential feature especially when renovating existing buildings.

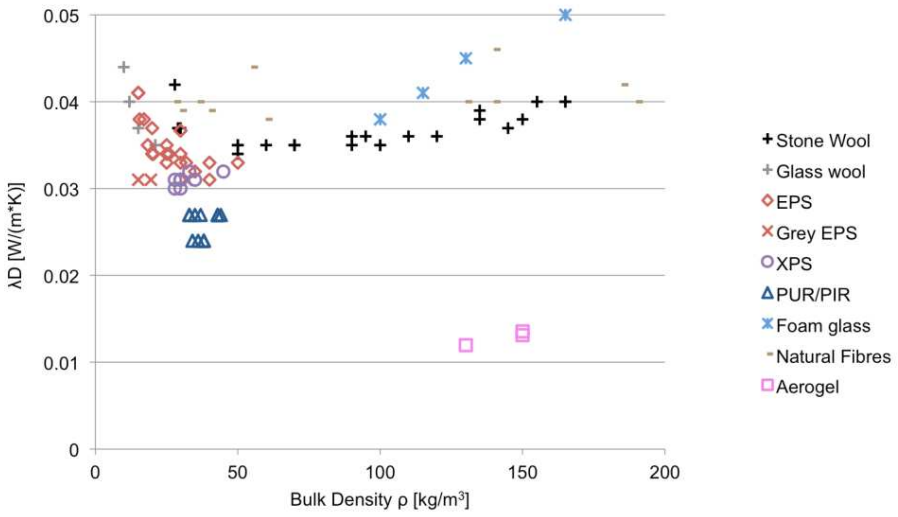

Fig. 3: Thermal conductivity versus density of products on the European market 2011, courtesy Büro für Umweltchemie, Zürich

Plastic insulation materials are also highly durable, require no maintenance and perform at the same high level over the whole life of the building. Needless to say, durability is the most effective way to save resources. Plastic pipes are durable, corrosion-free and smooth, thereby reducing water losses and deposits. The latter in turn decreases pumping energy or, in the case of sewers, avoids over-designing. Typically a 300 mm ID PVC slimed sewer pipe laid at 1:200 running full bore will achieve 90 l/s compared to 69 l/s for a 300mm ID concrete pipe [7].

3.4 End of life

Plastic waste is a minor component of B&C waste. A recent report estimated it ranges between 0.1 % and 2% of construction and demolition waste arising in the EU [8]. An earlier report estimated it at 0.7 % [2]. This is because a large proportion of plastics used in the construction industry have an intended life of many decades, and because use of plastics is a relatively recent phenomenon. Hence the amounts and proportion of plastic waste will obviously be growing in future, requiring careful consideration of the various options.

As construction products are usually tailored to a specific building, re-use of discarded products is in general not an option. Recycling is then the next preferred solution in the waste hierarchy of the EU Waste Framework Directive. However recycling of plastics from C&D waste is facing a series of obstacles [9]:

- Cost, time and space needed for dismantling and separation, especially in urban areas
- Lack of synergy between local/regional authorities and the private sector
- Low cost and/or poor control of landfilling
- Lack of sorting/crushing plants
- Cross-contamination and general mixing of materials

For example, most insulation products, either plastic or from other materials, are difficult to recycle, as these products are often contaminated by other materials, rendering recycling costly or impractical. On the other hand, plastic profiles and pipes are easier to collect and recycle. Almost 105,000t of window profiles and other profiles, as well as 24,000 t of pipes were recycled in 2011 as a part of the schemes funded by the PVC industry [10].

Across the EU-27 plus Norway and Switzerland, more than half of plastics building and construction waste is now being diverted from landfill through a combination of recycling and energy recovery. It is interesting to mention that trends show strong disparities in recovery rates from country to country. Germany provides an example of what can be achieved with the right infrastructure and regulations in place, recovering nearly all of its plastic building and construction waste while Southern Mediterranean countries send most of it to landfill. The overall recovery of plastic waste in the building and construction sector shows a positive trend, improving from 56.2% in 2010 to 57.6% in 2011.

Fig. 4: Treatment of building/construction plastic waste

4. Economic efficiency

4.1 Total Cost of Ownership (TCO) methodology

The TCO methodology is an economic analysis focused on the customer of a product. It adds up the costs borne by the owner or user over the entire life of the product: purchase, transport, installation, use, maintenance, dismounting and end-of-life management. All data are adjusted to net present value, thereby allowing a comparison of different products.

4.2 Application to some construction products

The TCO methodology has been applied to window profiles, water mains and sewage pipes, as well as flooring, as available and used in Germany and in Italy [11]. Compared to wood and aluminium windows, PVC plastic has the higher net present value over a 30 years lifecycle. The TCO of plastic pipes is the lowest among the materials commonly used, i.e. ductile iron for water mains, clay or concrete for sewage pipes. The TCO differences range between 19 and 52 %. Installation cost is the main cause of such differences for sewage pipes. In the case of water mains, the difference is due to purchase and use costs, the latter being related to a lower pumping energy required by plastic pipes as deposit formation is much less prevalent.

5. Social aspects

5.1 Safety

5.1.1 Reaction to fire

The European classification for reaction to fire is harmonized at EU level and is described in EN 13501-1. On the other hand, national fire regulations specify the allowed product classes for any given category of building (e.g. hospital, public building, high- or low-rise residential). All construction products placed on the market have to comply with these regulations. To achieve the intended level of safety, the application and the whole concept of a building are taken into account. Concerning the application of insulation materials for example, requirements are not only focusing on the classification of the products but also where they are used and how they are applied.

Plastics are combustible, like many natural construction products such as wood, and hence in some specific conditions it is necessary to add flame retardants in plastic products in order to achieve the required level of fire safety. The plastic industry is fully confident that EU legislations (e.g. REACH), as well as the institutions in charge of implementing these legislations, ensure the appropriate levels of consumer and environmental protection. Appropriately designed plastic products can reach fire classifications up to B.

5.1.2 Safety of workers during production and installation

Plastic raw materials are produced by large chemical companies in highly regulated conditions. The safety record of the European petrochemical industry is one of the best among all industry sectors. The weight of the products per functional unit is an important factor determining the level of occupational health risk further down the chain. Heavier products put a higher stress on the body of the worker. For example the insulation of a flat roof with 25 cm of stone wool weighs about 45 kg/m^2. An equivalent insulation with XPS or EPS is about 10 times lighter. Handling safety also relates to certain physical properties of the materials that affect the degree of care that has to be taken during installation in order to assure the durability of the materials or in order to prevent damages. Rigid insulation materials for instance are more difficult to handle than flexible ones since they require more attention in order to prevent gaps between the insulation boards and the building structure. Rigid materials are also more prone to deformation due to differences in temperatures and humidity, which requires also special care during installation. The flexibility of plastic products renders installation easier and safer than many traditional solutions.

5.2 Health/hygiene

5.2.1 Indoor air quality

Indoor air quality (IAQ) is the focus of increased attention, as natural air flows are more and more restricted in order to save energy. Appropriate ventilation is necessary to preserve health and comfort. IAQ related burden of disease (BoD) was analysed in a recent report from the European Commission. The main causes of BoD are combustion particles, building dampness, volatile organic compounds (VOC), radon and carbon monoxide. VOCs account for about 8 % of the total BoD. The main contributors of VOCs are paints and furniture. An assessment of the key sources of exposure concluded that building materials account for about 0.2 % of the total burden [12].

Most plastic construction products do not contain VOCs, and/or are shielded by a layer of e.g. plaster. The few that may emit VOCs into indoor air include flooring, decorative ceiling or wall covering products. These products are tested for emissions, for instance under the German AgBB scheme.

5.2.2 Maintenance and housekeeping

Plastic products have generally smooth surfaces which are easy to clean. They require neither painting/varnishing, nor chemical cleaning. This contributes to lowering the exposure of workers and occupants to potentially hazardous chemicals, as well as emissions to the environment. Easy cleaning also helps maintaining a high level of hygiene at home and, even more relevant, in health care facilities, schools and buildings open to the public.

5.3 Convenience, choice and innovation

Durability, minimum maintenance needs and easy cleaning as mentioned above are major contributors to the convenience of users.

The large variety of plastic materials affords a wide choice of solutions for many uses. They also give much playing room to architects and designers.

Plastics are still a young material and one can be confident that future developments will continue. The future is difficult to predict, but some possibilities might include:

- Transparent photovoltaic cells printed onto plastic films as window glazing bringing about high-efficiency, power-generating windows
- The resistance to corrosion, light weight and strength of fibre-reinforced plastics composites will enable the construction of durable load bearing concrete structures.

6. Conclusion

The sustainability criteria discussed in this paper overlap to a large extent with those used by building certification and rating systems such as e.g. BREEAM (UK), LEED (US), HQE (France), and DGNB (Germany). Rating systems based on a broad spectrum of environmental, economic and social criteria, and offering a more holistic view than single criteria systems (such as carbon footprint for example), should be welcomed, provided that they are based on an assessment of the entire life cycle of the building and of its components, and that they follow the principle of risk assessments rather than discriminating substances solely on the basis of hazard. Eco-labels should follow the same principles in order to convey meaningful information to the consumers.

This holistic view may appear complicated, but it is the only one capable of correctly assessing buildings, their components, and the materials they are made of. The diversity and complexity of the building industry requires such a broad perspective. Its environmental, economic and social importance deserves the effort.

Short Summary

Following EN 15978 [1], the informative module D allows crediting a building for the recycling potential of its materials and the exported energy. Whereas the relevance of this module has largely been associated with the environmental assessment of metals so far, it is not clear to what extent module D is relevant in the life cycle assessment (LCA) of buildings. In this paper a building renovation case study is considered to investigate and discuss the implications of including module D in a building LCA.

The environmental impacts of the building elements and materials are analysed using a cradle-to-grave LCA, including module D. The impacts related to the different life cycle stages are compared to each other and discussed in relation to the input and output materials. The results initiate a discussion on the controversial module D and illustrate the potential effects of this module compared to the rest of the life cycle.

Keywords: Life Cycle Analysis (LCA); Recycling; Module D; Renovation; Environmental Assessment; Building LCA; LCA Methodology; Cradle to Grave; System Boundary

1. Introduction

The consideration of recycling aspects in life cycle assessment (LCA) has been a point of discussion for several years. In general there are two contrasting approaches to account for recycling in LCA: (1) the recycled content approach, which considers the benefits of recycling at the input side of the life cycle and (2) the end of life recycling approach, which accounts for the benefits of recycling at the output side of the life cycle [2].

According to the European standards concerning the sustainability of construction works EN 15804 [3] and EN 15978 [1], a building's life cycle information is organized along three major life cycle stages: (A) the product and construction process stage, (B) the use stage and (C) the end of life stage. The system boundary at the end of the life cycle is set where outputs have reached the "end-of-waste" state, leading to the recycled content approach. However, for the building assessment information, the standard identifies an additional optional life cycle stage (D) describing the benefits and loads beyond the building life cycle. This stage, also called module D, allows crediting a building for the recycling potential of its materials or the exported energy. The calculation of module D thus allows using the end-of-life recycling approach.

The consideration of module D is argued to be important for metals [2], but it is not clear to what

extent this approach impacts the results for building LCA's. Moreover, the consideration of module D appears to be straightforward for certain product LCA's (e.g. metals), but the complexity increases when performing a building LCA. In this paper a building renovation case study is considered to investigate and discuss the implications of including module D in an LCA for buildings.

2. Case study

The renovation of a 4-storey high multi-family house located in Seraing, a city in the Liège agglomeration (Belgium), is analysed for this study. The building includes 3 apartments and a commercial space and has been renovated using industrial products claimed to be suitable for environmental friendly renovation. A deep renovation is pursued in order to meet the current needs and standards in terms of comfort, space and energy requirements.

The existing building was composed of brick walls (without thermal insulation) and a sloped roof with ceramic tiles (see Fig. 1). The main structure of walls and floors are preserved during the renovation. Due to city regulations, external insulation of the façade is not possible. As a result, the external walls are insulated from the inside, using a system wall with a metal structure, filled with mineral wool and covered with gypsum plaster boards. The original street façades are preserved and the façades of the new top floor and south side are covered with metal sheeting. All windows and doors are replaced and new interior walls are assembled using a dry wall system composed of a metal frame structure and gypsum plaster boards. The entire roof structure is removed and replaced with a steel structure and steel roof covering in order to provide a useable living space on the third floor (see Fig. 1). On the south side of the building, a new building annex is constructed to create an additional bedroom for each apartment.

As the renovation project includes quite some materials that are recyclable, the benefits and loads beyond the building life cycle (module D) are calculated in the LCA in order to illustrate the potential effects of this module compared to the rest of the life cycle.

Fig. 1: Case study: Multi-family house in Seraing with renovated steel roof, walls insulated from the inside and annex on south side of the building. Representation of the old situation (left) and the renovated situation (middle and right)

3. Methodological approach

LCA is a technique to assess the environmental impact of a product throughout its life cycle, from raw material extraction, via production and use phases to waste management. It is a scientific approach, broadly applied in practice and used to improve the environmental performance of industrial applications. Following the methodological framework defined in the ISO14040 standard on life cycle assessment [4,5] an LCA approach consists of 4 major steps: (1) the goal and scope definition, (2) the inventory of data, (3) the impact assessment and (4) the interpretation of results. The harmonised European standards EN 15804 [3] and EN 15978 [1] on the sustainability of construction works, describe the methodology and calculation methods to be used for the

environmental assessment of building materials and complete buildings. This study is performed according to the principles of ISO 14040 and the European standards [1,3].

3.1 Goal and system boundaries

The aim of this study is to evaluate the environmental impact related to specific retrofitting actions performed during the renovation of a building in Seraing and to discuss the relevance of including module D in a building LCA. The functional unit is a 4-storey high multi-family house with three living units and a commercial space, a total floor area of 280 m² and a reference service life of 60 years.

The LCA is a *'cradle-to-grave LCA including module D'*, with consideration of the 'product stage', 'construction process stage', 'use stage', 'end of life stage' (EOL) and the 'benefits and loads beyond the system boundary' as defined in *Table 1* and described in EN 15978 [1]. For materials going to recycling, the system boundary between the system under study and the system that will use the waste is set at the gate of the sorting plant. This means that all subsequent processes (transport to recycling facility and recycling process itself) are allocated to the product that will use the secondary material.

Table 1: Overview of life cycle stages considered in the LCA, according to EN15978 [1]

Product stage	A1-3	Production of new materials
Construction process stage	A4	Transport of new materials
	A5	Installation of new materials
Use stage	B4	Replacements: Disposal of materials that need to be replaced and production, transport and installation of the new materials
	B6	Operational energy use of building-integrated technical systems, which are covered by the Energy Performance of Buildings Directive
End of Life stage	C1-4	Demolition process, transport to the treatment facility, impact of EOL treatment and final disposal
Benefits and loads beyond the system boundary	D	Reuse-, Recovery-, Recycling- potential

Following EN 15978 [1], the informative module D declares the potential loads and benefits of secondary material, secondary fuel or recovered energy leaving the product system. This module is primarily intended to describe in a transparent way the potential benefits of avoided future use of primary materials and fuels – and loads associated with the recycling and recovery processes.

In this study, module D reports on the loads and benefits of:

- the recycling potential of materials
- exported energy generated by photovoltaic panels.

Materials for energy recovery (e.g. through incinerations) are not considered because of the lack of data available on the efficiency of waste incineration installations in Belgium. As a result, the impact of materials being incinerated is fully allocated to the building life cycle (within the system boundary).

The disposal of materials and equipment removed as part of the refurbishment is not taken into consideration because the impacts of these existing materials and equipment have already been accounted for in their previous life cycle. Only the structural elements which will last for another life cycle are retained during the renovation process, but these do not generate impacts within the current LCA.

3.2 Life cycle inventory (LCI)

3.2.1 Generic data and use of scenarios

The LCA is modelled using Simapro software. The considered building system can be broken down into a certain number of unit processes related to the production, transportation, construction and EOL of building materials and to the use of energy for heating, ventilation, ... For the collection of inputs and outputs related to these unit processes generic data is used from the ecoinvent database v.2.2 [6], harmonized with the Belgian/European energy mix.
The ecoinvent database contains LCI datasets for the production of various common building materials (cradle to gate LCI data = impacts from material extraction, transport to the production site, production process and infrastructure), and separate datasets for the different disposal options (incineration, landfill or recycling), as well as for various transportation modes (different types of trucks, train, boat,). Transport distances and waste treatment processes are based on specific scenarios, representative for the Belgian situation.

For the transport of the materials to the construction site and the waste treatment processes at the end of life, the study makes use of the scenarios established within the Flemish study OVAM MMG [7]. These scenarios describe the typical transport distances, routes and transportation modes for different product material groups. For the EOL scenarios, it is assumed that all demolition waste is transported to a collection point (e.g. sorting plant, crushing facility first, scrap yard) and is then redistributed amongst the various waste treatment options.

3.2.2 Recycling potential

Potential benefits or avoided loads related to recycling, reuse and energy recovery can be based on a specific scenario which is consistent with any other scenario for “waste” processing and is based on current average technology or practice [3]. The recycling scenarios considered for this study are represented in *Table 2*. For materials recycled in a closed loop (such as steel), any secondary materials used as inputs for the system are subtracted from the secondary material leaving the system at the end of life, in order to avoid double counting and calculate the net impacts for the net output flow. Recycled content is based on average current production technologies. Recycling rates for each product are determined based on the EOL scenarios.

Table 2: Scenarios used to determine the recycling potential at the end-of-waste point (to be declared in informative module D)

Material to be recycled	**Secondary material**
Steel	Secondary steel (closed loop)
Concrete, screed,	Secondary granulates for roadwork (open loop)
Concrete blocks, bricks, facing tiles,	Secondary granulates for roadwork (open loop)
Untreated sawn timber, wooden boards (MDF, OSB), parquet	Wood chips (open loop)
Interior plaster (crushed together with concrete granulates)	Secondary granulated for roadwork (open loop)
Facing tiles, ceramic wall and floor tiles,	Secondary granulated for roadwork (open loop)
PE-foil, vapour barrier,	Secondary PE granulates (open loop)
Gypsum plaster board	Gypsum plaster (open loop)
Aluminium in window frames	Secondary aluminium (closed loop)
Glass	Glass cullets (closed loop)

3.2.3 Quantification of the building

A material inventory was assembled based on drawings and the actual composition of the renovated building. These quantities represent the net amounts of materials and do not account for the losses that occur during transport, handling, or installation. The inventory considers all new materials used in the building, with the exception of materials for the water drainage and the exterior stairs.
Technical installations for heating and ventilation (boilers, radiators, photovoltaic panels, ducts, fans,), sanitary installations (kitchen and bathroom) and electrical installations (wiring, lighting,) are excluded from the study.

The life cycle of the building renovation is set to 60 years for the analysis. Building elements with a shorter life span (like windows or gypsum plaster boards) are considered to be replaced during this period. Assumptions regarding the probable service life of the materials and components are based on standard values used in the ecoinvent database v2.2 [6] and existing LCA tools, as well as values from literature [e.g. 8,9].

3.3 Life cycle impact assessment (LCIA)

After an analysis of different impact assessment methodologies [10,11], we opted to interpret the LCI results using the ReCiPe method [12]. This method makes use of the state of the art LCIA methodologies and it enables to present the results both at midpoint and endpoint level - thus allowing to quantify various environmental indicators (each with their proper unit) as well as to determine a global environmental score (expressed in points) after a process of normalization, grouping and weighting. The higher the score, the larger the environmental impact. Even though the ISO and EN standards do not recommend the weighting and aggregating of different impact categories it allows for an easier comparison and interpretation of the results.

As recommended by the author of the ReCiPe method, the present study makes use of the version ReCiPe endpoint Hierarchist method (Europe, average), which is based on the most common policy principles with regards to time-frame and other issues [12]. When discussing the “impact” of a material or building element in this paper, this refers to the single score (of aggregated impact indicators) unless when specified otherwise.

4. Results

First, we discuss the environmental impact of the total building over its considered life cycle stages. In the subsequent sections, these results will be broken down according to the different building elements and discussed for the different life cycle stages.

4.1 Total impact per life cycle stage

Fig. 2 shows the results of the full cradle-to-grave analysis, including module D, of the total building renovation case. The impact related to the energy use over the building’s considered service life (60 years) clearly dominates and represents about 80% of the building’s total life cycle impact. Within this energy use, the largest impact is related to the use of energy for heating. The energy gains from energy generated by the photovoltaic cells are reported in module D, but seem to be insignificant.

The impact of the materials introduced for the retrofitting works is organised according to the different life cycle stages: production, transport, construction, replacement, end of life, and recycling potential (Fig. 2). The largest material impacts result from the production stage. Next, the impacts resulting from module D and the replacements are in the same order of magnitude. Finally, the impacts related to transport, construction and end of life are negligible compared to the other life cycle stages.

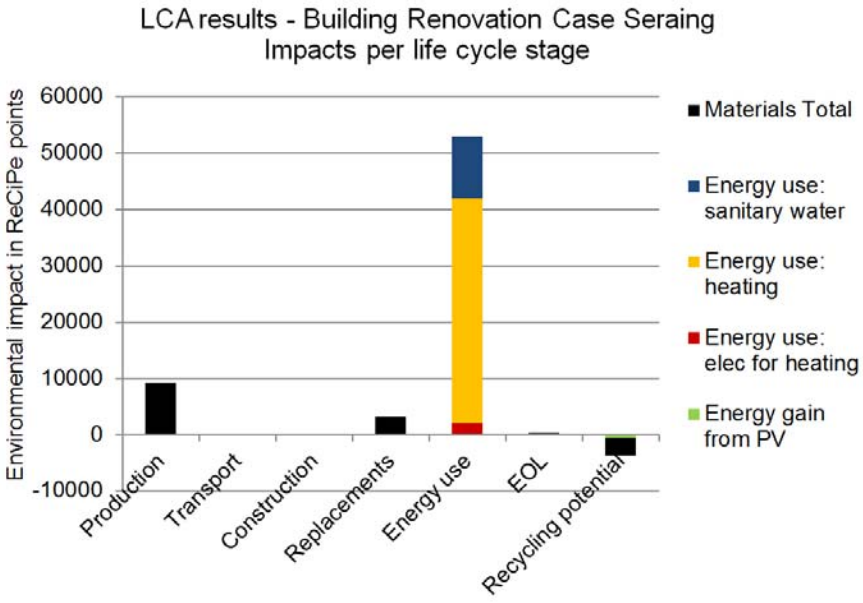

Fig. 2: Impacts of the total building renovation case per life cycle stage, including module D.

4.2 Production, installation and EOL of materials

When excluding the impacts of the energy use during the use phase, the results can be evaluated per building element (Fig. 3). The highest environmental impact among the different building elements is related to the materials for the roof and intermediate floors. Also the exterior walls, interior walls and windows and doors have a considerable impact.

ROOF - The environmental impact of the roof is mainly related to the production of low-alloyed construction steel (66% of the total impact). 10% of the impact for the roof can be allocated to the use of timber and 8% to the use of mineral wool.

INTERMEDIATE FLOORS - About 43% of the environmental impact of the intermediate floors originates from the parquet used for the finishing layer. An investigation of the different environmental indicators shows that the environmental impact of these hardwood floors is mainly linked to the environmental indicator ‘Agricultural Land Use’. It should be noted that no scientific consensus exist concerning this indicator and that these results thus should be considered within the proper context. The other relevant impacts of the intermediate floors can be linked to the oriented strand board (14%), the mineral wool (11%), the gypsum fibre board (9%) and the gypsum plaster board (6%).

EXTERIOR WALLS - The environmental impact of the exterior walls results from a number of different materials: the hollow concrete block walls (19%), the facing bricks (18%), the mineral wool used to insulate the main building (10%), the PUR rigid foam board used to insulate the annex (10%) and the steel used to cover the south façade and the annex (8%).

INTERIOR WALLS - The largest impact of the interior walls is related to the use of ceramic wall tiles in the bathroom (35%). The construction steel used in two new supporting beams determines the impact for 28%. The gypsum plaster board (17%), mineral wool (6%) and galvanised steel used for the supporting structure of the interior walls (metal frame) (5%) represent smaller portions of the impact.

WINDOWS - The impact of the windows can in large (78%) be related to the life cycle of the aluminium frames.

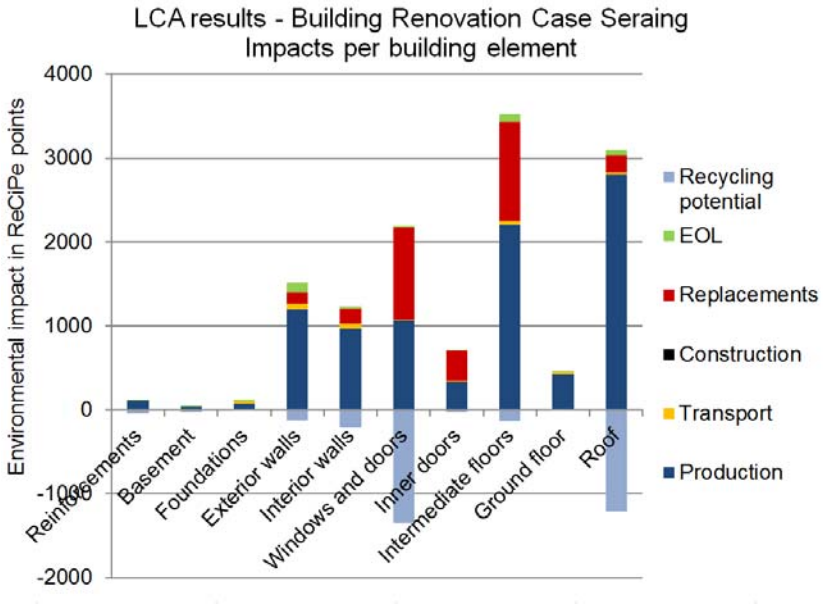

Fig. 3: Environmental impact of the materials over their life cycle, according to the different building elements, with indication of recycling potential (module D).

4.3 Replacements of materials

Fig. 3 shows that the impact of the replacements is significant for the windows and doors, which are replaced once during the considered life cycle. Also the replacements of the wooden floors after 30 years have a substantial impact. The impact of replacements in the interior walls will be limited as the gypsum panels are replaced after 30 years, but the metal studs and insulation are supposed to remain in place.

Most of the materials used for the building envelope (exterior walls and roof) do not have to be replaced during the reference service life. Consequently, the initial impact of the materials dominates the material impact for most building elements. However, we should note that the study does not account for repairs or partial replacements during the life time, which implies that the calculated impact is slightly underestimated.

4.4 Module D

The recycling potential of the materials and their associated environmental loads and benefits were modelled according to the scenarios described in *Table 2*. Materials with a recycling potential used within the current building are mainly: steel (recycled into steel), concrete or bricks (recycled into granulates) and untreated wood (recycled into wood chips).

The environmental impacts related to the recycling potential (module D) are represented in Fig. 3 as negative impacts and can be compared to the impacts related to the other life cycles. This shows that the potential benefits from recycling the materials are considerably high for both the roof and the windows and doors. For the roof, 98% of the avoided impacts are related to the high use of steel, where 95% up to 99% is recycled into new steel (see Fig. 4a for network diagram). Also for the windows, the majority of the avoided impacts can be linked to the high recyclability of aluminium (98% of module D impacts). The high recyclability of the glass panes (with 70% recycling rate) represents only a small part of the module D impact (see Fig. 4b for network diagram).

The impacts reported in module D for the other building elements are rather small (Fig. 3) because of the non or low recyclability of the materials (e.g. mineral wool, gypsum board), or because of the low benefits related to the recycling process (e.g. concrete, bricks). For the exterior and interior

walls, the potential benefits in module D can be linked to the use of steel for structural purposes (supporting beams and metal frame for dry wall system). In the intermediate floorings, the module D impact is related to the recyclability of the hard wood floors into wood chips.

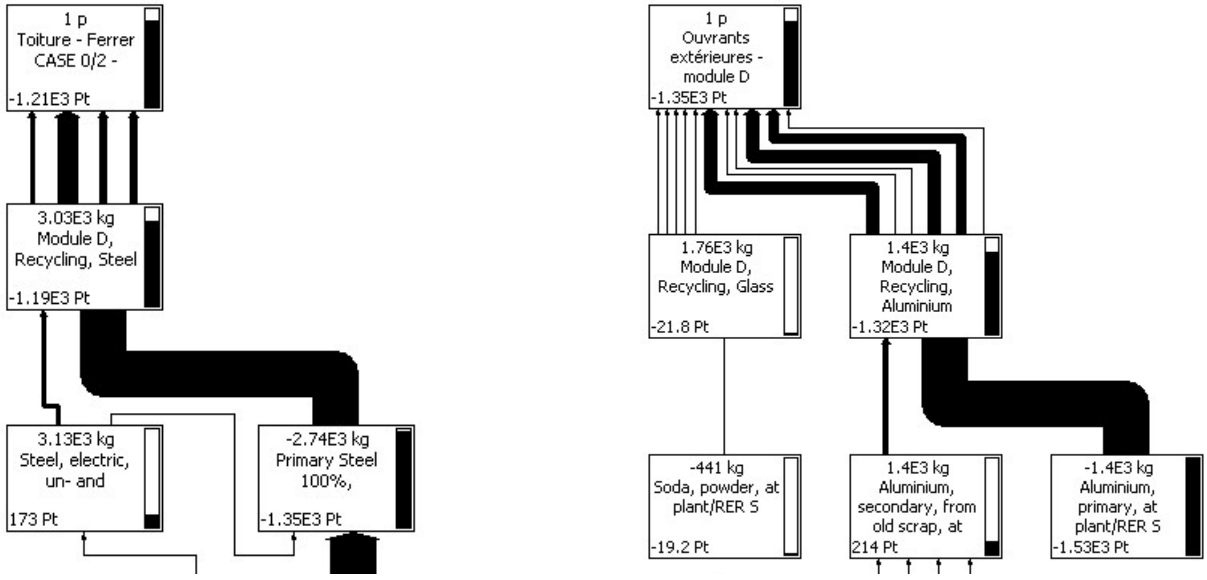

Fig. 4: Network diagram illustrating the materials representing the major impacts in module D for (a) the roof and (b) the windows and doors.

5. Discussion

5.1 Dominance of use phase

Comparing the environmental impacts generated over the different life cycle stages, the LCA results reveal that the highest environmental impacts are related to the energy use during the occupancy phase of the building. This is in line with several other building LCA studies, which illustrate that the building occupation phase is the most important stage in terms of environmental impacts - especially for conventional buildings - and that these impacts can mainly be related to the heating demand [e.g.13-15]. The results of this study confirm that the initiatives to perform better from an environmental point of view, should first be considered from the point of view of reduction of energy during the use phase. Alternative energy production systems, as well as higher insulation levels might lead to a decrease of the building's overall environmental impact.

However, it should be noted that the relatively high importance of the use phase compared to the impact of the materials is also largely related to the fact that it concerns a renovation project: besides the limitations in terms of thermal performance (e.g. thermal bridges, air tightness), only a limited amount of new materials are being added to the renovated building. Consequently, relatively seen, the impact of the energy during the use phase is likely to be higher for a renovation project than for a new construction.

5.2 Relevance of module D

The results of this case study analysis suggest that the consideration of module D at building level can be significant: the module D impacts are of the same order of magnitude as the impacts of the replacements, and are significantly larger that the impacts related to the transport, construction and EOL of the materials. This suggests that, even though module D is stated to be optional, it can provide some relevant additional information concerning the recycling of materials at the end of life.

However, it should be noted that the case considered for this study contains a lot of metals: the roof is composed of steel beams and a steel covering, part of the façade is covered in metal, metal

profiles are used in the dry wall system and the window frames are aluminium. Whereas the large amount of recyclable materials was partially the incentive for calculating module D in this LCA study, the results also reveal that the potential benefits reported in module D are strongly - or even almost strictly - related to the use of metals. This confirms the relevance of considering module D for metals [1] but makes it hard to discuss the relevance for other building materials. It seems obvious that materials with low recycling rates (like PE) do not show in the module D impacts. However, it is surprising that certain materials with high recycling rates (like glass or concrete) are hardly visible in module D.

Typical Belgian buildings usually use large amounts bricks and concrete materials with high recycling rates (around 95%). In the present case only a small amount of these materials is considered for the LCA as the majority of walls is preserved during the renovation. As a consequence it is hard to value the relevance of module D for these materials at the scale of the building based on this study.
Nevertheless, at the material level, the LCA of the bricks and concrete materials used in this study shows a rather small contribution to module D, which appears to be in the same order of magnitude as the impacts of the transport and EOL life cycle stages. The small module D impacts can be explained by the fact that bricks and concrete are considered to be down cycled into secondary granulates to be used for roadwork (common practice in Belgium). As a result, their avoided impacts relate to the mining and crushing of primary granulates. The latter process is far less energy and resource consuming than the production process of the concrete or bricks themselves and therefore will not outweigh the impact related to the production phase. Thus materials with high recycling rates do not necessarily relate to high (avoided) impacts in module D.

In general, one should be conscious of the fact that the impacts reported in module D do not tell the complete story about a material's potential beyond the system boundary. Whereas the module D impact might be relatively small for materials like concrete or bricks, it reveals nothing about issues like avoidance (or production) of waste or market demand for recycled materials. Future research on the specific implications of calculating module D for different material types could provide further insights in the actual relevance of incorporating module D in building LCA's.

6. Conclusions

Comparing the environmental impacts generated over the different life cycle stages, the LCA results reveal that the highest environmental impacts are related to the energy use during the occupancy phase of the building. However, for buildings with a better thermal performance (such as passive houses or nearly zero energy buildings) and for new constructions (with a larger of amount of materials used for the building), the relative importance of the use phase will become smaller and the decisions taken at material level will become more significant.

The present study reveals that the consideration of module D in a building LCA is possible and can be relevant. It provides additional information on the potential of materials beyond the building's life cycle and can represent a significant part of the total building impact. For the presented case, the impacts related to module D are larger than those related to transportation, construction and end of life. However, the case also shows that the impacts being reported in module D are strongly related to the use of metals in the building. Based on this study, we can state that module D will show a considerable impact for buildings containing a large amount of metals, but these results cannot be generalized to other buildings without further investigation. Research on the recycling impacts of different types of materials is desirable to get a more holistic view on the value of module D at building scale.

Short Summary

Most existing real estate portfolio management systems lay their focus on tangible assessment criteria, leaving the value of a building for a corporation in terms of user satisfaction or support of the core business aside. Therefore M.O.O.CON developed a holistic portfolio management system which enables the user to base portfolio decisions on an analysis of all organizational, technical and economical factors. This leads to feasible allocated resources on refurbishment projects that support achieving an organization's goals. The early planning phases of sustainable refurbishment projects are efficiently supported by assessing life cycle costing parameters for project alternatives. This method was successfully adopted from the federal province of Vorarlberg, which holds more than 120 buildings within their portfolio.

Keywords: Portfolio management, sustainable refurbishment, corporate, life cycle costing

1. Introduction

While enthusiastic self-imposed code of practices as well as EU directives (EPBD – energy performance of buildings directive) demand that Austrian federal states and municipalities apply high modernization standards when refurbishing their existing building stock, public administration faces a wide array of challenges [1][2].
Considering budgetary limits of federal states and governments, a four step methodology was developed that helps public administration to successfully tackle energy efficient retrofitting projects within their existing building portfolio while focusing on a rational and transparent decision making process.
This work presents a method that allows policy makers to first evaluate their existing building stock and identify leverage points before heading into complex and costly refurbishment projects. Stated procedure, which ought to be implemented in accordance with public officials, follows four steps:

1. Developing Criteria for portfolio evaluation
2. Evaluating the existing building stock
3. Compilation of specific strategy for each object
4. Initiating sustainable refurbishment project based on specific object strategy and analysis of project's life cycle costs

2. Methodology

Ever increasing competition and the long-term capital commitment connected to real estate have changed the perspective of which corporate real estate is viewed today. While corporate buildings used to be considered as passive capital, they are nowadays understood as assets which can be enhanced in value [3]. This has led to the question of how a portfolio consisting of various objects which differ in nature can be structured best.
Most existing portfolio management tools were developed for large property funds, thereby focusing on tangible assessment criteria such as earning capacity or technical conditions.

Public administration and municipalities, on the other hand, which also act as tenant, do have great interest in evaluating their building stock with a broader but objective method.
For this reason, M.O.O.CON developed a portfolio management system which takes all organizational, technical and economic criteria into account which suit the client's specifications and needs regarding its building stock.

2.1 Developing Criteria for portfolio evaluation

In a first step the corporate objectives for real estate are levied and documented in structured interviews. Based on these objectives and common systems for object- and service strategies (e.g. certification systems), the assessment criteria which are relevant for the user are determined.
These criteria are then clustered for specific object groups: office buildings, schools, housing et cetera.
Generic criteria for all building clusters sum up the complete set of criteria for evaluation. Figure 1 demonstrates the systematic approach of deriving the object strategy from evaluated buildings and leading to a portfolio strategy.
While developing criteria intangible factors such as user satisfaction or core business enhancement are relevant and need to be considered for these kinds of stakeholders.

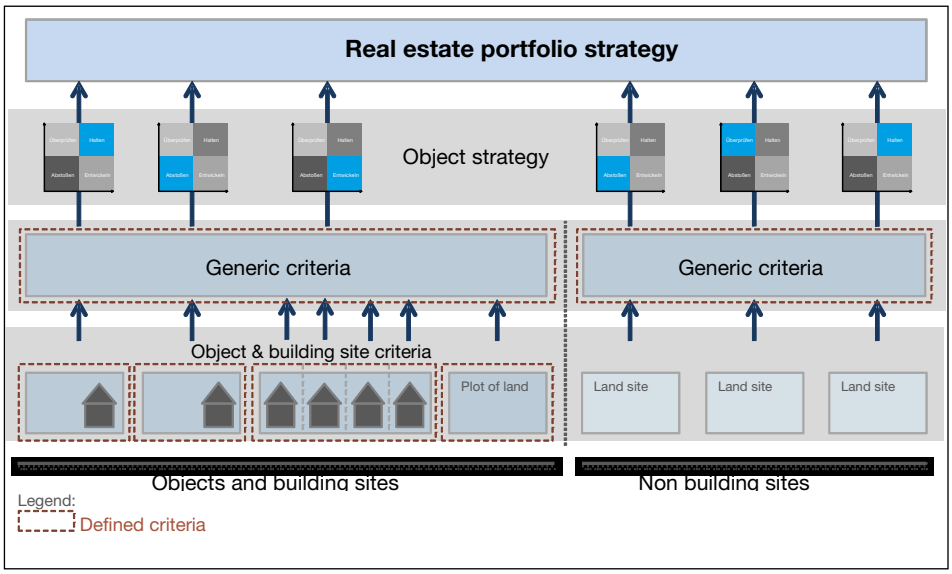

Figure 1 Systematic approach for a heterogeneous portfolio

2.2 Evaluating the existing building stock – Status quo

M.O.O.CONs portfolio management system focuses on the holistic analysis and strategy development of real estate portfolios. The basis of this analysis is represented by the portfolio model which contains assessment criteria that reflect the quality of each particular building. Each of the developed criteria can be assigned an evaluation weight, providing the possibility to

influence how much one criterion contributes to the final result (see figure 2).

Furthermore, each developed criterion will be assigned its weight for the evaluation. Subsequently, the grades will be awarded for each particular building and criterion. The combined weights and grades are then converted into the overall-grades for the building or the sub-categories.
The additional factors which influence strategic decisions (generic criteria) are then determined in a further step.

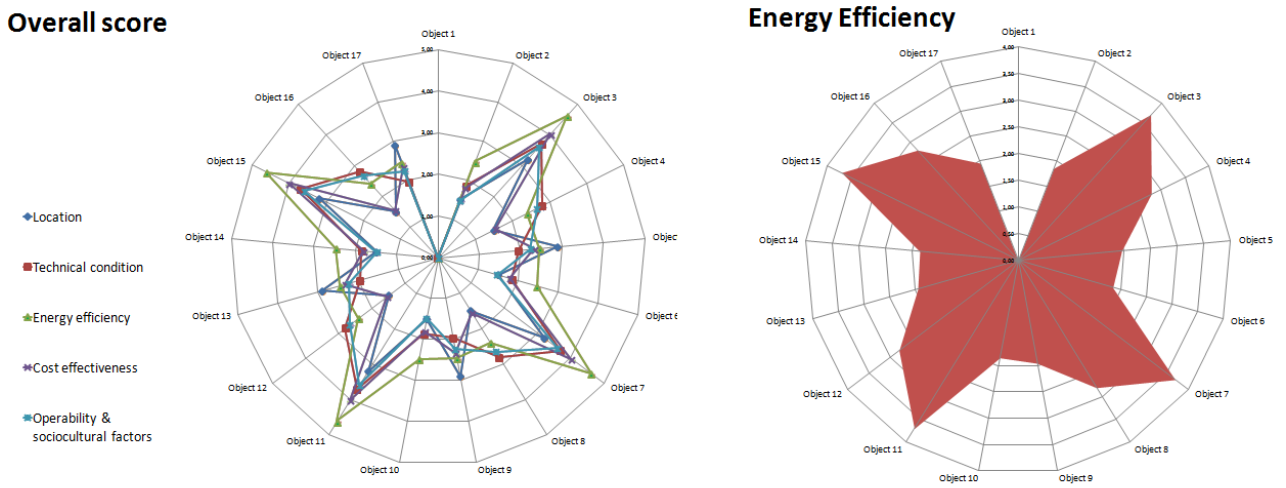

Figure 2 Evaluation of a portfolio with seventeen objects

2.3 Compilation of specific strategy for: each property and object

For the actual assessment of each object, grades are given for each weighted criterion. Based on the grades awarded and the assigned weight, a final grade can be calculated for the total object or the assessed sub-categories:

1. Location
2. Technical quality
3. Energy
4. Economical quality
5. Functional/socio-cultural quality

The visualization of the results for each assessed criterion, the sub-categories and the overall grade for each building in form of graphs enable the system user to identify outliers or pitfalls easily.

In addition to this object evaluation, all factors which influence strategic decisions are determined separately. These extra criteria lead to the strategic decision whether or not a building should be held or divested, regardless of the actual object assessment. The evaluation of both, the building and the strategy influencing factors, enable the system user to objectively decide about the future steps for the portfolio. These steps mainly distinguish between four different scenarios: hold, refurbish, examine or divest. Thereby the user can chose between different levels of detail. An example of an overview of a total portfolio analysis is shown below in figure 3.

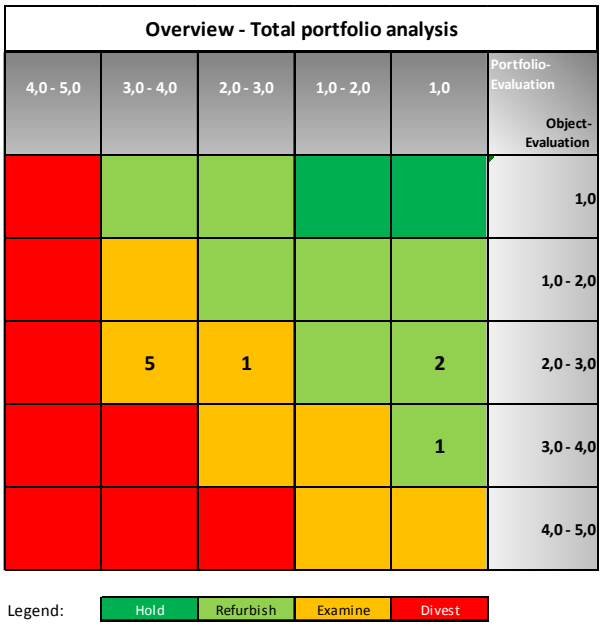

Figure 3: Overview total portfolio analysis

However, the analysis of the portfolio is not a means of itself. It creates a foundation for future scenarios, such as reducing the number of sites or identifying necessary refurbishments.

The described system and method were applied on an Austrian federal state which operates 88 public buildings with a total usable building area of 500.000 m². The paper presents the implementation of the portfolio management system. Based on the developed strategy all buildings categorized as “refurbish” are singled out. The necessary refurbishment scenarios for these buildings are compared by using life cycle costing.

2.4 Initiating sustainable refurbishment project based on specific object strategy

In accordance with the holistic process of evaluating an organization’s real estate portfolio and identifying buildings which call for action (see figure 3) to either:

- Refurbish or
- Examine

an object strategy derived from the client’s demand and requirement supports public officials to allocate resource to objects within its portfolio in a evidence based and controlled manner.
Thus avoiding incomprehensible public spending, while concentrating resources on key assets in a sustainable process.

In this case study for an Austrian federal state the next, logical step was to act upon one analyzed object strategy and investigate possible refurbishment scenarios for this specific building.
Due to the evaluation and preliminary defined goals for building standard and services a possible solution space for the existing building was quickly developed.

The existing building is an administrative building which houses offices, a conference center and ancillary services (e.g. cafeteria, storage, garage, data center). After more than 34 years of operation (built 1979), the office building faces a significant backlog concerning reinstatements and renewals resulting in

a) Depreciation of real estate
b) Questionable legal certainty regarding current norms and regulations (e.g. fire protection)
c) High costs for utilities and operation

d) Energy efficiency does not comply with self imposed sustainability goals

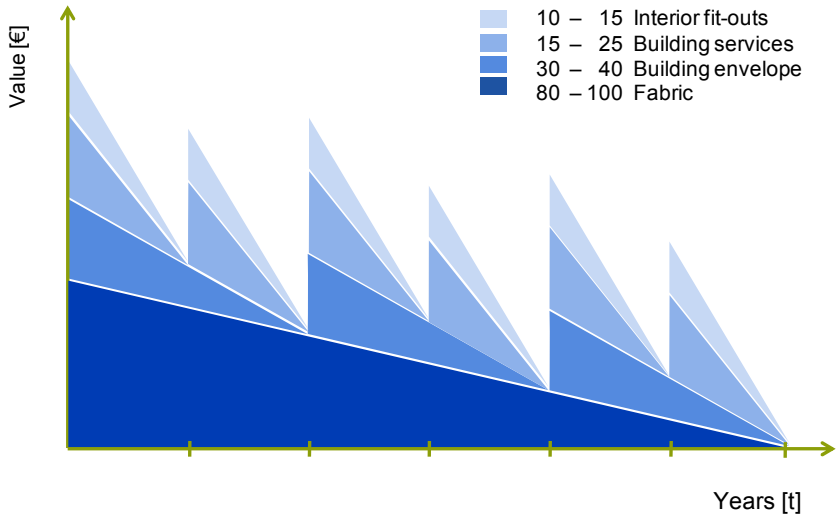

Fig. 4: Interval of renewals according to theoretical service life for different building components.

In a first step the buildings condition was examined from a life cycle point of view: which building components have reached or passed their given service life? Figure 4 shows an idealized model of a building's life cycle and its components while Figure 5a shows the given building's examination. Besides minor technical reinstatements and a modernization procedure along the way, the building's value decreased according to building components' rates of depreciation.

In several workshops consisting of client, users and facility management three basic refurbishment scenarios were developed and characterized using a probabilistic approach [6]:

1. Event driven refurbishment
   The current strategy of only reinstating components and facilities once they do not function anymore will be continued with minor renewals over the upcoming fifteen years. An assumption was taken that due to the delay of fundamental renewals of building envelope and central building services a breakdown of several systems within a short time frame will occur.
2. Fractional refurbishment
   This scenario follows the strategy to split up necessary refurbishment actions into separate tasks that are tackled over the course of several years with the idea of a economically smoothly balanced approach.
3. The third scenario follows the principle that a holistic refurbishment approach that yearns for high standards regarding energy efficiency and sustainability can only be achieved when necessary renewals are integrative tackled. Thus bundling the modernization of building elements and components that are functionally linked (e.g. modernizing the building envelope as well as the HVAC).

Figure 5b displays the results of the first life cycle cost analysis of roughly described scenarios above. The calculations also features a energy calculation based on EN ISO 13790 combined with significant improvements including a monthly balancing method. Thus making it possible to rate the refurbishments scenarios' energy demand and costs. Furthermore, costs for maintenance and cleaning are calculated for each scenario based on chosen building components (see Pongratz et al. [4]). The graphs in figure 5b shows cummulated costs for refurbishment and follow up costs along the scenario's life cycle.
When looking at the given refurbishment scenarios (Figure 5b), alternatives not only differ in the timing and execution of refurbishment, but also in varying strategies concerning the building's

energy system.
Supposedly efficient energy concepts may finally end up raising the building's life cycle costs due to complex building services equipment, which on the one hand achieve a certain decrease of the annual energy consumption level but that –on the other hand- leads to overwhelming maintenance requirements and operations costs outweighing the benefits.

The LCC analysis shows that comparing refurbishment scenarios with an established life cycle costing method (for further details on LCC-Tool and its methodology see: Pongratz et al. [4]) allows a timely review a project's framework as well as economically and energetically tangible impacts.

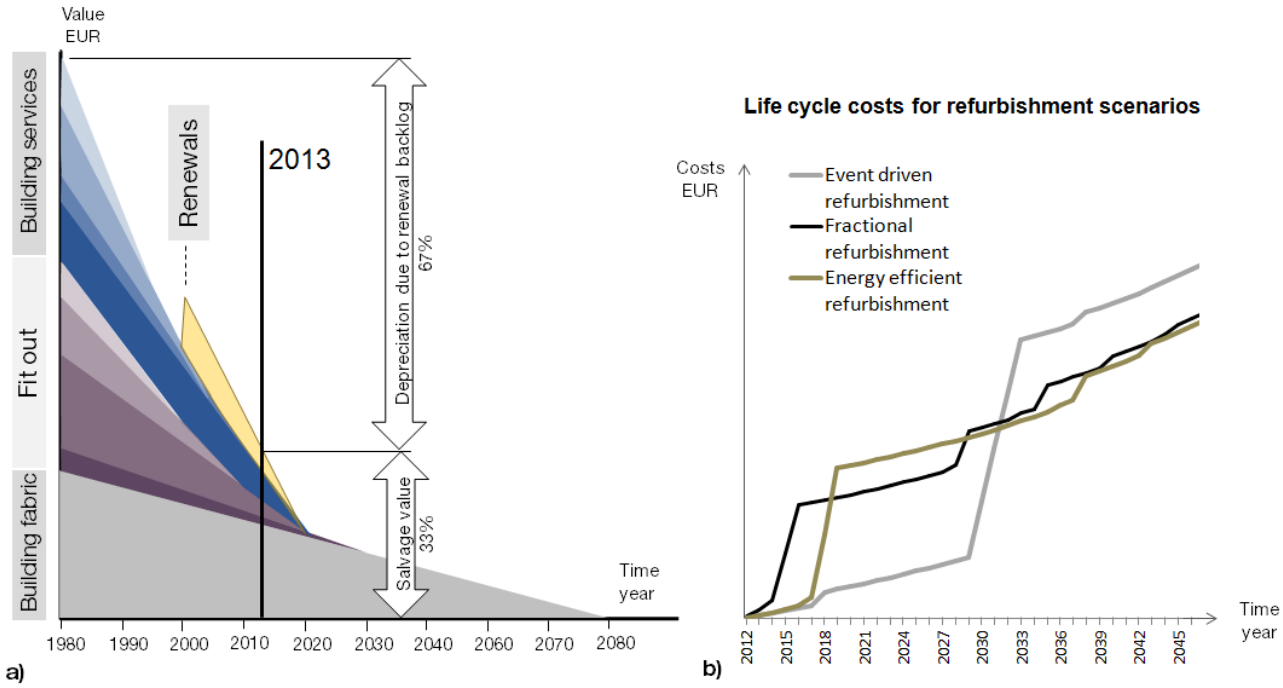

Fig. 5: Life cycle analysis for three refurbishment scenarios

3. Conclusion

Before concentrating on certain refurbishment projects within a given building stock, first an evaluation of the entire building portfolio allows the efficient allocation of resources. Most existing real estate portfolio management systems lay their focus on tangible assessment criteria, leaving the value of a building for a corporation in terms of user satisfaction or support of the core business aside. Therefore new portfolio management tools and methods need to be fully customized for public administration that manages buildings for own usage.
This allows a holistic and evidence based approach that support an informed decision making process. When an object strategy is derived, life cycle costing guarantees the continuous controlling of initially set goals of a developed portfolio strategy.

Although life cycle costing for buildings has been implemented in many national norms and building certifications, during early refurbishment project phases, i.e. during the phases when the project's fundamental structural parameters of environmental footprint and resulting costs are created and decided, LCC-tools have not yet found their way into general project management procedures [5].

LCC tools and their early involvement in the planning phases of refurbishment projects undoubtedly support the planning and decision making process underline procedures that account for more than only investment costs: building operation costs for e.g. energy, maintenance and cleaning need to be considered when evaluating possible refurbishment scenarios. Life cycle costing offers true costs for project alternatives and distinguishes between supposedly efficient looking scenarios and ones that do offer real benefits and advantages for the user, the organization and the environment over a building's entire life cycle.

Short Summary

To date a proliferation of sustainability claims in architecture is noticed. The major focus is on energy and related CO_2 and on the use stage of buildings. Although energy during the building use stage is highly relevant, a more comprehensive life cycle approach is needed to support decision making in order not to overlook relevant environmental burdens such as respiratory effects and land use. This proliferation of sustainability claims is not only noticed in the building sector. Also in other sectors confusion in the market on how to measure the environmental performance has appeared due to this proliferation of claims. This can lead to unfair commercial practices and greenwashing. As a base for addressing the current confusion in the market, the Environmental Footprint was developed and has recently been adopted by the European Commission. This method provides specific guidance for comprehensive, robust and consistent environmental assessment of products and organisations. It is based on four main principles: (1) multi-criteria, (2) life cycle thinking, (3) consistency and (4) ensuring maximally physically representative modeling. This paper presents the Product Environmental Footprint in the specific context of buildings.

Keywords: Labelling, Life Cycle Assessment, Multi-criteria approach, Product Environmental Footprint, Sustainable Buildings.

1. Introduction

Although the construction sector contributes to socioeconomic development, it also induces important environmental impacts due to its energy consumption, solid waste generation, global greenhouse gas emissions, adverse health effects, environmental damage, resource depletion and land use [1], [2]. It is therefore a relevant sector in terms of reducing the environmental impact. Sustainability and environmental impact of buildings have hence received a high interest in the last decades. In this context, a proliferation of sustainability claims of buildings is noticed to date, such as 'Passive House', 'Ecological Passive House', 'Net Zero Energy Building', 'CO_2 neutral building', 'Solar Self Sufficient Building', 'Autonomous object', 'Energy Autonomous City', 'Mixed-use Carbon Neutral development', 'Eco-village', '2000 Watt City' and many more [3], [4], [5], [6], [7], [8]. The major focus is clearly on energy and related CO_2 and on the use stage of buildings. By limiting the focus to a single environmental impact category and/or a single life cycle stage there is however a potential risk of burden shifting to other impact categories and/or other life cycle stages [1], [9].

In a response to that, more holistic evaluation methods (and related labels) have appeared such as the Leadership in Energy and Environmental Design (LEED) rating system ([10], [11]), the BRE

Environmental Assessment Method (BREEAM) ([12], [13]) and the German Sustainable Building Council (DGNB) [14] system. These are more holistic as these include other life cycle stages than the use stage and consider other impacts in addition to global warming (multi-criteria). As the different systems lead to different recommendations and labels [15], the confusion in the market however remains. Moreover, although these holistic evaluation methods are more comprehensive, they show some important drawbacks. This is elaborated in section 2 of this paper. To overcome the drawbacks a detailed and rather prescriptive Life Cycle Assessment (LCA) method is recommended and has been adopted by the European Commission (EC), the Product Environmental Footprint (PEF) [17]. This method is presented in section 3. The scope of the PEF method is however not limited to the construction sector. More specific PEF category rules for construction products and buildings are needed to define even more clear, relevant and actionable guidelines in order to guarantee consistency and comparability of PEF studies. Another European initiative is the development of the standards of the CEN TC350 which provide such more specific guidelines (Product Category Rules). The two most relevant ones in the context of this paper are the EN15804 [18] and EN15978 [19]. The development of future PEFCRs for construction products and the harmonization with the CEN TC350 standards are further discussed in section 4. Some conclusions and steps forward are summarized in the final section.

2. Existing comprehensive assessment methods for buildings

This section provides an overview of three widely used comprehensive sustainability assessment methods for buildings, i.e. LEED, BREEAM and DGNB system. The methods are here briefly presented in order to illustrate their scope and importance. We refer to literature for a more comprehensive description and analysis, including implementation to case studies [20], [21], [22], [23], [24]. Some issues for improvements and the related recommendation for a multi-criteria LCA based approach are moreover discussed. The description mainly focuses on the environmental issues, as this serves as background for the subsequent section which presents the EC PEF method and indicates how the EC PEF method can contribute to an improvement of the environmental impact assessment of the existing methods.

2.1 Overview of existing methods

2.1.1 Building Research Establishment Environmental Assessment Method (BREEAM)

BREEAM was developed in 1990 and as such is the oldest certification system for sustainable building. It has become one of the most widely recognised systems with more than 250.000 buildings certified [12]. It assesses the environmental performance of buildings and includes aspects related to energy, water use, the internal environment (health and well-being), pollution, transport, materials, waste, ecology and management processes.

BREEAM considers nine categories (*Table 1a*). There are a number of aspects that determine the BREEAM rating: rating benchmarks (*Table 1b*), environmental weightings (*Table 1a*), minimum standards (i.e. minimum number of credits achieved within the sub-criteria of the nine categories), credits achieved and additional credits achieved for innovation (maximum 10 additional credits, which equals a maximum of 10% to be added to the rating score) [25]. The certification levels range from pass to outstanding.

Life cycle environmental impact assessment is mainly addressed in the category ‘materials’ by providing a link with the *Green Guide to Specification* ratings [26]. This *Green Guide to Specification* provides environmental rankings (i.e. from A+ to E) of materials and components for different building elements used in different buildings. It is based on LCA using BRE's Environmental Profiles Methodology 2007 [27]. This methodology comprises 13 environmental impact categories, including amongst others climate change, human toxicity, water extraction, fossil fuel depletion and acidification. The characterisation factors are mainly taken from the CML 2000 method combined with characterisation factors developed by BRE for any gaps [27]. For the total BREEAM rating, maximum six credits can be obtained by following the Green Guide to Specification within the category ‘Materials’. As in total 12 credits can be obtained in this Category

and the weight of this category is 12.5%, only 6.25% of the total BREEAM rating score is based on LCA of the building materials used.

Table 1: $BREEAM_{2008}$: weighting scheme for new builds, extensions and major refurbishments (table 1a) and certification level (table 1b), ([25], page 3).

Table 1a

Category	$BREEAM_{2008}$
Management	12%
Health and wellbeing	15%
Energy	19%
Transport	8%
Water	6%
Materials	12.5%
Waste	7.5%
Land use and ecology	10%
Pollution	10%

Table 1b

$BREEAM_{2008}$ rating	% score
Unclassified	<30
Pass	≥30
Good	≥45
Very good	≥55
Excellent	≥70
Outstanding*	≥85

*Additional requirements for achieving a BREEAM Outstanding rating.

2.1.2 Leadership in Energy and Environmental Design (LEED)

LEED is developed in 1998 by the U.S. Green Building Council. LEED is a voluntary, consensus based national rating system for buildings designed, constructed and operated for improved environmental and human health performance. It evaluates the environmental performance of a building over its entire life cycle. In 2013 over 10.000 buildings have been certified [11].

A project must satisfy all LEED prerequisites and earn a minimum number of points on a LEED rating system scale. Homes for example must earn a minimum of 45 points on a 136-point scale (*Table 2b*). The certification levels range from certified to platinum. The points to be gained are subdivided in eight categories (*Table 2a*). These consist of a number of measures which are prerequisites and/or a number of measures resulting in credits of one or more points. As the number of measures differs between the different categories and the number of points for the measures differs, weighting factors are implicitly assigned (*Table 2a*). It is however not clear how the measures within each category were selected and how the number of points was assigned to each measure.

Table 2: LEED for Homes (v. 2008): Weighting scheme (Table 2a, [11]) and certification level (Table 2b, [10]).

Table 2a

Category	$LEED_{2008}$
Innovation and Design Process	8%
Location and Linkages	7%
Sustainable Sites	16%
Water efficiency	11%
Energy and Atmosphere	28%
Materials and Resources	12%
Indoor Environmental Quality	15%
Awareness and Education	2%

Table 2b

$LEED_{2008}$ certification levels	Number of points required
Certified	45-59
Silver	60-74
Gold	75-89
Platinum	90-136
Total Available points	136

2.1.3 German Sustainable Building Council (DGNB) system

In 2009 the DGNB introduced a new system that can be seen as a second-generation scheme as it built on the experiences of the existing schemes at that time such as BREEAM and LEED. In 2012 over 200 buildings have been certified in Germany and abroad [22]. It is more holistic than the previously discussed systems as it is not limited to environmental and health issues.

The DGNB system gives equal weight (22.5%) to the widely accepted three pillars of sustainability: environmental, economic and social pillars. It moreover considers the technical quality (22.5%), the process quality (10%) and the location quality (0%, which actually means it is not considered). The total score of the building is calculated based on the weighted individual scores on each criterion (about 50 in total). Based on this total score, a bronze, silver or gold certificate can be obtained (*Table 3b*). The gold certificate is reached when 80% of the possible maximum score is reached. As described by Schuster et al. "*this can only be achieved with a performance far better than required by law, e.g. with extremely high energy performance and/or low emission material selection"* [22].

In *Table 3a,* the indicators in the environmental pillar are summarised together with their weighting factors (in relation to the overall DGNB score). The environmental impact assessment is based on the CML 2001 characterization model and represents 13.5% of the total DGNB score [28].

Table 3: DGNB system: weighting scheme for ecological quality issues of overall certification (Table 3a) and certification level (Table 3b) [20].

Table 3a

Indicator	Weight
Global Warming Potential (GWP, kg CO_2 eq.)*	3.46%
Ozone Depletion Potential (ODP, kg CFC_{11} eq.)*	0.58%
Photochemical Ozone Creation Potential (POCP, kg C_2H_4 eq.))*	0.58%
Acidification Potential (AP, kg SO_2 eq.)*	1.15%
Eutrophication Potential (EP, kg PO_4 eq.)*	1.15%
Risks to the regional environment	3.46%
Other impacts on the global environment	1.15%
Microclimate	0.58%
Non-renewable primary energy demand* (MJ)	3.46%
Total primary energy demand and proportion of renewable primary energy* (MJ)	2.31%
Potable water demand and sewage generation	2.31%
Land use	2.31%

From 65%	Silver
From 80%	Gold

2.2 Need for improvement

Although assessment methods such as LEED, BREEAM and the DGNB system have clearly their strengths in terms of comprehensiveness and awareness raising, they also show some weaknesses. The most important need for improvement is the consistency and rigidness of the methods for the determination of the environmental benefits assigned to each building measure and the relative importance of each of the measures. Based on an LCA of the measures in the LEED method, Humbert et al. concluded that actually not all measures are environmentally beneficial but some result in an environmental burden instead [29]. This was for example the case for the measure '*provide alternative fuel vehicles or install alternative refuelling stations for 3% vehicle parking capacity*' within the category '*sustainable sites*'. This measure was translated into "*3% of the cars driven with bioethanol instead of gasoline*" by Humbert et al. and proved to lead to a positive impact on depletion of resources but to a damage to human health and ecosystems based on their LCA study [29]. Similar critics can be formulated for the BREEAM method as it was identified that it does not use an LCA approach consistently throughout the assessment. The environmental assessment of the DGNB method only comprises a limited number of impact categories and the impact assessment models used date from 2001. It therefore shows room for improvement.

A comprehensive LCA of the environmental impacts is hence recommended to improve the existing methods. Consistency over the different building types, but also over the different EU

Member States would be beneficial in terms of transparency and comparability. It would moreover be advantageous for the assessors to have a consistent method in different building locations in terms of time and money. The EC PEF method exactly aims at providing consistent, LCA based, clear and actionable guidance and is further elaborated in the subsequent section. Besides the EC PEF method, the CEN TC350 developed LCA standards for construction products and buildings, i.e. the EN15804 and EN15978 standards respectively [18], [19]. These are further discussed in the subsequent section related to more specific PEF category rules for the construction products.

3. The EC Product Environmental Footprint (PEF)

3.1 Background

The EC PEF method has been developed by the Joint Research Centre (JRC) of the EC in close cooperation with the Directorate General for the Environment (DG ENV). It was recently published as an annex of the recommendation linked to the Communication "*Building the Single Market for Green Products - Facilitating better information on the environmental performance of products and organisations*" [16], [17], [30]. The aim of the PEF is to bring comparable and reliable environmental information in order to build confidence for consumers, business partners, investors and other stakeholders. It should provide the basis for addressing the current confusion of sustainability claims which is not only noticed in the building sector.

The EC PEF method is an LCA based method to calculate the environmental performance of a product (i.e. good or service). PEF information is produced for the overarching purpose of seeking to reduce the environmental impacts of products taking into account supply chain activities (from extraction of raw materials, through production and use, to final waste management). The EC PEF method provides guidance for modelling the environmental impact of the flows of material, energy and the emissions and waste streams associated with a product throughout its life cycle. It builds upon the ISO 14040 and ISO 14044 standards [31], [32] and the International Reference Life Cycle Data System (ILCD) Handbook [33]. The EC PEF method is however more prescriptive than any of these documents in order to increase consistency and reproducibility. The relation with the ISO standards and the ILCD handbook are schematically presented in *Fig. 1*. Besides these reference documents, existing footprinting methods were consulted at the start of the development process of the EC PEF method such as PAS 2050 [34], Greenhouse Gas Protocol [35], [36] and BPX 30-323-0 [37]. Briefly summarised it can be concluded that existing methods are not prescriptive enough (to guarantee consistent and comparable outcomes) and not comprehensive enough (i.e. limited to a single issue instead of multi-criteria) to fulfil the goals set for the EC PEF method. A detailed description of the analysis of existing footprinting methods can be found in [38].

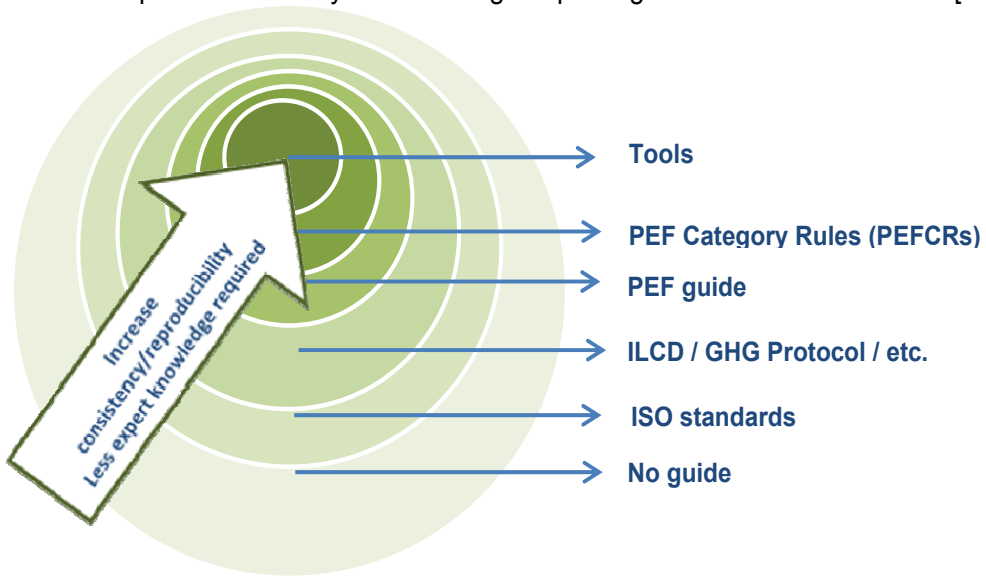

Fig. 1 Situating standards and methods for product environmental footprinting along the continuum from flexibility to prescriptiveness/reproducibility

3.2 Scope

The EC PEF method can be applied to all products including construction products. The system boundary includes all life cycle stages from raw material extraction through processing, production, distribution, storage, use and End-of-Life (EoL) treatment of the product (i.e. cradle-to-grave), as appropriate to the intended application of the study. As the EC PEF method has a wider scope than only building products, additional, even more specific, requirements for the building sector will be necessary to increase reproducibility, consistency and relevance of PEF studies of construction products. These additional guidelines are referred to as Product Environmental Footprint Category Rules (PEFCRs) and are further discussed in section 4.

3.3 Prescriptiveness

The EC PEF Guide has a high level of prescriptiveness and hence a low level of flexibility. This was seen as essential in order to obtain more consistent and comparable results. The EC PEF Guide provides for example strict guidelines regarding the data quality, allocation, EoL allocation, cut-off, impact assessment, biogenic carbon removals and emissions, temporary carbon storage and nomenclature. This is in contrast with many other currently available methods which in general allow the user to choose out of a range of possibilities. The data quality requirements and environmental impact assessment are described in more detail in the subsequent sections as these are important issues for all environmental assessments, including buildings.

3.4 Data quality requirements

Strict data quality requirements are included in the EC PEF Guide in order to ensure good quality results. A semi-quantitative assessment is required addressing six criteria: technological representativeness, geographical representativeness, time-related representativeness, completeness, parameter uncertainty and methodological appropriateness and consistency. The single scores are combined giving equal weight to each criterion in order to obtain the overall data quality rating. The overall rating ranges from poor to excellent. For the processes accounting for at least 70% of contributions to each impact category, data shall achieve at least an overall “good quality” level, for at least 20% of the remaining impact “fair quality” data shall be used, and for the remaining processes (maximum 10% of the impact) at least best available data shall be used (*Fig. 2*). The European reference Life Cycle Database (ELCD) and the International Reference Life Cycle Data System Data Network (ILCD DN) will play a crucial role in achieving this fundamental goal of coherent and quality assured data [39].

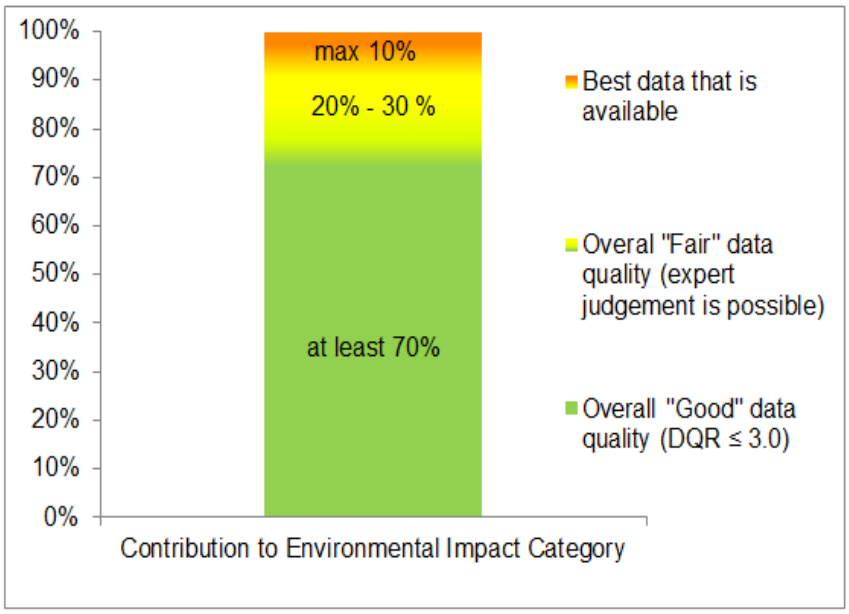

Fig. 2 Data quality requirements according to the PEF Guide.

3.5 Environmental impact assessment

The EC PEF method includes a comprehensive list of 14 impact categories and prescribes the midpoint models, related indicators and characterisation factors to be used (*Table 4*). This is based on the ILCD recommendations [33] agreed upon internationally and is therefore widely supported.

Table 4: Product Environmental Footprint: impact categories, assessment models and indicators.

Impact Category	Assessment Model	Indicators
Climate Change	Bern model - Global Warming Potential over a 100 year time horizon.	kg CO_2 eq.
Ozone Depletion	EDIP model based on the ODPs of the World Meteorological Organization (WMO) over an infinite time horizon.	kg CFC-11 eq.*
Ecotoxicity for aquatic fresh water	USEtox model	CTUe **
Human Toxicity - cancer effects	USEtox model	CTUh ***
Human Toxicity – non-cancer effects	USEtox model	CTUh ***
Particulate Matter/Respiratory Inorganics	RiskPoll model	kg PM2.5 eq. ****
Ionising Radiation – human health effects	Human Health effect model	kg U^{235} eq. (to air)
Photochemical Ozone Formation	LOTOS-EUROS model	kg NMVOC eq. *****
Acidification	Accumulated Exceedance model	mol H+ eq
Eutrophication – terrestrial	Accumulated Exceedance model	mol N eq
Eutrophication – aquatic	EUTREND model	fresh water: kg P eq. marine: kg N eq.
Resource Depletion – water	Swiss Ecoscarcity model	m^3 water use related to local scarcity of water
Resource Depletion – mineral, fossil	CML2002 model	kg Sb eq. ******
Land Use	Soil Organic Matter (SOM) model	kg (deficit)

* CFC-11 = Trichlorofluoromethane, also called freon-11 or R-11, is a chlorofluorocarbon.
** CTUe = Comparative Toxic Unit for ecosystems
*** CTUh = Comparative Toxic Unit for humans
**** PM2.5 = Particulate Matter with a diameter of 2.5 µm or less.
***** NMVOC = Non-Methane Volatile Organic Compounds
****** Sb = Antimony

4. Product Environmental Footprint Category Rules (PEFCRs)

As mentioned in section 3.2, PEFCRs for the construction products will need to be developed in future in order to further increase consistency, reproducibility and relevance for the construction sector and to enable comparisons and comparative assertions. The PEFCRs should moreover reduce the time and efforts needed to conduct a PEF study by limiting the scope in terms of relevant processes/life cycle stages and impact assessment categories. Coherence of PEFCRs will be ensured trough the foreseen sectorial level guidance for their development. Existing product category rules (PCRs) for construction products should be consulted when creating the PEFCRs for construction products and buildings, especially the widely used EN15804 and EN15978 should be carefully considered. In addition, other existing PCRs of construction products should be taken into account as well, such as the BREEAM PCR [27]. Their requirements and assumptions regarding for example the reference service life of buildings and components, the technological, geographical and time-related representativeness of processes should be carefully considered.

5. Conclusions and steps forward

The current proliferation of methods for assessing the sustainability of buildings leads to inconsistency and hence confusion. Although comprehensive methods exist taking into account several sustainability issues and life cycle stages, the methods to date are mainly rating-based methods, also referred to as qualitative systems. They consist of a subjective weighting of credits assigned to a list of measures, covering different issues such as energy use, material choice and water efficiency. The need for a more consistent and comprehensive Life Cycle Assessment (LCA)

based (quantitative) method is highlighted. The presented Product Environmental Footprint (PEF) method, recently adopted by the European Commission, gives an answer in terms of environmental impact assessment to the needs identified. The next step forward consists of developing Product Environmental Footprint Category Rules (PEFCRs) for construction products in order to increase consistency, reproducibility, relevance and comparability of building and building product assessments. In order to move towards a harmonised European method for construction products and buildings it will be important to envisage an alignment between the PEFCRs for construction products and the CEN standard EN15804.

6. Acknowledgement

Part of the work on the Product Environmental Footprint (PEF) was supported by means of an Administrative Arrangement by DG ENV.

Abstract
LCA is widely recognized as the most relevant tool to evaluate building environmental impacts [1]. However, its use is still facing limitations which make it restricted to experts and researchers. Over the last few years, many works and initiatives have focused on methodologies and user-friendly tools to spread building LCA practice and ease its understanding [2],[3],[4],[5], encouraged by the growing interest for this method as a tool to achieve a more sustainable development [6]. However, few works have tried to adapt the tools to the specific needs of the different building stakeholders.

The objective of our work is to make LCA more accessible to non-experts willing to assess their building projects at different stages. Depending on the goal and scope of the study, data, methods, calculation rules, etc. within LCA tools have to be adjusted. All these adjustments require advanced knowledge in order to ensure proper representativeness, respects of certification schemes requirements, etc. Such adaptations have been formalized in a recent European project [9] by defining different study types (screening, simplified and complete) and providing a series of guidance for each type. We propose a first implementation and assessment of this approach for the building products and equipment aspects of a full building LCA. Modular approach has been identified as a possible answer to data adaptation problem [11]. This includes a modular description of components, products and materials but also different types of LCA data (e.g. generic data or specific EPDs) that are able to support different goals and scopes, from early design to detailed assessment.

Our work focused on developing such a database based on the modular principle, implementing it on an existing LCA tool (ELODIE), and validating its use for different types of studies. This paper provides an overview of the approach at different scales, supported by

case studies that show its relevance and consistency depending on the considered goal and scope. Examples will provide an overview of the methodology and demonstrate its usefulness. They will illustrate the distances between results from LCA of early design eco-conception and final certification results or existing building models. The investigated approach is dedicated to further facilitate the deployment of LCA amongst non-expert users. Integration of such an approach in building LCA tools could facilitate the decision making at the first steps of a building project, when the potential influence of design on costs and environmental impacts is the highest.

Keywords
Sustainable building; LCA; Environmental impacts; Macro-component; Generic data.

1. Introduction

Worldwide statistics show that the building sector generates the highest energy consumption. For this reason, many regulation rules and technological improvements emerged since last mid-century, aiming a drastic drop of this consumption. Nowadays, buildings are still responsible for at least 40 % of energy use in most countries. Parallel and often correlated to this energy consumption, buildings are also emitting about 30 % of greenhouse gases (GHG). Then, efforts are maintained by politics, industrials and personal initiatives to amplify this decrease. Emerging from the statement that all pollution sources are linked and interacting, multicriteria study forces itself on the scientific community as a way to perform a complete environmental assessment can be perform avoiding transfers of pollution. These transfers could occur from a source to another or from one phase of the life cycle to another. Then, the multicriteria approach allows to consider these transfers and to make a real systemic optimization.

Over past few years, multicriteria assessment tools have been developed and so building LCA tool emerged [1]. In that way, it is now possible to perform a global optimization of different aspects without pollution transfer. These tools offer new design perspectives by taking environmental aspect into account in a global sustainable process. For instance, thanks to such method [2],[3],[4],[5], one can explore both energy consumption and waste production at the same time. Additionally, it also allows evaluating physical resource uses and other environmental impacts (water pollution and consumption, air pollution, greenhouse gases emissions…). The use of mineral resources is also of high concern in the construction sector. For example, the production of gravels in France in 2010 was about 365 millions of tons according to [7]. Also, the building lifetime, often about 80-100 years, justifies the position of the construction sector to significantly contribute to a more sustainable development [6].

A complete building LCA is not a simple aggregation of LCA of component and construction materials. Buildings have a very long service life. A building LCA has also to take into account the impacts related to the energy consumption (values to be taken from thermanl anlysios software). The other contributors of a building are also the operational water consumption, the transportation of the users of the buildings, the construction site processes. However, the assessment of the impacts related to the building products and technical equipment is still the most time consuming aspect during a building LCA. Generally speaking, a bill of quantities of materials can have plenty of materials and products often presented in units, kilograms, m² or m^3. Inventorying all the materials and linking them to an environmental data is thus time consuming. Also, building LCA tools are usually more specifically oriented towards one objective and then one construction project phase [8].
Because of this time consumption and this tool specialization, the evolution from eco-design to performance evaluation of building environmental quality is still limited. To promote the holistic approach, tools must provide a real continuum all along the building project stages. This is particularly important since early design stages are not only used for alternatives

comparisons but also as a first assessment to reach a required performance level. In that way, the continuum needs to be assured and so, create a higher synergy between all the stakeholders.

To ensure this continuum, the use of different study types as described in the European project, EeBGuide [9] will likely present a growing interest in the future. To summarize, the three study types, screening, simplified and complete, are proposed with an appropriate level of completeness and data requirements in the description [10]. To do so, scalable description systems are foreseen as one solution to be embedded within building LCA tools. A scalable description system, historically implemented in building LCA software like LEGEP [11] will offer a way to consider smaller entities within a whole assembly, avoiding getting into the detail when it is not part of the goal and scope of the study. For instance, a generic data representing an average external wall could be implemented in a LCA database so that the user could directly select it without selecting each materials and products implemented in it. Such an assembly is then considered as a "macro-component". Linked to the scalability approach, the selection between both generic data (representing a whole set of products, by a weighted average for example) and specific data (representing a particular commercial reference) allows the users to set his level of accuracy: from aggregated and generic building parts with uncertainties to more specific and more accurate compound by compound description.

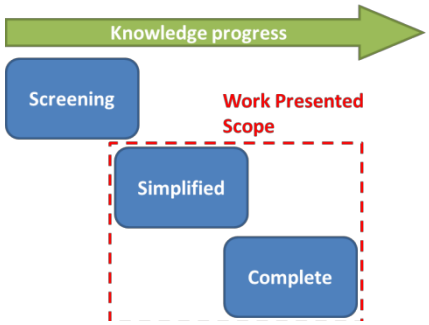

Figure 1: Positioning of this study within the three study types as exposed in the EeBGuide project *vs.* the project knowledge progress

Figure 1 presents the scope of this paper according to the three study types presented in the EeBGuide project. More particularly, this whole study is focused on the building products and technical equipment contributor. Also, the presented approach is restricted to the "simplified" and "complete" types, as approach to deal with a screening LCA, consisting on using aggregated ratio of parts of the building is already documented in previous papers [12].

The work exposed below describes the methodology developed to obtain scalable datasets. The methodology is based on the general guidance and standards on LCA [13],[14][15]. The discussions all along this paper will expose the potential implementation of the approach in building LCA tools as well as limitations and prospects.

2. Overview of datasets included in building LCA tools

Most of existing tools are mainly oriented towards one construction project phase. In fact, these tools are often developed under a specific context considering a pre-defined goal. A complete modularity of database would potentially be needed in order to offer the right information on the whole construction project.

Name	Developer	Country of development	Mostly oriented towards	Type of data (number)	Import new data	Scalable data

Table 1: Brief summary of some building LCA tools and their objective

Table 1 gives a listing of some building LCA tools as examples of solutions offered to construction stakeholders. This listing is not to make any comparisons and does not pretend to be exhaustive. It has been filled according to information given on websites or user guides. Also, the "mostly oriented towards" column gives the information as exposed and highlighted by the developers; it is not exclusive and all these tools can be used differently depending on user's expertise. As shown on Table 1, only few tools are offering a fully scalable data even if many of them are oriented towards both early phases of planning and operation phase. Since we are mainly interested in the scalability and modularity, the type of data will not be considered further than the difference between generic (i.e. a data roughly describing the impact of a product or component mainly based on industry data averaging or use of European generic data e.g. based on previous studies [16]) and specific data (industry data provided by companies and representing a commercial reference of a product).

3. Modular description scale methodology

The goal of this section is to give some explanations about the approach by presenting the building LCA tool used for this work as well as the methodology to determine and calculate the macro-component values. We would like to insist on the validation aspect of this work which should in the end help stakeholders to clearly position their early phase results to a targeted performance value.

3.1 Presentation of the building LCA tool ELODIE

ELODIE is a French building LCA software assessing the environmental impacts due to construction materials and products, the operational energy and water use, the construction site processes and the transportation of users. ELODIE provides an environmental multicriteria profile of building considering 15 indicators based on CML, 2001 and French standard (NF P01-010 and XP P01-020-3, evolving towards NF EN 15804 [17] and NF EN 15978 [18]). However, the set of indicators discussed here will be restricted to some of the most commonly used:

- Total primary energy
- Non-renewable energy
- Abiotic depletion potential (ADP)
- Water consumption
- Global warming potential (GWP)

The software uses Environmental Product Declarations (EPD) provided by manufacturers and available in the INIES database [19] as well as homemade generic data. INIES is the French free access reference database of Environmental Declarations of Building Products (EPDs). The INIES database hosts two types of data:

- Single manufacturer's EPD
- Group of manufacturer's EPD

In the present study, generic data are used as far as possible either on the form of industry average (e.g. large group of manufacturer's EPD or existing generic data). Thus, using group of manufacturer's EPD seem consistent in early design as we may not know the exact producer of the component or the product.

The work is divided in two parts. First, environmental profiles at different scales are manually calculated (except for materials and products already having an EPD). Secondly, a modular description scale configurator can be developed to have automation in macro-component description and impact calculation.
In the next section, only the first stage is presented as it is a required step to validate the methodology.

3.2 Methodology

This section is dedicated to the description of the vocabulary and calculation rules applied to the modular system configuration.

3.2.1 Classification and nomenclature

In order to efficiently use the aggregated data, a clear and understandable classification and nomenclature has to be adopted. The main objective of this nomenclature is to match stakeholders' needs and vocabulary. For this reason, it is mainly based on the classification given in the French project HQE Performance, looking at the determination of reference values for different types of low-energy buildings [12]. Obviously, this classification was defined with the help of French construction stakeholders and may differ from other classification in other countries.

Main parts	Sections	Macro-component families
External works	1. External works	1.1 Distribution network (on parcel)
		1.2 Storage
		1.3 Roadworks, flooring, fencing
Shell and loadbearing structure	2. Foundations and substructures	2.1 Foundations
		2.2 Underground walls and structure (stairs, parking area…)
	3. Superstructure - Masonry	3.1 Horizontal elements - Slab floors
		3.2 Horizontal elements - Floors
		3.3 Horizontal elements - Beams
		3.4 Balconies
		3.5 Vertical elements - External walls
		3.6 Vertical elements – Cross walls
		3.7 Vertical elements - Posts
		3.8 Stairs and slopes
	4. Roofing - Proofness - Framework	4.1 Flat roof
		4.2 Roof and framework
		4.3 Roof technical elements

Table 2: Description of the different scales nomenclature and links between them

Table 2 shows the selected nomenclature with the different scales of description. Each macro-component family can contain different solutions. For example, the "3.5 Vertical elements - External walls" could include the different construction systems. This study only focuses on bright cells in Table 2. "External works" and "Technical trades" will not be addressed, mainly due to missing data for these categories of products. One can easily figure out that some "Shell and loadbearing structure" sections can integrate materials/products or even macro-components from "Architectural trades". In fact, suspended ceilings will be taken into account in "3.2 Horizontal elements – Floors". This could be judged both a problem and a solution; a problem since it does not encapsulate clearly certain elements but a solution since it is the way to get sufficiently aggregated solutions to drop the description time.

3.2.2 Calculation rules

It is reminded that we are only considering the construction materials and products contributor to the LCA. Even if the scope appears limited, it is justified by:

- The time consuming aspect of this contributor
- The potential increasing contribution of this contributor due to decreasing of the others (higher energy efficiency, better water management…)
- The high level of complexity in translating exhaustive lists of materials into LCA tools

We consider a macro-component (MC) made of *n* different layers.

The selection of the Reference Service Life (RSL) is performed assuming that the highest RSL among the layers is the baseline to calculate replacements of other layers.

$$RSL_{MC} = \max_{1 \le i \le n} \{RSL\}$$

Equation 1: Reference Service Life identification formula within the components set

Equation 1 mathematically translates the macro-component RSL definition. For all other components, the replacement rate is obtained by dividing the RSL_{MC} by the considered component RSL.

$$I_{MC} = \sum_{1}^{n} q_n \times I_n \times \left\lceil \frac{RSL_{MC}}{RSL_n} \right\rceil \times \tau_n$$

Equation 2: Calculation of the macro-component environmental impacts

$Wherein$:

q_n: $material\ n\ quantity$

I_n: $material\ n\ environmental\ impact\ on\ the\ whole\ life\ cycle$

$\left\lceil \frac{RSL_{MC}}{RSL_n} \right\rceil \in \mathbb{N}$: $material\ n\ replacement\ rate$

τ_n: $material\ n\ conversion\ coefficient\ to\ adapt\ the\ functional\ unit$

Equation 2 gives the aggregation formula to calculate the equivalent macro-component scale environmental impact from the material/product scale, taking into account the replacement rate of each layer.

The as-calculated I_{MC} and RSL_{MC} can at the time be considered as the environmental declaration of the macro-component to be used in LCA software.

One can see that the systemic information obtained thanks to this macro-component approach could lead to major improvement of the calculation rules. In fact, we consider an aggregation of materials/products ensuring some functionality in the building but this aggregation can also give information about:

- Accessibility
- Position of the macro-component in the building and/or the project in a territory
- Stack order

As an example, the accessibility of one material in the macro-component could help defining new replacement rate closer from practices in the field. In the same way, the position of the project in a territory could lead to a better description of some macro-components such as foundations according to the seismic area.

3.3 Illustration of a macro-component description

This part highlights the potential interest of a comparing tool of macro-component by illustrating it with a simple example.

Name	**Glass wool insulated concrete block masonry external wall**			
Functional Unit	Provide a concrete block masonry external wall functionality with a minimum thermal resistance of 3,1 m²,K/W on 1 m² including replacement for a 100-year reference service life			
Description	Arrangement	quantity	FU	RSL (year)
	External painting	1	m²	50
	Concrete block masonry	1	m²	100
	Stainless steal	1	kg	100
	Glass wool	1	m²	50
	Plasterboard	1	m²	50
	Interior painting	1	m²	30
Name	**Glass wool insulated burnt clay brick masonry external wall**			
Functional Unit	Provide a burnt clay brick masonry external wall functionality with a minimum thermal resistance of 3,1 m²,K/W on 1 m² including replacement for a 100-year reference service life			
Description	Arrangement	quantity	FU	RSL (year)
	External painting	1	m²	50
	Burnt clay brick masonry	1	m²	100
	Stainless steal	1	kg	100
	Glass wool	1	m²	50
	Plasterboard	1	m²	50
	Interior painting	1	m²	30

Table 3: Description of both studied systems

As shown in Table 3, describing the two considered systems, only one layer distinguishes them. In fact, only the masonry is different in these cases, one with concrete block and the other with burnt clay brick.

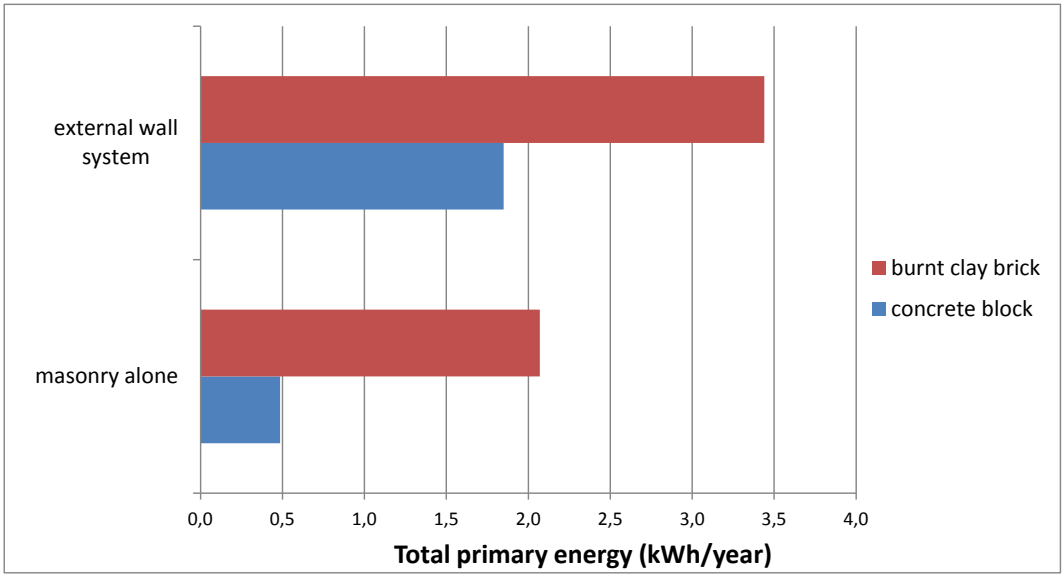

Figure 2: Relative comparison of concrete block (blue) and burnt clay brick (red) masonries in two cases: alone; in an external wall system

Figure 2 shows the total primary energy indicators obtained with two masonry systems in both cases:

- The masonry alone: this makes visible a concrete block impact representing less than 25 % of the burnt clay brick impact.
- The masonry integrated in an external wall: the classification is still the same with the burnt clay brisk system implicating a higher impact. However, the concrete block system now represents more than 50 % of the burnt clay brick one.

So, at first sight, the conclusion could be the same. Yet, a further interpretation could lead to a totally new thinking: "*since the discrepancy is not as important when considering the system, why could I not think about finding another macro-component, assuming another function in the building to counterbalance this smaller difference?"*

Finally, the modular scale is firstly a way to retain the systemic approach and helps considering an element as part of a whole.

4. Results and discussion

The results below are examples to illustrate the process and give first highlights and enhancement ways. They are a first brick in the wall that will have to be further explored and studied to build the entire work.

A set of 80 generic macro-component data has been calculated on the basis of the previously exposed methodology. A key point of the study is that we only took into account of the most commonly used constructive systems in France (for single and community housing). Large-scale case studies have been conducted by volunteers and construction stakeholders on both single housing (9 samples) and community housing (14 samples) described with macro-components. The results have been compared to the detailed description of the same works performed in the framework of the ongoing HQE Performance experimentation.

The objective is mainly focused on the qualification and much more essential the quantification of discrepancies between a detailed description with specific data of the building and a simplified one, using predefined macro-components. As it is a main fact to put things into perspective, we would like to remind that the macro-components implemented in this demonstration tool are not customizable. One can easily figure out that this strong hypothesis may lead to substantial differences in results. Indeed, the more the building will be close to the reference (here a building using the commonly used techniques), the less deviation we will have in the results.

4.1 Reproducibility

This point is of prime importance to increase the confidence in tools for the different stakeholders. The building LCA non-reproducibility causes are mainly due to:

- Metrics interpretation and typing errors
- Data choice
- Description perimeter = boundaries of the system

The macro-component description method becomes a solution to decrease the margin due to the two first points highlighted above in this way:

- Metrics interpretation and typing errors: since the number of inputs to perform a macro-component description is drastically decreased compared to a fully detailed description.
- Data choice: thanks to the use of pre-selected generic data that can confidently be used for eco-designing.

The description perimeter still faces the subjective interpretation problem to fix it. However, the macro-components can act positively by including complementary products that could easily be missed out when performing a detailed description.
Two examples within the single housing set have been calculated by two different experimenters to check the reproducibility capacity.

			User 1			User 2		
			Detailed description	Macro-component description	Relative gap (%)	Detailed description	Macro-component description	Relative gap (%)
Energy consumption	Total primary energy	(kWh / m² NFA / year)	36,4	42,9	17,9	36,4	40,9	12,4
	Nonrenewable energy	(kWh / m² NFA / year)	29,3	33,9	15,7	29,3	32,3	10,2
Abiotic depletion potential		(kg Sb_{eq} / m² NFA / year)	4,04E-02	5,31E-02	31,4	4,04E-02	5,15E-02	27,5
Water consumption		(L / m² NFA / year)	69,5	62,4	-10,2	69,5	56,7	-18,4
Global warming potential		(kg $CO2_{eq}$ / m² NFA / year)	7,24	8,08	11,6	7,24	7,56	4,4

Table 4: LCA results in detailed description for a single house and macro-component descriptions performed by two different users; green highlighted values for smaller than 20 % (arbitrarily determined)

Table 4 shows the results obtained by two users in a macro-component description and the comparison with one detailed description (obtained in HQE Performance). One can see the quite close results between the two users.

			User 1			User 2		
			Detailed description	Macro-component description	Relative gap (%)	Detailed description	Macro-component description	Relative gap (%)
Energy consumption	Total primary energy	(kWh / m² NFA / year)	46,6	64,8	39,1	46,6	66,3	42,3
	Nonrenewable energy	(kWh / m² NFA / year)	36,8	49,9	35,6	36,8	51,8	40,8
Abiotic depletion potential		(kg Sb_{eq} / m² NFA / year)	5,41E-02	7,43E-02	37,3	5,41E-02	7,76E-02	43,4
Water consumption		(L / m² NFA / year)	119,6	80,2	-32,9	119,6	85,5	-28,5
Global warming potential		(kg $CO2_{eq}$ / m² NFA / year)	10,3	12,3	19,4	10,3	12,9	25,2

Table 5: LCA results in detailed description for a single house and macro-component descriptions performed by two different users; green highlighted values for smaller than 20 % (arbitrarily determined)

Table 5 is a second example on which similar results between the two users can be observed even if the gap with the detailed description is higher.

Both exposed examples give a good reproducibility (highest gap of 8 points between both relative gap) even when the discrepancy with the detailed description is high.

4.2 Accuracy

Here is a brief summary of the statistical study carried out with 14 projects of community housing. Despite, a reduced number of projects to conduct a consolidated statistical analysis, this work furnishes a first oversight to highlight the interest of the approach.

		Minimum relative gap (%) (1)	Maximum relative gap (%) (1)	Average relative gap (%) (2)
Energy consumption	Total primary energy	5,4	67,1	6,6
	Nonrenewable energy	1,7	88,4	**7,8**
Abiotic depletion potential		0,5	94,4	**-4,7**
Water consumption		1,6	77,4	**-36,5**
Global warming potential		6,8	53,3	**-14,4**

Table 6: Recap chart of minimum and maximum relative gaps observed among the 14 projects and the calculated average relative gap; (1) for absolute value and (2) for real number; ; green highlighted values for smaller than 20 % and red highlighted values for higher than 50 %

Table 6 gives, on both first columns, a summary of the observed minimum and maximum relative gaps between the detailed and the macro-component simplified description among the 14 projects. These relative gaps are in absolute value to correctly take into account both negative and positive values. This demonstrates that some projects can be accurately described with macro-components and others less precisely. This can easily be understood by considering the data. In fact, the macro-components are described with generic data while the detailed description is performed with specific data. If the specific data is close enough from the generic one, the relative gap is low and in return, if the specific data differs widely from the generic one, the relative gap is high. This also highlights the limitation of generic data widely preferred to specific ones in eco-designing process. From then on, it appears that a clear representation of the statistical distribution considered for the

calculation of the generic data as well as an evident positioning of this value within the distribution is the only way to give people all the keys to interpret the results.
Table 6 also shows the average relative gap calculated from the 14 projects and helps to put into perspective the maximum relative gaps.

Figure 3: Schematic illustration of a statistical distribution by a boxplot and the positioning of obtained results within this distribution; black circle = mean value; red stars = outside 1st and 3rd quartile values; green stars = inside 1st and 3rd quartile values

Figure 3 gives an illustration to summarize the previous observations. One can see the boxplot representing the statistical distribution of the 14 samples. The calculated generic macro-components, chosen according the representativeness and the use frequency at the territorial scale, lead to a generic building represented by the black circle. Then, the relative positioning of the sample values compared to this mean is given by stars, green ones for *close to the mean* values and red ones for *not so close to the mean* values.

This trend is confirmed by the statistical analyses on 9 individual housing projects (results not shown) leading to similar conclusions.

Finally, this condensed summary helps to understand the interest of the approach and also highlights some enhancement possibilities as well as limitations that would have to be considered but unlikely avoided.

4.3 Time saving

Last but not least, few words about the time saving coming out the use of macro-components. The average time is 1 hour and 45 minutes to describe the shell and loadbearing structure and the architectural trades. Then, by emphasizing the simplification and adaptation approach in the broad sense to all other contributors, one can comfortably figure out the potential to conduct a complete building LCA in a half-day. This has to be compared to the four/five days spent in the framework of the HQE Performance to perform the detailed description. These are informal information given by the users but not exactly timed. However, the gap is so important that we can still get a good idea of the approach potential.

5. Conclusion

This work as a whole leads to first validation results and potential enhancement possibilities for a clear positioning of simplified building LCA results. Even if some observations seems to state the obvious, it is of prime interest to clarify this positioning and allow people to eco-design not only to compare variations but also to aim for and assure performances.

The approach can now correctly be recognized as an adaptation method to offer time saving with a potentially good accuracy. Some limitations can already be identified and we can easily foresee that some of them will not be avoided. However, these limitations could likely be circumvented by providing interpretation tools in a total transparency. As an example, ways to read into generic data as well as uncertainty displaying would facilitate result analyses and decision making. The interest of the approach is even more justified by the possible reproducibility increase that would lead to a great confidence in tools and an easier continuity and result exchanges between stakeholders.

This study will be continued to consolidate these first results and improve the robustness of the approach. A statistical analysis being performed at a national scale, the ongoing HQE Performance project, will also help the validation and make the conclusions clearer. The as-obtained results will also lead to improvements in order to ensure the modularity from the "screening" to the "complete" studies. All this work is a validation of the specifications and the tool is under development to offer scalability to the ELODIE database. This feature has to allow the creation of macro-component from the building products with flexibility to match user needs.

Short Summary

This paper presents a life cycle assessment (LCA) case study of an office building. The case study investigates how the setting of free parameters (adopted from the CEN/TC 350 standards) influences the results of the building's LCA in the DGNB certification scheme for sustainable buildings. The parameters concern the reference study period and the energy supply scenarios. Furthermore, a set of toxicological impact categories are included in the assessment to test whether the toxicological impact potentials follow the same trends as the impact categories already included in the DGNB methodology

Keywords: building LCA, reference study period, energy scenarios, impact categories, DGNB

1. Introduction

Increased focus on sustainable production and consumption has led to numerous mappings of energy use and environmental impacts from different sectors of today's society. This mapping serves two main purposes: to quantify the potential environmental impacts of a sector and to assess where impact improvements of a sector can be made. The building and construction sector operations, associated with housing and office- and industrial services, make up as much as 40 % of society's final energy consumption [1]. Furthermore, building occupancy and structure account for up to 20-35 % of most other environmental impact categories associated with buildings such as greenhouse effect, acidification, smog formation, eutrophication, land-, resource- and water use and waste generation [2].

In a Danish context, the founding of the Green Building Council Denmark in 2010 marked the beginning of a collective effort from a range of stakeholders in the Danish building industry to develop a nationally tailored sustainability assessment framework for buildings. The German developed DGNB International certification was chosen as the role model scheme on which to base a Danish certification scheme. Since then, the parties involved have worked on the adaptation of the system to meet Danish regulations and conditions [3]. In the meantime, on a European level, the finishing of the European CEN/TC 350 standard series on Sustainability of Construction Works is approaching [4]. It is the explicit goal of the DGNB International to have the certification scheme complying with these European standards, and the Danish version of the DGNB scheme must therefore also take this framework into account in the adaptation process.

Both the CEN/TC 350 standards and the DGNB International certification scheme make use of the LCA methodology to evaluate the environmental sustainability of buildings, but whereas the CEN/TC 350 standards present a broad framework for the evaluation of sustainability, the DGNB International is a concise recipe for the evaluation process, complete with system boundary settings and benchmark values. In this sense, the DGNB International scheme serves as (one of

many possible) translations of the CEN/TC 350 standards into an applicable scheme for sustainability evaluation.

Important system and scenario settings for the LCA in the DGNB International are:

1. The choice of reference study period, i.e. the period in which the environmental effects of the building's life cycle are accounted for and distributed over. For office buildings the study period is defined as 50 years
2. The choice of energy supply for the building's use stage, i.e. the data input concerning the technologies producing energy for the building's consumption of heat and electricity. For office buildings the input of electricity is specified to be the European grid mix and the reference input of district heating to be a mix of 65 % thermal energy from natural gas and 35 % thermal energy from hard coal
3. The choice of impact categories, i.e. the environmental damage categories assessed in the study. In the DGNB International scheme two resource use categories are assessed (concerning the non-renewable and the renewable primary energy use) and five environmental impact categories (global warming, eutrophication, acidification, smog-formation and ozone depletion potentials)

These system and scenario choices defined by the DGNB scheme were questioned in the Danish adaptation process of the certification scheme. This paper presents the case study that was performed to explore the environmental impacts and hence the quantitative environmental sustainability implications of the system and scenario choices.

2. Method and study design

The case building was assessed using the DGNB simplified LCA methodology [5], which include the life cycle stages and processes shown in table 1. The life cycle stages covered by the DGNB simplified approach is a simplified version of the life cycle stages included according to the CEN/TC 350 standards.

Table 1: Life cycle stages and processes included in the case study

Product stage	**Use stage**	**EoL stage** (End-of-life and benefits and loads for the next product system)
• Raw material supply • Transport to manufacturer • Manufacturing	• Operational energy use (heat and electricity for building operation only) • Replacements of materials and components	• Waste processing • Disposal • Reuse, recycling, recovery potential

The life cycle impact assessment was carried out applying the CML 2001 methodology [6]. Since one purpose of the case study was to investigate how a broadening expansion of the included impact categories could potentially change the environmental impact profile of the building, four toxicological categories (presented in *italic* in the list below) supplement the other seven categories assessed in accordance with the DGNB scheme:

- Acidification potential (AP) in [kg SO_2-equivalents]
- Eutrophication potential (EP) in [kg PO_4-equivalents]
- Global warming potential (GWP) in [kg CO_2-equivalents]
- Ozone depletion potential (ODP) in [kg R11-equivalents]
- Photochemical ozone creation potential (POCP) in [kg ethene-equivalents]
- Primary energy use, non-renewable (PEn.ren) in [MJ]
- Primary energy use, renewable (PEren) in [MJ]

- *Freshwater aquatic ecotoxicity potential (FAETP) in [kg DCB-equivalents]*
- *Human toxicity potential (HTP) in [kg DCB-equivalents]*
- *Marine aquatic ecotoxicity potential (MAETP) in [kg DCB-equivalents]*
- *Terrestrial ecotoxicity potential (TETP) in [kg DCB-equivalents]*

For the study we set up and analyzed different product system scenarios for the case building. Table 2 lists the free parameters and the setting of these across the four scenarios assessed. Inclusion of toxicological impact categories in the LCIA step is carried out only on the reference scenario 1.

Table 2. Scenarios and parameters assessed in case study

	Scenario 1 Reference	**Scenario 2 Long reference study period**	**Scenario 3 Danish energy supply**	**Scenario 4 Forecast energy supply**
Study period in years	50	100	50	50
Electricity supply	EU-25 grid mix [7]	EU-25 grid mix [7]	Danish grid mix, 2010 [8][9]	Danish grid mix, average 2010-2060 [10]
Heating supply	District heating (100 % natural gas) [11]	District heating (100 % natural gas) [11]	Danish district heating mix, 2010 [10][12]	Danish district heating mix, average 2010-2060 [13]

2.1 The case study

The case study office building is the headquarters of a larger Danish company. Main characteristics of the building are presented in table 3.

Table 3. Case building main characteristics

Building type	Office
Location	Bagsværd, Denmark
Expected use	45 h/week
Gross floor area (GFA)	31,135 m2 distributed on 8 storeys (2 of these are underground, partly serving as parking space)
Building structure	Concrete, steel
Building envelope	Flat roof, ¼ of roof area made up by steel framed glass dome, façade of glass, white glazed tile, aluminium lamellas
Expected energy consumption (building operation only)	13.8 kWh/m2/year district heating 12.3 kWh/m2/year electricity from grid

2.1.1 Product stage.

The product stage modules accounted for cover the materials used in the following 8 building component categories: foundations/floor slabs, structural parts/columns, staircases, roofs, ceilings/floors, external walls/facade, internal walls/doors, and central heating/cooling. In accordance with the DGNB International simplified methodology the inventory does not include connecting parts (e.g. screws, bolts, concrete anchors), exterior activities (e.g. landscaping), nor user specific electronic equipment (e.g. personal computers, refrigerators, desktop lamps).

Around 50 different building materials were identified in the case building. Table 4 lists the mass of the building materials distributed on 11 main material categories.

Table 4. Mass of building materials in main categories

Building material category	Concrete, screed and mortar	Gravel and natural stone	Steel	Gypsum based materials	Glass	Insulation materials	Tiles and ceramics	Paints and primers	Wood based materials	Plastics	Aluminium
Total mass [1000 kg]	38,660	6,280	3,950	675	340	290	210	105	85	75	70

2.1.2 Use stage.
The use stage modules of the product system model cover the expected use of energy (i.e. heat and electricity for building operation) and the expected consumption of building materials for replacements across the entire reference study period, here set as 50 years in accordance with DGNB International.

Data on the energy demand of the case building originate from the mandatory energy simulation of new buildings in accordance with the Danish building regulations [14]. The expected energy use for building operation complies with the requirement for the Danish low energy building class 2015.

Building materials are modelled to be replaced at the end of the required service lives respectively [15].

2.1.3 EoL stage and benefits and loads beyond the system boundary
Mineral waste (e.g. concrete, screed) is assumed to be recycled as road filling material, wood and plastics are assumed incinerated with energy recovery and insulation materials are assumed landfilled. Metals are assumed recycled and central heating and cooling appliances are directed according to the information given in their respective datasets.

2.2 Modelling of energy mixes

The case study further tested how a change from regional energy supply (EU-25) to national energy supply (Danish) influenced the results of the environmental profile. In conventional building LCAs, a status quo input of energy in the building's operation stage is used, i.e. the energy technologies used for the supply is assumed the same over the full 50 years of study period. In this study we tested the influence on results of using a projected future energy scenario with a higher share of renewable technologies in the years to come. The future energy scenarios were modelled partly as linear projections from the 2010 statistics. Endpoints in the projections are "expert projections of year 2050 scenarios" for both heat [13] and electricity [10].

The specific compositions of the energy mixes used in the modelling of scenario 3 and 4 are presented in figures 1a-b.

It was necessary to project the future energy scenarios further than the 2050 scenarios in order to reflect the full 50 years of reference study period. The period 2050-2060 is projected as a 2050 status quo. The dynamics of the energy supply composition in the full period 2010-2060 is reflected in the system modelling by applying average contribution shares from each technology within the 50-year reference study period.

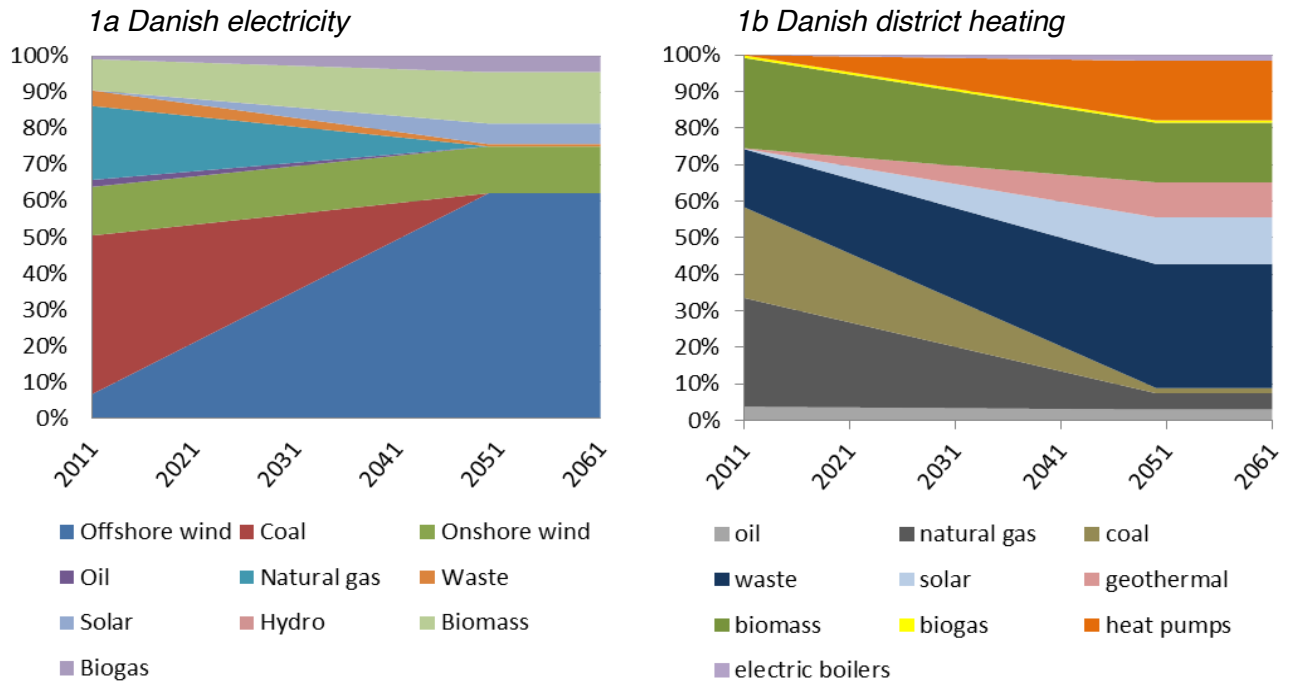

Fig 1a. Scenario of fuel/technology shares in the Danish electricity production 2011-2061 [16]

Fig 1b. Scenario of fuel/technology shares in the Danish district heating production 2011-2061 [16]

3. Results

Results obtained from the reference scenario 1 for the life cycle stages covered are presented in figure 2a. For all environmental impact and resource use categories, the use stage modules (heat and electricity consumption, replacements) have the largest impact contribution to the total impacts. Material-related impacts (production and replacements) are contributing with more than 50 % of the total impacts within the impact categories EP and POCP and 35-40 % of the embodied energy demand (renewable and non-renewable).

The results from scenario 2 highlight how the contributions to the total change when the reference study period is prolonged to 100 years. The total differences from the reference scenario's impact results are presented in figure 3. The 10-20 % lower impacts/m^2/year in the impact categories are caused by the decreased impact contributions from the building materials used in the completed building prior to the use stage. Since the impacts are given per m^2 per year, the impact contributions from building materials are distributed over twice the number of years (i.e. 100 years) as in the reference scenario. Thus, the contributions from building materials to the impact categories, presented in figure 2b, decrease from 20-50 % of the total impact in the reference scenario to 10-35 % of the total impact in scenario 2.

The use of the Danish electricity and district heating mixes in the modelling of the use stage yields impact results in scenario 3 that vary considerably from the reference scenario applying European energy mixes. Figure 3 reveals how the impact from the building increases with up to 5 % within the impact categories EP and GWP. For other impact categories, the total impact results are lower than the reference, up to 33 % lower within AP and 56 % lower within ODP. The impacts from PEren are app. 175 % higher in scenario 3 than in the reference scenario 1. Looking at figure 2c and the contribution from the different life cycle stages to the total results, scenario 3 also shows large changes in the share contributed from the building's energy demand (electricity and heat). In the impact categories AP, ODP, POCP and PEn.ren the contribution from the energy demand decreases by 10-20 percentage. In the EP and GWP impact categories the contribution from the energy demand increases by a few percentages from the reference scenario 1 to scenario 3. For the PEren category the contribution from the energy demand increases by 25 percentage points.

In scenario 4 the energy mixes were modelled in order to reflect a projected development of the technology composition of the energy production. Figure 3 illustrates how the impact from the case building increases considerably in the PEren category with a more than 300 % increase in scenario 4 relative to the reference scenario. In all other categories impact results are lower than the reference scenario results, ranging from 2 % lower impact in the EP category and to 53 % lower impact in the ODP category. Figure 2d illuminates how the contribution from the energy demand to the total impacts is dramatically reduced compared with the reference scenario. The contribution from the building materials (original building and replacements) is noticeable within each impact category with PEren as the only exception.

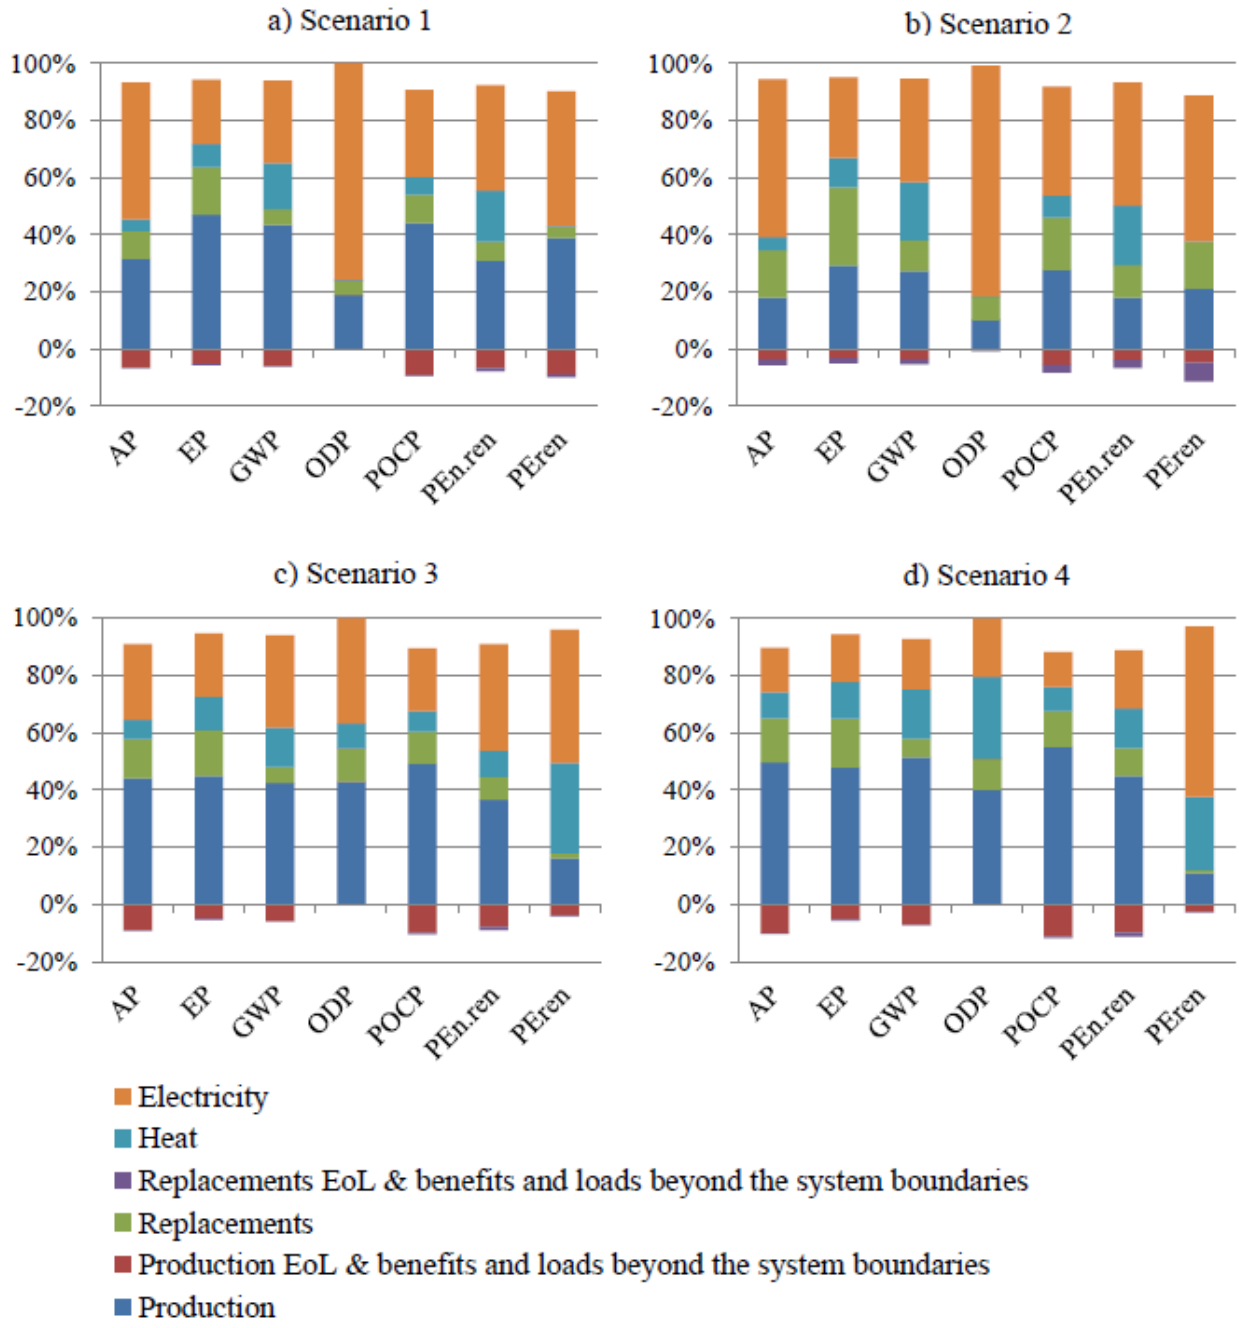

Fig 2a-d. Environmental impact results and resource use contributions from the individual life cycle stages of the different scenarios

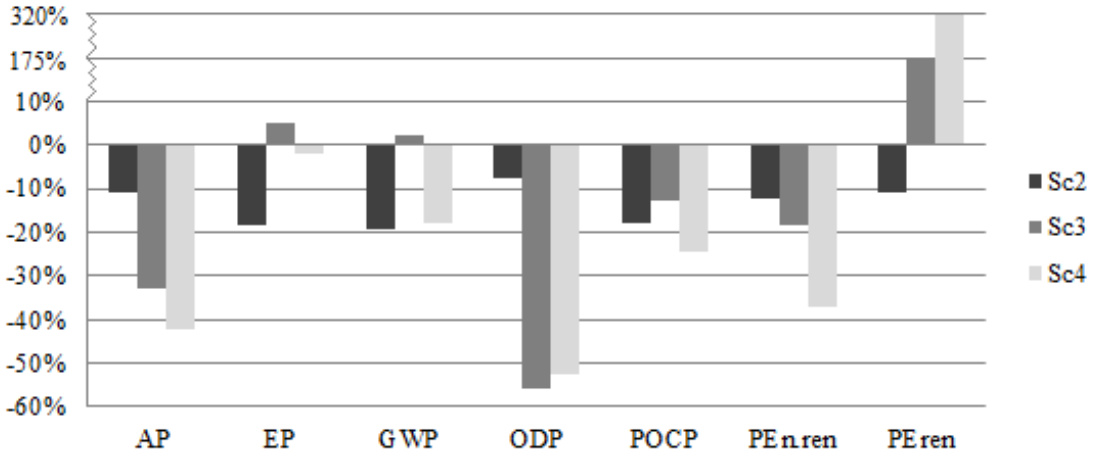

Fig 3. Differences in impacts potentials per m^2/year for scenario 2, 3 and 4 relative to scenario 1

The toxicological impact potentials from scenario 1 are given relative to the contributing life cycle stages in figure 4. Building material related impacts from the original construction and replaced materials are dominating the total impacts across all four toxicological impact categories with contributions amounting to 60-80 % of the total impact. In the FAETP category the impact from replacements is contributing with the same share of the total impact as the production of all the originally installed building materials.

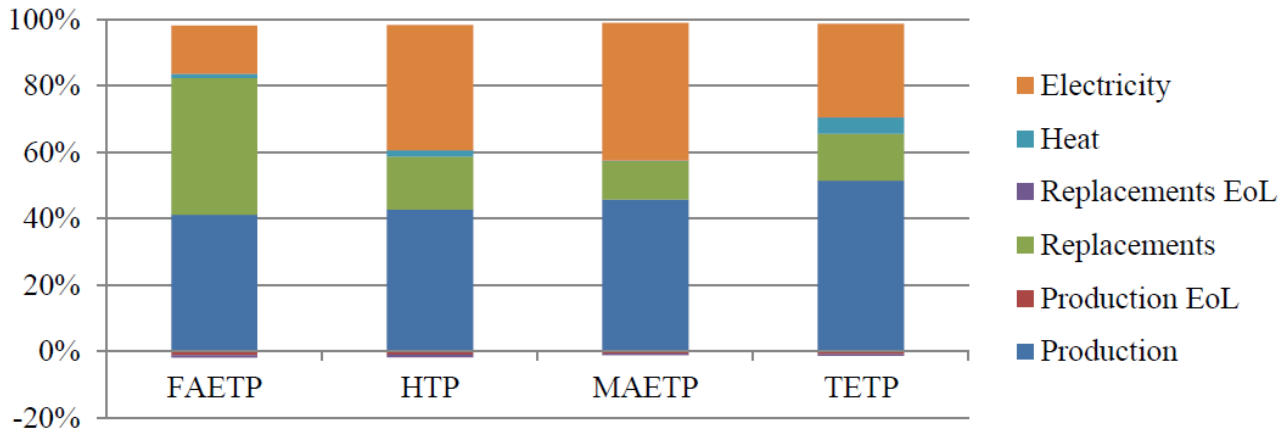

Fig 4. Toxicological impact contributions from different life cycle stages – Scenario 1

4. Discussion

As the results from this case study illustrates, the environmental burden of a building can vary as much as 20 % in some impact categories depending on whether a study period of 50 or 100 years is used (cf. figure 3). Other studies have similarly shown considerable changes in impact results for one or more impact categories [17, 18, 19, 20, 21] depending on the reference study period.

Traditional structural elements, concrete and steel, have expected service lives in the range 80-100 [15] and a required service life of a building containing these structural elements could thus easily be defined as 100 years. The use of a shorter reference study period does not justify the use of long lasting/high quality building materials. Such assumptions could possibly lead building designers to choose materials that are not necessarily environmentally beneficial. However, an expected life span and reference study period of 100 years is a long time span when scenarios are founded on current data, energy consumptions and EoL technologies. The uncertainties connected with this kind of long study periods, would hence make the results more unreliable as a whole.

Environmental impacts from energy consumption in a building's use stage have generally proven a major contributor to impact potentials of buildings [17, 22, 23, 24, 25], and the type of energy input does therefore have a potential strong effect on the environmental results. The impact results from scenario 1 to scenario 3 confirm this picture with substantial changes within some impact categories. The use of national energy mixes in the LCA modelling is hence necessary to obtain more exact results. Furthermore this way of modelling the energy supply complies with recommendations on defining energy supply system boundaries in LCA where local data should be preferred, i.e. the local district heating grid and the national electricity grid mix [26].

The focus of LCAs on energy consumption in buildings is generally on the influence of changes in the building's energy demand [27, 28, 29]. Scenario 4 explores the relevance of changes in the energy supply mix for the building. The results from scenario 4 revealed considerable changes in all impact categories, reductions in all (e.g. a 20 % reduction in the GWP and a 40 % reduction in the PEn.ren categories) but one case (PEn.ren, cf. figure 3). The energy system will in reality develop, and most likely to a composition with more input from renewable energy sources [10]. Results like those obtained from scenario 4 may hence come closer to the actual impacts of the building. However, the energy supply development could take place in a number of ways; new technologies are introduced, known technologies are improved, and a simple model of the future energy scenario will not be able to take all of these aspects into account. For the sake of comparison possibilities of building LCAs at early stages of the building's life span the status quo future scenarios (i.e. no energy supply mix dynamics) serves adequately.

The most commonly included impact categories in building LCAs are GWP, AP, EP, ODP and primary energy consumption. Toxicological impact potentials however, are rarely included in the LCA of buildings [30, 31]. Results from our study show how the toxicological impact profiles of the building do not follow the same trends as the other impact categories. Building materials, originally installed and replaced, contribute more than energy consumption to all toxicological impact categories assessed. This is opposing the general trends in the other assessed impact categories where the energy consumption, with a few exceptions, accounts for the largest impact share. The inclusion of toxicological impact categories can thus be seen as an important broadening of perspective. However, the toxicological impact categories would be difficult to include in the DGNB scheme because the background data on toxicological impacts is not included in the European standards on environmental product declarations of building materials, the EN 15804 [32].

5. Conclusion

This case study investigated some of the free parameters of the CEN/TC 350 standards on sustainable construction work. The free parameters investigated; the reference study period and the choice of energy data have been set in the practical application of the standards in the DGNB certification scheme for sustainable buildings. In the adaptation of the DGNB scheme to Danish conditions it has been desirable to know how the parameters affected the results of the environmental profile of the building.

The results of the case study illustrate how a 50-year study period cannot justify the use of long-lasting materials. On the other hand, a study period of 100 years increases the uncertainty of the scenarios on energy input and replacement.

National or local data on energy production should be preferred to regional data, so as to give a more correct picture of the actual environmental effects of the building. This approach is already being followed in the Danish DGNB adaptation process. The use of dynamic energy scenario modelling may prove to provide results which come closer to the actual situation of the building. However, the uncertainties connected with this kind of projections can be considerable.

The contributions from the life cycle stages to the toxicological impact categories do not follow the trends found in the other impact categories. The inclusion of toxicological impact categories thus widens the perspective of the environmental profile of the building. In practice however, it will be difficult to include the toxicological impact potentials as part of the certifications scheme, because the background data is not readily available in the standardized environmental product declarations.

Summary

Life Cycle Assessment (LCA) based Environmental Product Declarations increasingly become a default communication format for construction product manufacturers – e.g. based on the new EN 15804 standard [1]. In sustainable building certification schemes, particularly in those of the DGNB and its partner organizations across Europe, e.g. ÖGNI in Austria, LCA of buildings is well established as default mechanism [2, 3]. In both areas – product LCA for EPDs and building LCA for certification – the method has matured from research into daily application and planners increasingly use LCA for decision support during the planning process.
This in turn raises the question: What future developments can we expect for LCA in the construction sector?
This article indicates different upcoming developments in LCA that are either already under way – yet not necessarily generally visible – or that are likely to come. Some developments indicate increasing harmonization of calculation methods, e.g. across Europe. The European research project “EeBGuide”, for instance, yielded a comprehensive set of guidelines and provisions to uniformly conduct LCA studies in the construction sector [4].
Other developments include the assessment of new environmental aspects such as scarcity of abiotic resources, water consumption, land use, biodiversity or toxicity, always covering a product’s or building’s life cycle.
Also the improvement of LCA for use in the planner’s daily work reflects a visible trend in the field of LCA. This includes simplified methods for building LCA and automatic connections of LCA models and software to planning tools. The link of LCA to decision support in building planning – e.g. by identifying major drivers for environmental impacts of building, reported through LCA – forms another basis for future LCA-developments.
The article outlines which trends are in sight and the need for research activities in the different fields is mentioned. Focus of those discussions hereby lies on the need for pragmatic implementations of new developments into the practical use of LCA.

Keywords: Life Cycle Assessment; Environmental Product Declarations (EPD); Building Certification; EeBGuide; Future Developments.

1. Introduction – LCA in the building and construction sector

Life Cycle Assessment is a method used to assess the environmental performance of product life cycles. It is used in the building & construction sector to assess several environmental indicators that are part of building certification systems. It is also used to declare the environmental performance of construction products within Environmental Product Declarations. In addition to that, LCA is used e.g. in research projects to investigate the environmental preference of new technologies against existing technical systems.
LCA has matured from a method used solely for research purposes to an instrument that is regularly used and that currently finds its way e.g. into architects' workflows. It is well established as a method, and for specific purposes, it is readily available for use by non-LCA-experts. In order to make LCA available for no-LCA experts, methodological choices and calculation rules have been defined and consistent LCA databases have been implemented as a basis for consistent and transparent LCA studies. For the specific application of LCA, some tools are available for use [5].
Two major fields, where LCA is used on a regular basis are laid out below. These fields outline the basis for upcoming developments in the field of LCA that are detailed afterwards.

1.1 LCA in building certification

Within the German building certification systems of the German Sustainable Building Council (Deutsche Gesellschaft für Nachhaltiges Bauen, DGNB) and of the German federal ministry for building & construction (Bundesministerium für Verkehr, Bau und Stadtentwicklung, BMVBS), LCA plays a core role for the assessment of buildings [3, 6]. Both systems are closely related and define LCA as a mandatory assessment method for sustainable buildings. The German federal government also defined the assessment of the sustainability of buildings – and hence LCA – to be a mandatory element of the planning of certain public buildings [9].
The certification systems contain detailed calculation methods for building LCAs, the federal ministry for construction released a publicly available database for LCA data of construction products, called 'Ökobau.dat' [10] and benchmarks are defined for the environmental performance of building life cycles.
The British building certification system BREEAM ('BRE Environmental Assessment Method') also has a long history of incorporating LCA into the certification system. The consideration of LCA, however, is done on the basis of standardized assessments of building elements and LCA-based ratings of these elements. These elements are listed in the 'green guide to specification' [11] which serves as the basis for building assessments.
The certification system LEED ('Leadership in Energy and Environmental Design', U.S.A.) allows a full building LCA to be conducted for obtaining an optional credit. Several impact categories are defined and the LCA is required to demonstrate a certain reduction of impacts against a reference building. [7]
All in all, LCA has already found its way into several building labelling schemes where it is applied on a regular basis.. However, an increasing use of LCAs is expected, partly along with an increasing use of building certification, partly due to the efforts to adopt LCA into existing schemes.

1.2 LCA for Environmental Product Declarations

Besides applying LCA on entire buildings, construction products are the second large subject for LCA in the building & construction sector. Product LCAs describe the environmental impacts over a product's life cycle, using specific assumptions on how the product will be utilized and later recycled.
Product LCAs form the basis for Environmental Product Declarations (EPD) of construction products. Such declarations – type III declarations as defined in ISO 14025 [12] and for construction products specifically described in EN 15804 [1] – declare the environmental profile of

a manufacturer-specific construction product.
EPDs are registered within an EPD programme, which organizes the development of calculation rules – Product Category Rules (PCR) – the independent verification of the EPDs and the dissemination of the EPDs.
The advantages of EPDs are primarily that LCA practitioners have a sound data source for product-specific LCA profiles at-hand. This improves the quality of building LCAs and permits the reflection of the specifically built building, using the product LCAs for the construction products used. For manufacturers, in turn, the dissemination of environmental profiles of their products enables prospective customers to decide on the product use on the basis of also environmental data. This also means that in construction projects, where LCAs are to be conducted, e.g. because a building certification is intended, the mere availability of an EPD may lead to the decision for the respective product, as the availability of LCA data is of major importance.

1.3 LCA in research

LCA as such is subject to research, yielding a continued evolution of LCA. These directions include the development of indicators e.g. for water consumption [19], for land use [20]. Developments also are directed towards better availability of inventory data ('LCA datasets') to address the practitioners' needs for regionally (e.g. nationally) specific data and for a wide range of e.g. building material data.
In general, however, a strong focus lies in the use of LCA for practitioners, rather than in the continuation of methods development for LCA.
LCA is also frequently used in research projects to discuss the environmental advantages of one technology against another (e.g. European FP7 research projects Cost-Effective [13]).

2. Upcoming developments

While LCA is well established in the building & construction sector in the named ways, a number of new developments concerning LCA in the construction sector are well under way or are emerging. They include an increasing relevance of LCA for political activities and legislation, harmonization activities on different levels and by various methods, as well as the introduction of new indicators. On the back of such developments, real trends may come along. Following the description of developments in sight, an interpretation concerning those trends is given.

2.1 LCA in legislation and on political agendas

The new European Construction Products Regulation (CPR) [14], replacing the Constructions Products Directive, calls "sustainable use of natural resources" as one of seven basic work requirements for the marketing of construction products across Europe. So far, no specific guidance is given on how to address this novel basic work requirement. The European Parliament, however, identified Environmental Product Declarations as a feasible means meet the respective requirements of the CPR. As a consequence, LCA of construction products may contribute to meet the legal requirements for trading construction products in Europe.
In addition to the call for EPDs of construction products, the EPD-rules of the EN 15804 standard are currently implemented in some of the harmonized standards of construction products. Such standards define the technical specifics for construction products and their testing to be compliant with European legislation. The inclusion of LCA-based assessments into European Technical Assessments (ETA, formerly known as European Technical Approvals) and national approval routines in one way or another may also well be expected.
This yields a situation, where LCA-based product information as part of EPDs is conceivable to be mandatory for all building products within the European market. The current on-going developments in France regarding the environmental labelling of products can be seen as a first step in this direction [21]. This could have a major impact on the use and distribution of LCA in

Europe. A significant pressure on simplification, harmonization and appropriate tools for LCA would be the consequence, in order to enable non-LCA experts to perform product LCA studies.
In addition to EPDs based on EN 15804, the European Commission's Joint Research Centre developed an LCA-based Product Environmental Footprint (PEF) [16]. This method is intended to promote the use of life cycle based environmental assessment by simplifying LCA and is not limited to the category of building products. The method has been established too recently to be able to comprehensively discuss its' relation to EN 15804 based assessments or its' practical applicability

2.2 Harmonization for wider acceptance

The first step for harmonization of methods is obviously the development of standards that define LCA as a method to assess the environmental performance of buildings, construction products and services. This is the case for the European standards EN 15804 – assessment of the environmental performance of construction products [1] – and EN 19578 – assessment of the environmental performance of buildings [15]. The standards, along with corresponding ISO standards under development (ISO TC 59 / SC 17), represent a basic level of harmonization of LCA calculation rules with a broad consensus. Additionally the ILCD handbook [22] is giving general guidance and provision on how to conduct LCA studies. Further harmonization activities are for instance initiated by the Sustainable Buildings Alliance (SBA). The SBA, being a forum of international building certification institutions, developed a set of core metrics for building certification, which includes LCA based "common carbon metrics" [17].
A European project that was explicitly dedicated to providing consistent calculation rules for LCAs in the construction sector was the EeBGuide project (www.eebguide.eu). The project duration was from Nov. 2011 to Oct. 2012 and yielded a comprehensive guidance document for LCA studies of buildings and building products [4]. While the project's core objective was to provide LCA-guidance for European research projects, a clear focus of the guidance document also lies on harmonizing existing LCA approaches and providing rules that can be used for various purposes and still are capable of yielding consistent results. In addition to that, the work conducted also had a strong focus on practical applicability and robustness of the results [23].

2.3 New indicators

LCA is used to assess the environmental performance of a technical system with regard to various fields of environmental concern. 'Typical' indicators – indicators that have been frequently used in the past – include Global Warming Potential (GWP), Eutrophication Potential (EP) or Photochemical Ozone Creation Potential (POCP). As a consequence of the discussions of the different standardization bodies, indicators found their way into standardization that have not been frequently used by all LCA practitioners. Such indicators include Abiotic Depletion Potential for non-energetic material resources and for material resources with heating value. Other indicators cover fresh water consumption or Life Cycle Inventory information such as use of secondary material as material or as energy source. In addition to that, the recommended Life Cycle Impact Assessment Methods (LCIA) of the ILCD include indicators that are similar, yet technically different to CML-indicators [4]. Indicators such as water consumption or land use, are subject to LCA research, yet have not been brought to a level where they may be used in daily operations by non-LCA-experts. All in all there is a tendency within the LCA community to try to quantify environmental consequences that have not been assessed quantitatively in the past, such as land use or impacts on biodiversity.

2.4 Conclusions: Trends

While trends are difficult to be proven by means of rock-solid evidence, this is an attempt to identify trends derived from the above given developments. Hence, this should not be seen as a 'final' list,

but rather as an invitation for discussion. One major trend is surely the wide recognition of LCA beyond scientific application. LCA is already in use for planning and financing decisions in the sustainable building sector and is increasingly coming into the focus of building product manufacturers. This trend may lead to tremendous movements and changes in the LCA field, more so, if it really ever happens to become a legally mandatory assessment method. (In fact, it should be noted that for very specific purposes, it already is legally mandatory – e.g. as part of the mandatory sustainability assessment of the new construction of public federal buildings in Germany [5].)
The second large trend that is believed to be visible is derived from the developments of harmonization, standardization and indicator development: while LCA moves into the public focus, demands grow towards the method that it should be able to reflect the environmental consequences of human interventions more comprehensively and more comparatively. This trend may and quite likely will initiate increasing research activites towards both of these two demands: harmonization and indicator development.
Based on the presented developments and the concluded trends, research fields open up. The following section attempts to outline the areas where specific research on LCA-related topics is needed.

3. Need for dedicated research

LCA has reached a state where it is well used by practitioners of various professions. LCA experts provide support for building planning, product manufacturers start to incorporate EPD-generation functionality into their ordering and planning tools and architects start to use LCA as planning tool on a daily basis.
Nonetheless, on the level of research and scientific advancement, it should not be forgotten that a method like LCA needs constant adjustments to be able to address new aspects. It is crucial, however, to direct research to dedicated fields of interest. Some of these fields are given below. They may also be understood ideas to develop research activities in these fields. Yet, it should be noted that the mentioned fields are mere examples and other fields exist additionally and may be equally relevant.

3.1 Benchmarking building performance

Benchmarks and LCA benchmarks in particular are very important not only to rate a building, product or service but also to get a general understanding for the environmental impact of any human intervention. Thus, in building certification schemes, a comparison of the results of one building with a given benchmark should be performed, rather than just conducting an LCA study without benchmarking [18]. The understanding of such benchmarks, their technical justification and possibilities for future developments of benchmarks is an important, yet somewhat neglected aspect. Existing benchmarks may be based on a limited number of data and assumptions. A cross-examination against large statistical samples may confirm the original assumptions for benchmark generation or may yield to partial revisions. All of the currently available building labelling schemes so far lack these scientifically sound benchmarks, both on a broader European level and on a national level. The European research project OPEN HOUSE [24] gave an initial outlook on LCA benchmarks for buildings on an European level, but so far, the number of case studies is not sufficient for statistically robust benchmarks.
Also, having the general aim of building certification – being the transformation of the built environment into a more sustainable state – in view, benchmarks should be defined in a way that a long-term market transformation may be initiated. For some indicators, political goals may define long-term emission reduction targets which could be supported by adequate benchmarks, if the scientific link between building benchmarks and political targets can be given.

3.2 Understanding the relevance of planning decisions

In the past, LCAs of buildings have mostly been isolated case studies of individual buildings, new constructions or retrofit measures. Some common rules have been identified in the past, such as that insulation in typically used ranges is always preferable for the life cycle impacts of a building.

Yet, beyond such very basic conclusions, it is extremely difficult or impossible to draw general and valid conclusions from different case studies that have different scopes, system boundaries, assumptions, etc. In order to better understand the environmental performance of buildings and the relevant drivers, such conclusions concerning the relevant decisions of planners are of major importance. Certification systems utilizing LCA provide the grounds to investigate LCA studies with regard to finding the drivers for environmental impacts. These LCAs are based on common databases, pre-defined calculation rules, etc. Statistical and empirical analyses of these LCAs may lead to a better understanding of the environmental performance of buildings.

3.3 Simplifying LCA

As LCA increasingly becomes available to planners and architects, the method evolves to an instrument actively used in planning processes. This, however, also means that LCA cannot remain an expert instrument available only to those who have in-depth knowledge on LCA as a method, but it must also become available to practitioners on a more applied level. For this, the LCA methods urgently require simplification. Simplifying LCA, could be done by merely cutting off some aspects rather randomly. Yet, this would greatly increase uncertainty, whether the LCA covers the major environmental impacts reliably.
For simplifying LCA, a sound understanding of generally less relevant aspects is necessary. With such knowledge, the method could well be brought to a level, where planners could easily apply LCA in their daily work with less intense training than today.
Hence, simplification and harmonization of LCA in terms of methodology and relevance is important.. There is a great need for professional LCA software for non-LCA experts. Within such software, specific calculation and methodological rules, standardized reporting templates and a simply user interface need to be implemented [25].

3.4 Indicators to assess current environmental issues

LCA is typically used with a set of well-known environmental impact categories. In the construction sector, a number of aspects, however, is also of importance. Some of these aspects are available in principle to be assessed within an LCA. These indicators include for instance the consumption of potable water, the use of land as a resource, impacts on biodiversity, but also the emission of hazardous substances from construction products, the management of waste (during construction and during use).
Three core challenges exist with new indicators in LCA:

- they need to be supported by the relevant LCI data, hence, LCA databases must provide these LCI data adequately, without asking the practitioner for extensive additional data collection,
- they need to be aggregated over the entire life cycle of a product into single values without losing their core information, and
- they need to be accurate enough to reflect the decision options that are available, as LCA is generally used for decision support.

Yet, providing indicators that are of interest to those who apply LCA for their purpose, will improve the acceptance of LCA and will hence generally improve the consistent assessment of the environmental performance of products and buildings.

4. Conclusions

Life Cycle Assessment as a method to investigate the environmental performance of products and technical systems is well established in the building and construction sector. LCA already serves to assess buildings and construction products in building certification systems and for Environmental Product Categories.
Upcoming developments include, among others, increasing efforts to harmonize the method and the integration of the method into political agendas and legislation. However, the continued development of the method of LCA should hereby not be forgotten. A number of subjects for further development can be identified and should be pursued. These fields leave wide open spaces for research activities, which are often tasks for consortia of several involved stakeholders.
Some of the research fields are described: understanding benchmarks for buildings and the relevance of certain planning decisions is necessary to improve the use of LCA as planning tool and for certification. In that context, the development of justified simplification approaches is also essential to improve the method's use for planners. And finally, the development of indicators to address the information demand is necessary work.
For all new developments, two things should also be kept in mind: LCA is a method to support decisions of one kind or another; it is never an end in itself. As LCA is relevant for decision making in numerous situations, it is a method that must provide meaningful answers and if the intention is – as it is the case in the construction sector – to have planners and building practitioners to work with LCA, then the method must be provided in a way that is useful for those who should use LCA. Researchers working to improve and advance LCA should always keep this in mind and should always assure that their work is not only scientifically sound and innovative, but also helpful for those, who are intended to use LCA.
Typically, scientific papers should conclude with an outlook on upcoming developments in the field that the article addresses. If the article's subject is an overview on upcoming developments, any further outlook would not make much sense. Instead, the reader should be encouraged to take up the hints given in this article to find research topics that have been identified as in need for further research and he could match those research topics with his own fields of interest and research in order to supply the LCA community with new developments. Such developments then yield any further and very much wanted outlook.

Short Summary
Sustainability assessments quantify impacts and aspects in order to analyse the environmental, economic and social performance of products and services.

EN 15643 states the methodology of Life Cycle Assessment (LCA) as one of the most efficient possibilities to determine environmental impacts and aspects based on transparent data and an extensive life cycle analysis.

In recent years the application of the LCA methodology increased intensively within the construction sector. On the level of construction products LCA established as an effective option to demonstrate environmental impacts of single products with a tendency to Environmental Product Declarations (EPD), which offer a high credibility due to their independent verification. The rising number of building certification systems increases the need of LCAs for the building construction. In contrast regarding built infrastructure the LCA methodology was applied marginal so far and mainly on research level.

This paper analyses and compares the application of LCAs within the Austrian and international construction sector. It is shown, which potentials exist on national and international level, and which gaps need to be filled in the upcoming years especially with regard to built infrastructure. Finally suggestions for further LCA-based research and development projects, which should focus on the applicability and the future profit for the Austrian construction sector, are made.

Keywords: Life Cycle Assessment, Environmental Product Declaration, buildings, built infrastructure

1. LCA - State of the Art

1.1 Sustainability

The Brundtland Report released by the World Commission on Environment and Development (WCED) in 1987 defines sustainable development as “development that meets the needs of the present generation without compromising the ability of future generations to meet their own needs and to choose their own lifestyle” [1].

In 1992, the definition of sustainable development was further concretized during the United Nations Conference on Environment and Development (UNCED) in Rio de Janeiro. At this conference Agenda 21 [2], a developmental and environmental action program for the 21st century, was created. In total 172 countries agreed on this document as a guide for sustainable development at the UNCED. Agenda 21 has become the guideline of public action in many countries and is considered to be a common basis for the future development of the world. Through this guiding document, the concept of sustainability was developed, founded on its three target dimensions: social solidarity, economic efficiency and environmental protection. These three dimensions can be defined as columns carrying the concept of sustainability with equal loads. In other words, sustainable development can only be achieved by simultaneous and equitable implementation of environmental, economic and social goals.

1.2 Life Cycle Assessment (LCA)

The methodology of Life Cycle Assessment (LCA) analyses and observes a product regarding its environmental impacts over its entire life cycle or over specific analysis periods [3]. An LCA is generally executed in four steps:

a. Definition of Goal and Scope
b. Life Cycle Inventory Analysis (LCI)
c. Life Cycle Impact Assessment (LCIA)
d. Interpretation

The goal of an LCA study can be defined by answering simple but essential questions [4]

- What is analysed?
- Why is the LCA carried out?
- For whom is it carried out?
- Will the LCA compare results of different products?

The goal of the Life Cycle Assessment has a great influence on the depth and accuracy of the analysis and therefore on the scope of the study. The scope of an LCA is described by the product system and the functional unit.
The product system is defined by setting the system boundaries and defining all process within the boundaries, i.e. all processes analysed in the LCA.
The environmental impacts stemming from the processes analysed relate to the so-called functional unit, i.e. the product systems analysed have to fulfil a specific function and therefore generate a certain benefit. This benefit should be the basis for the choice of the functional unit [5].

The Life Cycle Inventory (LCI) quantifies relevant inputs and outputs of the analysed product systems, e.g. materials and fuels applied as well as emissions and waste products.

The LCIA sorts, characterizes, weights and aggregates the inputs and outputs quantified in the LCI (energy, materials, emissions, etc.) according to the selected environmental indicators and their characterization and weighting factors. ISO 14040 states that the weighting and aggregating to “weighted indicator results” (e.g. ReCiPe Endpoint) is not allowed for public LCA studies comparing product options.

The LCA model analysing a product over its entire life cycle, including all processes from raw material extraction until waste treatment after the product is no longer useable, is called the “cradle-to-grave” model [3]. This model is mainly utilized to determine the environmental relevance of decision options, in other words, to compare the environmental impacts occurring over the whole lifetime of products fulfilling the same function and offering the same benefit [6].
The “cradle-to-gate” model analyses all processes until the finished product leaves the production plant. This model is applied for example to determine the environmental potentials of alternative production processes of a product, whereby it is essential that the optimized production conditions do not influence the environmental impacts of the use and end-of-life phase of the product [4, 5].
The “cradle-to-cradle” model can be used for the analysis of products that are recyclable for the most part. Thus, the cycle from the end-of-life phase to the production phase can be closed. This model is applied to demonstrate the environmental performance of products that are utilized with the same function after a recycling process [4].

1.3 Progress of standardisation

In Austria, the technical and functional performance in the context of sustainability assessments of buildings has not been specified yet. In contrast, the technical and functional requirements are defined in the Austrian OIB-guidelines 1-6 [7], which are largely in line with the essential requirements of the construction product directive [8, 9]. A first definition of technical and functional per-

formance is given below. Thus functional requirements are qualitative requirements used to describe a defined goal (e .g. demand on energy efficiency construction methods). The fulfillment of functional requirements is determined by the following different performance requirements (or technical requirements):

- Quantitative performance requirements (product-specific, construction-specific and building-specific) and descriptive/defining performance requirements
- The aggregation of the fulfillment of all described functional requirements as well as quantitative performance requirements and/or descriptive performance requirements leads to functional qualities and technical performance characteristics of a building, in accordance with the technical regulations e.g. [10].
- In other words, "functional quality" depicts the aggregation of the degree of fulfillment of the functional requirements. "Technical quality" reflects the degree of fulfillment of the aggregation of the individual technical requirements.

2. LCA in the construction sector

2.1 Construction Products – EPD

Taking into account the meaning of sustainability it is an important issue in the new Construction Product Regulation (CPR) of the European Union [11], which became completely and directly in to effect on 1 July 2013 in all member states of the European Union. In addition to the previous valid Construction Product Directive (CPD) [12] the sustainable use of natural resources is now implemented as a new basic requirement for construction works, which means that idea of sustainability has to be considered in all phases of construction works.

As a result the ecological assessment of buildings will gain a higher importance. But due to the high individuality of construction works (generally no mass production of buildings) assessments of the end products are a higher effort compared to other sectors of industry. As a consequence the ecological assessment of buildings must be reasonably based on a several-stage-assessment.

The foundation for the assessment of buildings is the assessment of single construction products, so called EPDs (Environmental Product Declarations). EPDs are executed as Type III environmental declarations according to ISO 14025 [13] and EN 15804 [14]. Evaluations are based on databases (e.g. “GABI” [15], “ecoinvent” [16]) certified by platform operators (e.g. Germany: IBU [17]) and verified by an independent board of experts. The ecological assessment is often completed by additional information concerning handling, application, health and safety.

By now EPDs for single products are available for almost all kinds of constructions products starting with the beginning of the product chain (e.g. cement, aggregates) ranging to pre-fabricated elements (e.g. pre-fabricated concrete elements). Assessments are carried out for single products of single producers as well as for product types for a whole industry sector of a product type.

Environmental product declarations (EPD) are important components for the assessment of structures and buildings. Nevertheless the effect of one product on the sustainability of the whole building is often low. Calculations of the Association of the German Cement Industry show the impact of construction materials on the ecological assessment for sustainable buildings by the example of cement [18]. The ecological impact of cement on the product concrete is calculated at significant 77 percent. For the construction phase of a typical building it is already down at 37 percent and considering all parts of a sustainable building certificate (e.g. maintenance, energy demand for use, social assessment) the impact of the cement production is only at about 1 percent.

The producers’ competition will probably force more and more companies to ecological assess their products. But due to differences of background databases, assumptions, allocations and simply due to the time factor of elaboration (e.g. rapid changes in the energy mix of electricity)

comparisons within the same product group will always be imprecisely and hardly useful. Moreover this area of application for EPDs would assume the knowledge of the exactly used product already in the planning process of a construction. That is – considering the present process of planning and building – not realistic.

The more promising application of EPDs will probably not primarily be the comparison of single products, but the as input data for the comparison of building systems. Taking into account the impact of construction products to the sustainable assessment of a building it should be precisely enough to work with EPDs of product groups. This approach allows the evaluation of construction systems in the first planning phase. If data is available for all product groups, a further improvement in the level of detail by the elaboration single product EPDs could be contemplated.

2.2 Buildings

In the past few years, an increasing number of building certification systems have been placed on the market [19]. Due to multi-characteristic influences in the context of sustainability assessments of buildings a complete evaluation criteria-structure is essential. A very large number of international building certification systems have existed since the 1990s. In the following, the two most common, LEED and BREAM, will be briefly described. In Austria, three national certification systems currently exist, DGNB/ÖGNI, klima:aktiv and ÖGNB (TQ-B). As regards assessment of buildings, these certification systems implement different approaches to environmental performance, e.g. completely or partly using LCA methodology. The differences between the three certification systems used in Austria are described below taking into account certifications on "new construction dwellings". Apart from already existing building certification system, reference is also made to the ongoing R&D European projects developed under the FP7 framework European as OPEN HOUSE[1] or SuPerBuilding[2].

2.3 International building certification systems

2.3.1 LEED

The Leadership in Energy and Environmental Design (LEED™) Green Building Rating System is a third-party certification program developed by the U.S. Green Building Council (USGBC) in 2000. Its latest version is LEED v2009. LEED is a point-based system for buildings of all types and sizes where building projects earn LEED points for satisfying specific green building criteria. The five categories include sustainable sites (SS), water efficiency (WE), energy and atmosphere (EA), materials and resources (MR) and indoor environmental quality (IEQ) and an additional category, innovation in design (ID) which addresses sustainable building expertise as well as design measures not covered under the five environmental categories.
According to [20], the USGBC is moving in a careful way to integrate life cycle information into the LEED framework. This means that LEED's implementation of LCA is partial in many ways (implicit). Each credit was evaluated against a list of 13 environmental impact categories, including climate change, indoor environmental quality, resource depletion and water intake, among many others [21].
Comparing it to other building certification systems, LCA aspects are not assessed in an explicit (transparent) way, i.e. an explicit LEED credit, to compare buildings using LCA benchmarks. As stated in [16] the LEED credits actually implemented are not always the most beneficial for the environment.

2.3.2 BREEAM

[1] OPEN HOUSE - Benchmarking and mainstreaming building sustainability in the EU based on transparency and openness (open source and availability) from model to implementation. http://www.openhouse-fp7.eu/

[2] SuPerBuilding - Sustainability and Performance assessment and Benchmarking of Buildings . http://cic.vtt.fi/superbuildings/node/2

BRE Environmental Assessment Method (BREEAM) [22] is a voluntary design and assessment method for sustainable buildings that was established in the UK by the Building Research Establishment (BRE). It can be used to assess the environmental performance of any type of building. BREEAM uses an explicit weighting system derived from a combination of consensus-based weightings and ranking by a panel of experts within the categories: management, health & wellbeing, energy, transport, water, materials, waste, land use & ecology, pollution and innovation (additional).
In the materials group, the number of credits achieved for this BREEAM issue is based on a spreadsheet-based calculator for each applicable element's Green Guide rating using the Ecopoint method. The Ecopoint used is a single score that measures the total environmental impact of a product or process as a proportion of overall impact occurring in Europe. Green Guide ratings are derived by sub-dividing the range of Ecopoints/m² achieved by all specifications considered within a building element and are based on LCA data generated using the BRE Environmental Profiles Methodology. These can, therefore, not be compared with the indicator values according to CEN or other building certification systems.

2.3.3 DGNB

The German Sustainable Building Council (DGNB) [23] together with the Federal Ministry of Transport, Building and Urban Affairs (BMVBS) developed a voluntary certification system for sustainable buildings in 2007. The building certification system of DGNB is based on the CEN/TC350 approach. The DGNB certification system criteria-set includes five weighted topics (main criteria groups): ecological quality (22.5%), economic quality (22.5%), social quality (22.5%), technical quality (22.5%), quality of process (10%) and one additionally not weighted, separately evaluated topic (main criteria group) quality of the location.
The assessment is based on a holistic life cycle approach considering the before-use phase, use phase and end-of-life phase with a reference study period of 50 years.
DGNB implemented an explicit LCA method [24]. The goal of the assessment is to quantify and document the environmental performance of the building under consideration (office building, retail, hospital, school, etc.) by means of applying LCA methodology and to compare the results with a defined benchmark.

2.3.4 SBTool

The SBTool[3] is based on the philosophy that a rating system must be adapted to local conditions before its results can become meaningful. The system is therefore designed as a generic framework, with local non-commercial organizations being expected to define local context conditions and to develop appropriate weights and benchmarks. The system has been designed to facilitate such a regional calibration; in fact, the system requires the insertion of regionally meaningful benchmarks.
SBTool covers a wide range of sustainable building issues, not just green building concerns, but the scope of the system can be modified to be as narrow or as broad as desired, ranging from 120 criteria to half a dozen;
The system allows third parties to establish parameter weights that reflect the varying importance of issues in the region, and to establish relevant benchmarks by occupancy type, in local languages. Thus, many versions can be developed in different regions that look quite different, while sharing a common methodology and set of terms. The main advantage, however, is that an SBTool version developed with local knowledge is likely to be much more relevant to local needs and values than other systems;
The system provides separate modules for Site and Building assessments, with Site assessments carried out in the Pre-design phase and Building assessments carried out in Design, Construction or Operations phases;

[3] Overview of the SBTool assessment framework, Nils Larsson, iiSBE and Manuel Macias, UPM Spain, April 2012

SBTool takes into account region-specific and site-specific context factors, and these are used to switch off or reduce certain weights, as well as providing background information for all parties. Weights for criteria that remain active are re-distributed, so that the total always remains 100%.
There is a capacity to carry out assessments at four distinct stages of the life-cycle and the system provides default benchmarks suited to each phase.

2.4 National building certification systems in Austria

2.4.1 Klima:aktiv (building and refurbishment)

The klima:aktiv building and refurbishment certification system for New Construction Office [25] is divided into four assessment categories according to a system of 1000 points. The categories are design and construction (Category A maximum 120 points), energy (Category B, maximum 600 points), building materials and construction (Category C, maximum 160 points) and comfort and indoor air quality (Category D, maximum 120 points).
Klima:aktiv assessment allows LCA to be carried out in two different ways: on the one hand, category C 2.1a (ecological benchmark of the whole building) and alternative category C 2.1b (ecological benchmark of building envelope). The assessment considers three environmental impact categories GWP, AP and PEI.n.e. (or CEDnr). For the final assessment these three environmental impact categories are aggregated into one ecological benchmark (OI 3).
In the first case, the assessment goes only partly in line with the CEN/TC 350 approach. The Use phase only focuses on environmental impacts. Due to the fact that the construction and maintenance processes are considered by the assessment, environmental impacts caused by energy demand during use phase are not included in the aggregated results. Environmental impacts are partly embedded in category B 2.2 (CO_2 emissions) and B 2.3 (cumulative energy demand).
In the second case, due to time-related focus of the before use phase and the spatial-related focus of the building envelope as well as the declaration of environmental impacts in CO_2-emissions, the environmental assessment concept does not correspond to the CEN/TC 350 concept, which is based on a holistic approach. The influence of neglecting spatial and/or time related aspects is shown in detail in.
At most, 100 points (or 10%) can be achieved by using case one, and 75 points can be reached by accomplishing LCA in case two. Taking into account the previously mentioned categories B 2.2 (125 points) and B 2.3 (125 points), a total of 350 points using case one, and 325 points using case two, can be achieved.

2.4.2 ÖGNB (TQB)

The ÖGNB (Austrian Association of Sustainable Building) [26] certification system (also named TQB) is separated into five main categories behind a 1000 point system as in the klima:aktiv certification system. The main categories are quality of the location and infrastructure (Category A, maximum 200 points), economic and technical object quality (Category B, maximum 200 points), energy (Category C, maximum 200 points), health and comfort (Category D, maximum 200 points), materials and construction (Category E, maximum 200 points).
LCA is embedded in category E.3.1 ecology of materials and construction. In contrast to klima:aktiv, the environmental assessment is based on the new assessment concept which was developed during a national research project named "Nachhaltigkeit Massiv" [27] which allows focusing on the spatially related system boundaries of flexible assessment. The time-related system boundary chosen for ÖGNB-assessments for dwelling-types considers before-use, use and end-of-life-phase. Compared to case two assessments in klima:aktiv, the spatially related system boundaries have been enlarged. Next to the building envelope, finishes are also included, but the technical equipment is not included due to missing data-sets. Environmental impacts are assessed in a similar way to the klima:aktiv assessment system, thus it is also not in line with CEN/TC350. The reference study period is stated to be 100 years. At most, 60 points (or 6%) can be achieved with LCA within the sustainability assessment by ÖGNB certification system.

2.4.3 ÖGNI

The Austrian Green Building Council (ÖGNI) [28] was founded in 2009. Due to a cooperation agreement with the DGNB, signed in June 2009, a substantial basis for the operation of the council was established, and thus the German certification system for sustainable buildings (DGNB) has been successfully adapted to Austria. The DGNB/ÖGNI certification scheme criteria-set includes the same criteria as DGNB. Each of the main topics is divided into several assessment criteria. For instance, the Global Warming Potential, Total Primary Energy Demands and Proportion of Renewable Primary Energy, Thermal Comfort in Winter and Summer or Energetic and Moisture Proofing Quality of the Building's Shell are considered for the evaluation of a building. For each criterion, measurable target values are defined, and a maximum of 10 points can be assigned. The measuring methods for each criterion are clearly defined. The certificate follows the concept of integral planning that defines the aims of sustainable construction with the related building performances at an early design stage. This means sustainable buildings can be designed which are based on the latest state of technology, and their performance can be communicated with the relevant criteria in the pre-certificate at the planning stage and in the certificate after completion. The consulting auditor accompanies the owners during the certification process and prepares an accompanying planning and construction documentation in accordance with the specifications of the documentation guidelines. Having completed the building, the auditor compares and checks the building specifications with the realized project.
Finally, DGNB/ÖGNI reviews the entire certification process and performs a conformity inspection based on the documentation guidelines, makes plausibility checks and takes control samples, and checks whether everything was executed properly according to the documentation. If all requirements are fulfilled, the owner receives a certificate [29].

2.5 Infrastructure

2.5.1 Characteristics of infrastructure construction

The infrastructure construction section is dominated by public contracting authorities, which do not mainly focus on environmental assessment as criteria for their decisions by now. Nowadays their emphases are basically placed on construction costs, availability and safety concerns. Thus, contrary to the structural surface engineering (industrial, office and residential buildings) tools of sustainability assessment are far less in use for civil engineering underground and for infrastructure constructions.

Furthermore, infrastructure buildings often have significantly different characteristics in comparison to the other construction sectors in which sustainable building certificates are already in general use and at least partly established. Main construction characteristics of infrastructure buildings are for example their high life expectancy and high consumption of raw materials. All these peculiarities are different to the assessment with conventional methods and must be considered in the life cycle assessment model. Hence, for instance a characteristic for the use of natural raw materials (e.g. gravel) must be implemented. Besides, the thigh environmental impact of transport distances as a consequence of raw material consumption is shown in research projects [30].

But the biggest challenge is the evaluation and consideration of general public interest. The question is how the construction itself and its public availability can be set in equation with an ecological impact. Moreover not only the building period must be evaluated but also the utilisation phase. High maintenance efforts and short service periods due to a wrong construction system do not only cause costs for the building owner but also affect the public. Besides, generally also the impact on the environment (e.g. by emissions caused by congestion due to repair works) is bigger compared to buildings of other construction sectors.

This complex environment might be the reason why ecological assessment of infrastructure construction was only rarely part of research programs and hardly ever executed in construction projects. On the other hand exactly due to this complexity research on this topic should be forced more intensively in the future.

2.5.2 Road Infrastructure

Generally the lifetime of buildings can be separated into three main parts: the construction phase, the use phase (including maintenance, reconstruction and the real use) and the end of life phase (demolition).

Existing studies show that the environmental impact of an infrastructure in the construction phase could be reduced by optimization of the raw materials and production of the construction materials [31, 32]. For the two main construction materials for road surfaces examples for the reduction potential are reduced clinker content in concrete and the use of secondary fuels and reclaimed materials for asphalt production. Transport distances of raw materials are another factor, which influence the environmental impact of the use phase [33].

But these potentials must always be compared with the impact of the whole lifetime construction. Maintenance strategies and their environmental potential (reduction up to 60% depending on the quality of execution [32, 34, 35]) have also to be taken into account.
Moreover it is known that the environmental impact of traffic during the life time is about 100 times higher than all the effects of construction and maintenance.
Thus, the most important question in the assessment of a construction technique is their costs over the whole lifetime. This does not apply only to the economical costs, but also to the social and environmental impact of the construction.

There are still a lot of side effects of the material selection, which could have serious environmental impacts but are not considered in the studies so far.

Research projects, dealing with the comparison of different road surfaces and their stiffness properties display the fuel consumption as the main environmental factor for road constructions over the lifetime. These studies show a benefit of the concrete in comparison to asphalt surfaces. The resulting fuel consumption depending on the stiffness of different road constructions shows significant differences in connection with the type of construction. A fuel saving potential up to 3.9 percent [36] depending on the construction type causes an immense impact on the environmental potential over the lifetime.

Another example for a passive environmental impact of the construction is the reflection of material surfaces. On the one hand the albedo of constructions can directly affect the global warming by reflecting light back into the universe, on the other hand this effect could be increased by the heat island effect (increased urban temperatures in large cities caused by solar heat absorption due to dark surfaces) and additional use of energy for air conditioning. The albedo of the surface is also a factor in tunnels. A lighter surface appearance does not only improve the traffic safety but also lower the energy costs for tunnel lighting [37].

In the end of life phase an easy low energy demolition process and the direct reuse of demolition products on the highest possible quality level is essential (avoidance of “down cycling”).

2.5.3 Existing assessment tools for road infrastructure

Assessment systems analysing the sustainability of road infrastructure projects can be found in the US and in Europe. Most of these assessment instruments also use a mixed assessment method utilizing monetized, quantitative and qualitative indicators.

The NISTRA instrument (Switzerland) [38], the NATA Approach from the UK [39], the GreenLITES [40] and the Greenroads [41] assessment approaches, both from the US, are examples of such assessment systems.

In 2001 the Swiss Federal Road Office (ASTRA) decided to develop an instrument that allows the assessment of road infrastructure projects considering the three sustainability target dimensions (“Sustainability Indicators for Road Infrastructure Projects” (Nachhaltigkeits-Indikatoren für

STRAsseninfrastrukturprojekte NISTRA). The revised version of NISTRA published in 2010 utilizes the cost-benefit analysis (CBA) and the utility analysis (UA) methodologies as well as descriptive indicators to assess road infrastructure projects.

The indicator system of the NISTRA instrument can be split up into 39 indicators (8 social, 21 economic, 10 environmental).

The Greenroad approach analyses the planning, the new construction and the use phase (processes related to the use of the road) of road projects with a focus on the enhancement of the environmental performance and possible lifetimes of the road pavement, and requires a Life Cycle Cost Analysis (LCCA) and a detailed Life Cycle Assessment (LCA) for each evaluation carried out. The overall goal of the Greenroad system is not to demonstrate and compare results for different road projects, but to minimize its negative environmental, economic and social impacts, and to give road projects a sustainable certificate according to their assessment results.

3. Conclusions

3.1 General improvement of ecological construction assessments

The ecological assessment of building products and constructions is an important part for proceeding to a sustainable society. By now a large scope of tools, such as standards, are available to state an ecological footprint of products in several stages to the final building. But there are some problems that interfere the wide application of ecological evaluation.

- Lack of comparability and usability due to different systems and parameters in the evaluation of environmental performance. This shows that ideal characteristics are still not found. This gap must be closed in future.

- Uncertainty of background data due to unclear raw data and arbitrarily set system limits. Studies on the same topic often lead to completely different findings. Such contrary results must be avoided by better raw data and a better conformability.

- Significance regarding the whole building must be displayed. The focus must be set on the parts with the highest impact on the environment. Hence the main focus of further research works must be set on the detection of the essential products and processes of constructions.

- Period of validity due to daily changing background data. There is still a special need for a definition of the validity of an ecological evaluation.

If these aspects could be more clearly in the future the acceptance and application of decision makers would probably be higher. In addition also the other constituents of sustainability – beneath ecology - should be kept in mind. The social and macroeconomic benefits of constructions are often not easy to evaluate, but of extreme importance. Thus, the ecological evaluation must always be set into relation of all these parts.

3.2 Austrian EPD program for building products

In the last years a board of Austrian research institutes prepared the start-up of an Austrian EPD platform for building products by developing the basic documents needed for an EPD program:

- Basic document for the preparation of an EPD
- General rules for the LCA part of the EPD
- Analysis guidelines for emissions to air and environment

By the beginning of July the Austrian EPD program will start his operational work, so the first EPDs

can be submitted for verification and publication.

The Austrian EPD program should then build the base for a bottom up approach leading to Life Cycle Assessments of buildings, built infrastructure and building components utilizing datasets representing the Austrian situation. This can be seen as first step towards stable characteristics for ecological assessments within the Austrian building sector.

3.3 Research need for infrastructure buildings

Within the construction industry infrastructure buildings are much less analysed regarding to their ecological impact than other buildings. The high potential for further research in this field is based on the following properties of infrastructure buildings:

- Long lifetimes
- High consumption of materials
- Enormous Impact of utilisation phase
- Influence of maintenance strategies
- Social end macro-economical side effects

The road LCA studies carried out in Germany, Switzerland and The US demonstrated the necessity of an ecological study analysing at least Austrian highway constructions regarding their environmental characteristics in order to build the ecological base for a future sustainability assessment tool such as NISTRA [38] or Greenroads [41].

Furthermore, there should be a focus on LCA studies and sustainability assessments of further civil engineering structures such as railways, tunnels, power plants, etc. where the overall ecological consequences of the situation with and without the project need to be compared.

Short Summary

The specific building stock of Red Vienna represents 16% of total Viennese housing stock [1]. This stock is of significant cultural value, as a monument of an era, which determined the worldwide unique Viennese housing policy. Moreover, it represents a high social value, still bearing a large ratio in provision of affordable housing. The stock is more than 50 years old and in need of refurbishment and adaptation to the modern housing requirements. These are determined through the trends such as ageing society, increasing of housing areas [2] and of user comfort. On the other hand, the issues such as scarceness of resources and energy and minimisation of emissions must be considered in refurbishment process.
This paper presents a case study carried out on a specific housing block of the Red Vienna period. In the course of research, the economic (life cycle costing and yields), ecologic (CO_2 emissions) and socio-cultural impacts (monument protection, accessibility, assisted living) of several refurbishment variants were evaluated through quantitative and qualitative analysis. The research points out the large potentials in structural refurbishment of building stock for development of assisted living models, which prove to be substantially more cost efficient than the institutional care, providing a better comfort for the inhabitants, and also the necessary social mix through trans-generation housing in the social housing facilities.

Keywords: Life Cycle Costs, Social Housing, Assisted Living, Thermal Refurbishment, Sustainability Criteria

Towards research model

For the evaluation of refurbishment strategies by the means of sustainability criteria, a case study methodology was chosen. As specific reference object a housing estate “Elderschhof” in second Viennese district (erected in the years 1931 to 1932, owned by the federal state Vienna and administered by Wiener Wohnen) was chosen. In the first step, several refurbishment strategies were compiled:

Table 1: Summary reconstruction strategies

Reconstruction strategies	A Thermal refurbishment	B Barrier-free ground floor	C Installation of elevators and stairlifts	D Stairlifts
Starting Position	Existing building 2011	Existing building 2011	Existing building 2011 - without elevators	Existing building 2011- without elevators
Thermal reconstruction	X	X	X	X
Technical modernisation			Elevators, stairlifts	stairlifts
Modification in apartments on ground floor		Furnishing category A and universal accessibility	Furnishing category A and universal accessibility	Furnishing category A and universal accessibility

In further steps, the thermal refurbishment represented through variations of façade-insulation - systems was evaluated for life-cycle costs (LCC) [3] and the life-cycle analysis (LCA) [3].
For the thermal refurbishment of facades following variants were examined:

- Modernisation of the façade without thermal insulation measures (without TIM)
- Exterior thermal insulation composite system EPS (ETICS EPS)
- Exterior thermal insulation system mineral wool (ETICS MW)
- Thermal insulation plaster (TIP)
- Interior insulation (II)
- Vacuum insulation panel (VIP)

Finally, the developed thermal and structural refurbishment measurements were evaluated upon the sustainability criteria: economic (LCC, capital strain of rental income) [3], ecologic (CO_2 emissions) [3] and socio-cultural (monument protection, accessibility, assisted living); through qualitative analysis. The structural refurbishment strategies were compared to the gross expenses of public authorities [4] for various nursing services.

Conclusion

The study implies large potentials of existing stock for care at home, instead of much more cost intensive institutional care; reinforcing the value of stock as social capital. The comparison of the life-cycle costs concerning a structural refurbishment with the gross expenses of the public authorities points out, that nursing expenses are a multiple of the life-cycle costs caused by a structural refurbishment for accessibility in an existing building. In terms of thermal refurbishment, due to the large energy consumption during the operation, the most preferred measure is the holistic refurbishment (complete envelope) through the highest energy and CO_2 saving potential. The façade options with low potential of heating demand reduction have, despite the positive sustainable performance concerning production and maintenance, high economic and ecological life-cycle values (cumulated over 50 years), which cannot be neutralised by the positive monument conservation effects. In terms of lifecycle costs and achieved energy and CO_2 savings the ETICS EPS refurbishment variant shows the best performance over the period of 50 years, however is not compatible in terms of monument protection. As alternative, the interior insulation, causing higher ecological impact and higher skills in application, can be taken in account. The qualitative evaluation of the structural refurbishment and exploration of the potentials for providing the appropriate housing for aging society proves variant D (disclaims the use of existing elevators, but instead installs the stair lifts and enables the barrier-free living of the ground floor) as the optimal variant, both in terms of LCC as in social criteria for affordable housing (low heating costs and rent).

Short Summary

The specific building stock of Red Vienna represents 16% of total Viennese housing stock. This stock is of significant cultural value, as a monument of an era, which determined the worldwide unique Viennese housing policy. Moreover, it represents a high social value, still bearing a large ratio in provision of affordable housing. The stock is more than 50 years old and in need of refurbishment and adaptation to the modern housing requirements. These are determined through the trends such as ageing society, increasing of housing areas and of user comfort. On the other hand, the issues such as scarceness of resources and energy and minimisation of emissions must be considered in refurbishment process.
This paper presents a case study carried out on a specific housing block of the Red Vienna period. In the course of research, the economic (life cycle costing and yields), ecologic (CO_2 emissions) and socio-cultural impacts (monument protection, accessibility, assisted living) of several refurbishment variants were evaluated through quantitative and qualitative analysis. The research points out the large potentials in structural refurbishment of building stock for development of assisted living models, which prove to be substantially more cost efficient than the institutional care, providing a better comfort for the inhabitants, and also the necessary social mix through trans-generation housing in the social housing facilities.

Keywords: Life Cycle Costs, Social Housing, Assisted Living, Thermal Refurbishment, Sustainability Criteria

1. Current issues: housing stock and the new social requirements

The existing Viennese housing stock consists of 170.000 buildings [1]. 50% of them are already older than 50 years [1]. The buildings built in the era of Red Vienna in particular, represent 16% of the whole building stock of Vienna [1]. These are marked with an insufficient state of repair and a dwelling supply, which does not fit with modern demand considering the size of housing units and facilities. The result is an urgent need of thermal and structural refurbishment. Appropriate renovation, considering the type of building-hull refurbishment with the most sustainable effect over the life-cycle in terms of economy, ecology and monument conservation has to be determined. An aging society with the tendency to two person-households [2] leads to changing of housing requirements. Simultaneously, an aging society causes an increasing demand of care giving institutions. To delay the move into a home for the elderly creates necessity for creation of small affordable and barrier-free housing units, which enable the stay of high-maintenance persons at their beloved home. Therefore, structural renovations in the existing housing stock are necessary. Alternatively the new construction of homes for the elderly can bare the increasing demand of care. Regardless of the individual need affecting the intensity of care the benefits of structural reconstruction in the existing housing stock in combination with institutions for mobile nursing and assisted living should be compared to the new construction of homes for the elderly. Beside the large demand of refurbishment, the Viennese social housing stock has the task to supply inexpensive housing units to create affordable housing for everyone of society. The aspect of affordable living, as well as monument protection of cultural important buildings, such as the building stock of Red Vienna is, and the guidelines of sustainability have to be considered in structural and thermal refurbishment.

2. Towards research model

For the evaluation of refurbishment strategies by the means of sustainability criteria, a case study methodology was applied. As specific reference object a housing estate “Elderschhof” in second Vienese district was chosen. The Elderschhof (11 414 m^2 gross floor area, 7 floors) is a housing block owned by the state Vienna and administered by Wiener Wohnen. It was erected in the years 1931 to 1932 and is an example of the building activity during the era of Red Vienna.

In the first step, several refurbishment strategies were compiled: only thermal refurbishment, thermal refurbishment with: barrier-free ground floor, with elevators and stair lifts, with stair lifts only (Table 1).
In further steps, the thermal refurbishment represented through variations of façade-insulation - systems was evaluated by the means of the life-cycle analysis (LCA), using the software Legep [3] which is based on ökobau.dat data [4], for a) only production and maintenance, and b) production and operation; and life-cycle costs (LCC). For the calculation of the life cycle costs (LCC), the “total cost of ownership” approach was used, considering only the emerging costs over the life-cycle of a building, which have to be carried by the owner [5]. Outpayments are discounted to the present value of the date of investment and are the base for LCC-evaluation of the investigated buildings [6]. The LCC are calculated over the period of 50 years [7].

Finally, the developed thermal and structural refurbishment measurements were evaluated upon the sustainability criteria: economic (LCC, capital strain of rental income [8]), ecologic (CO_2 emissions) and socio-cultural (monument protection, accessibility, assisted living) through qualitative analysis.
The structural refurbishment strategies were compared to the gross expenses of public authorities for various nursing services.

Following reconstruction strategies were developed and evaluated based on ÖNORM B1600 [9]:

Table 2: Summary reconstruction strategies

Reconstruction strategies	A Thermal refurbishment	B Barrier-free ground floor	C Installation of elevators and stair lifts	D Stair lifts
Starting Position	Existing building 2011	Existing building 2011	Existing building 2011 - without elevators	Existing building 2011- without elevators
Thermal reconstruction	X	X	X	X
Technical modernisation			Installation of elevators in all staircases and stair lifts on the groundfloor in staircase 2, 4	Installation of stair lifts on the groundfloor in all staircases
Modification in public space			Modification of the business office to a recreation room/nursing care base	Modification of the business office to a recreation room/nursing care base
Modification in the apartments		Reconstruction of apartments on the ground floor to furnishing category A and universal accessibility	Reconstruction of apartments on the ground floor to furnishing category A and universal accessibility	Reconstruction of the apartments on the ground floor to furnishing category A and universal accessibility

For the economic operation of nursing services like assisted living 10-20 barrier-free apartments are necessary [10, 11]. The existing elevators at the examined housing block cannot be used with a wheelchair because of the insufficient size of the elevator cabin. The elevator is situated on a ground floor landing, which is one stair flight higher than the yard level. As a solution the reconstruction of the apartments on the ground floor was chosen. Stair lifts will be installed at the stairs leading from the level of the yard to the ground floor.

3. Findings

3.1 Evaluation of Strategy A: Thermal Refurbishment

For the thermal refurbishment of facades following variants were developed and examined:

1. Modernisation of the façade without thermal insulation measures (without TIM)
2. Exterior thermal insulation composite system EPS (ETICS EPS)
3. Exterior thermal insulation system mineral wool (ETICS MW)
4. Thermal insulation plaster (TIP)
5. Interior insulation (II)
6. Vacuum insulation panel (VIP)

The life-cycle analysis of the building hull examines following respective versions in the software Legep [3]:

Table 3: Respective variants of facade systems according to OIB-Richtlinie 6 [12]

	λ [W/m · K]	d [cm]	u-value [W/m^2 · K]
Without TIM	-	-	1.694
ETICS EPS	0.035	20	0.159
ETICS MW	0.040	20	0.179
TIP	0.130	7	0.886
II	0.040	6	0.520
VIP	0.008	5	0.179

Façade systems with high insulation properties, like EPS, MW and VIP require high financial input for production, maintenance and replacement and simultaneously generate a high economic impact. Especially the respective version VIP has enormous production costs compared to the other options. The alternative modernisation of the façade without thermal insulation measures and thermal insulation plaster - TIP offer low economic and ecological values concerning production and maintenance.
The evaluation of operational phase - heating energy demand savings potential resulting from façade refurbishment variants compared to the existing state of Elderschhof is determined through calculations of energy certificates along the lines of the OIB-Richtlinie 6 [12].

Table 4: Facade systems, heating demand according to OIB-Richtlinie 6 [12]

	Heating demand [kWh/m^2·a]	Savings potential to stock (171,69 kWh/m^2·a) [%]
Without TIM	123.74	28
ETICS EPS	39.16	77
ETICS MW	40.37	76
TIP	79.18	54
II	59.88	65
VIP	40.36	76

The life-cycle analysis over the period of 50 years of a theoretical extensive thermal modernisation with the variation of the façade system, provides following results concerning the LCC, the primary energy demand (PED), the global warming potential (GWP) and the capital strain of the rental income depending on the availability of subsidy by the federal state of Vienna [8] (Table 4).

Table 5: Variant A, results summary

	Capital strain of rental income incl. subsidy [€/m^2.mth]	Capital strain of rental income excl. subsidy [€/m^2.mth]	LCC (present value) [€]	LC PED [kWH]	LC GWP [kg CO_2-Äq.]
Without TIM	2.88	3.44	15 788 844	153 471 966	29 078 051
ETICS EPS	2.86	4.27	15 002 127	120 005 595	21 822 030
ETICS MW	2.95	4.36	15 079 191	121 388 327	22 168 426
TIP	2.72	3.75	15 121 241	135 337 980	25 175 898
II	2.50	3.95	14 642 429	127 394 235	23 379 028
VIP	4.22	5.81	15 877 376	119 930 005	21 751 520

Façade systems with high insulation properties EPS, MW, II, VIP are more sustainable over the life-cycle of 50 years, than the options without TIM or TIP. The low costs and the global warming potential caused by production and maintenance of the variants without TIM or TIP are neutralised through the high heating demand. The variants´ EPS, MW, II, VIP amount of produced GWP over 50 years is 20-25 % lower than that one of the variants without TIM or TIP.

The economic advantage of façade systems with high thermal insulation properties is reached after 20 years. The LCC regarding increasing energy costs point up the façade´s economic differences over the period of 50 years. Façade systems with high insulation properties EPS, MW, II, VIP cause low LCC, which are the hirers´ economic advantage. Those respective versions require high investment costs, especially variant VIP, a disadvantage for the building´s owner. The capital strain of the rental income over the period of 10 years for the variant without TIM is 15-70 % lower than compared with EPS, MW, II or VIP. That means a high reduction of the rental income yield.
Based on these results the qualitative evaluation of the façade systems concerning sustainability is carried out with the help of following criteria:

- economic
- ecological
- cultural historical / monument conservation

The economic sequence is influenced by the life-cycle costs considering as well the present value as the follow-up costs. The GWP is determining the ecological ranking of the variants. The ranking monument conservation is carried out by the means of the office for federal monument´s guideline “energy efficiency on historic monuments” [13]. The façade systems EPS, MW and VIP are equally weighted concerning monument preservation because of the same impact on structured facades (Table 5).

Table 6: Façade systems, qualitative evaluation through weighing

Qualitative evaluation	Economic	Ecological	Cultural historical
Without TIM	6	6	1
ETICS EPS	1	2	4
ETICS MW	3	3	4
TIP	5	5	3
II	2	4	2
VIP	4	1	4

The evaluation is carried out with the help of a network diagram (1=best, 6=worst result). The results concerning sustainability are pictured as areas. The façade system with the smallest area has to be favoured.

1. ETICS EPS (6.06)
2. II (8.66)
3. VIP (10.39)
4. ETICS MW (14.29)
5. Without TIM (20.78)
6. TIP (23.82)

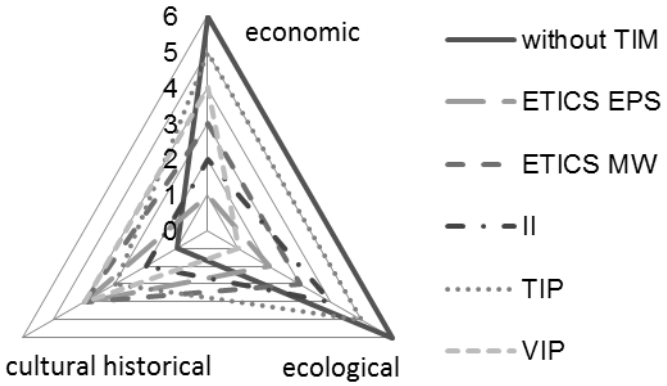

Fig. 1: Façade systems, qualitative evaluation

The evaluation of facade systems in the context of a thermal refurbishment shows that the most sustainable variant is the exterior thermal insulation composite system EPS. Disadvantage is, that it is not compatible with the principles of monument protection. An alternative is the interior insulation, which causes higher ecological impact. The façade options with high heating demand have high economic and ecological values, which in this proposed weighing cannot be neutralised by the evaluation concerning monument conservation.

3.2 Evaluation of Strategies B,C, D : Structural Refurbishment

Due to the results from chapter 3.1 the façade system EPS will be chosen for the evaluation.

3.2.1 Quantitative evaluation

Variant D has the lowest GWP compared to the other refurbishing options because of the abdication of an elevator (Figure 4). The ecological impact of the variants A, B and C equates the extent of the building measures. The difference between the lowest and the highest ecological impact is only 1.65 % of the overall GWP of variant C. The ecological potential connected with the choice concerning the façade system is higher. The subsequent installation of an elevator causes

additional GWP in a range of 1-2 % compared to the GWP of variant A, but a great ease of daily life.

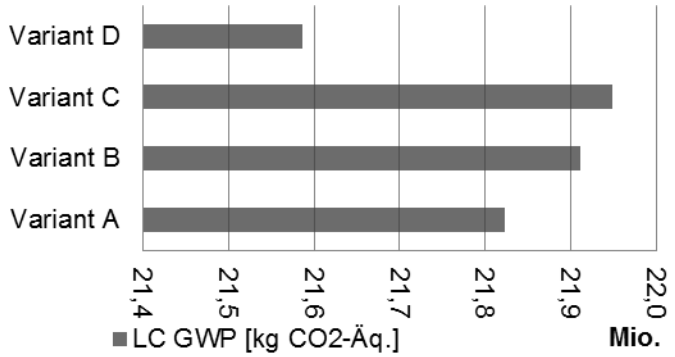

Fig. 2: Variants evaluation, ecological

The investment costs of the refurbishment variant A creates the lowest capital strain of the rental income and the highest yield. Variant D (no elevator) has a lower capital strain of the rental income and the lowest yield of all refurbishment variants. Variant B and C have a higher capital strain of rental income than the variants A and D. The structural refurbishment in variant B, C and D improves the furnishing category of the apartments on the ground floor and increases the associated rent. The strategy of renting determines whether the apartments come up to future housing requirements or the rent stays affordable.

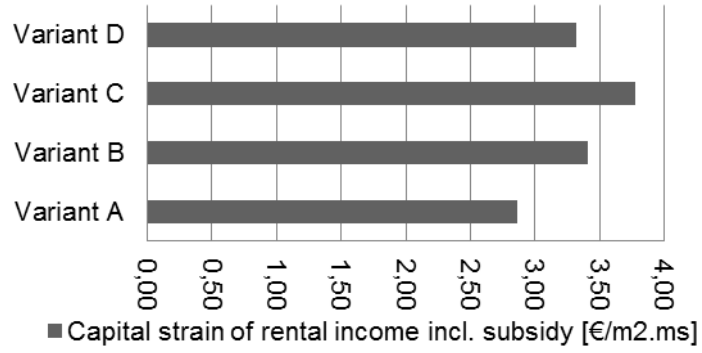

Fig. 3: Variants evaluation, strain of rental income

Variant D has the lowest LCC and is 9 % cheaper than variant C. The main reasons are the high elevator´s costs for service and maintenance. The additional costs caused by building measures in the apartments and the subsequent installation of an elevator are minimal compared to the overall building costs. The structural refurbishment of the variants B, C and D creates barrier-free designed apartments to ensure a self-organised life of people, who are in need of care or disabled, and delays or prevents the move into a nursing home.

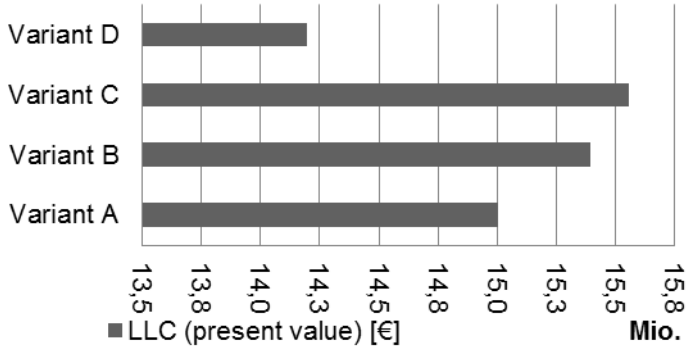

Fig. 4: Variants evaluation, LCC

3.2.2 The qualitative evaluation

The data base for the qualitative evaluation is represented in the Figures 4-6 shown above for each refurbishment variant. The evaluation is carried out with the help of the following criteria (not weighted) in a network diagram (1= best result, 6= worst result):

- economic
- ecological
- social (barrier-free design of the building, recreation room and nursing care base)
- functional (the building´s potential to come up to future housing requirements and the flexibility concerning changing use.)
- cultural historical / monument conservation

Table 7: variants, qualitative evaluation

Qualitative evaluation	A	B	C	D
Economic	2	3	4	1
Ecological	2	3	4	1
Social	3	2	1	4
Functional	3	2	1	4
Cultural historical	2	3	4	1

The results concerning sustainability are pictured as areas. The refurbishment variant with the smallest area has to be favoured.

1. Variant D (12,36)
2. Variant A (13,79)
3. Variant B (16,17)
4. Variant C (19,50)

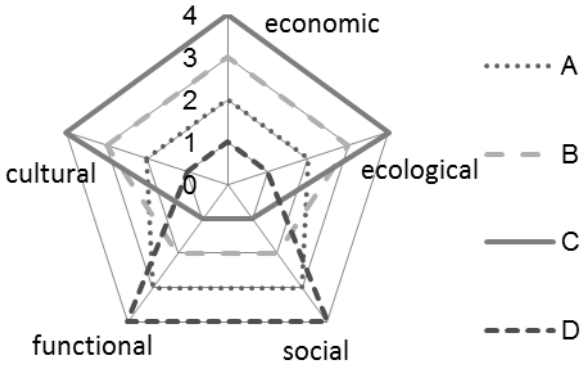

Fig. 5: Variants, qualitative evaluation

Variant D owns the best ecological, economic and cultural historical results. (The abdication of the subsequent elevators´ installation keeps the life-cycle costs including costs for maintenance, service and replacement low and the rent for dwellings affordable cheap. The low investment costs cause a low capital strain of the rental income.) The best cultural historical ranking is based on the abdication of a subsequent installation of an elevator. In each individual case it has to be decided whether the maintenance of the existing building structure is more important than an elevator. In variant A an elevator exists, but no adaptation of the building stock to future housing requirements is realised. If an elevator exits in the existing dwelling, variant A has to be favoured compared to variant B. Variant C with high potential concerning building measures to create barrier-free apartments and a nursing care base owns the largest area in the network diagram. The extensive building measures affect the ecological, economic and cultural historical evaluation negatively. Within the framework of refurbishment, planning decisions concerning the refurbishment variants and the weighting of the evaluation criteria are mainly influenced by the purpose of the decision maker.

3.3 Comparison LCC refurbishment assisted living - gross expenses of the public authorities for various nursing services

Referring to variant B the life-cycle costs caused by a structural refurbishment on the ground floor

of the Elderschhof (13 apartments, inhabited gross floor area of 1 474 m^2) can be determined with a value of € 650 893.
The annual gross expenses of the public authorities for various nursing services [14] are shown in the table 8.

Table 8: Nursing expenses

Nursing services	Gross expenses of public authorities [€]	Looked after persons	Annual costs per person [€]	Accumulated costs over 50 years [€/p]	Costs over 50 years for 13 apartments/ persons [€/p]
Mobile care services	470 133 325	127 891	3 676	183 802	2 389 431
Inpatient care services	2 121 480 105	71 798	29 548	1 477 395	19 206 135
Day care centres	23 091 331	4 564	5 059	252 973	3 288 643
Assisted living	147 485 564	10 806	13 648	682 424	8 871 517

The comparison of the life-cycle costs concerning a structural refurbishment with the gross expenses of the public authorities points out that nursing expenses are a multiple of the life-cycle costs caused by a structural refurbishment for accessibility in an existing building. The nursing costs itself differ widely. In patient nursing homes cause minimum the double costs of assisted living. As a result the installation of assisted living in existing building stocks can save nursing costs and creates a high economic and ecological benefit compared to the new building of nursing homes. According to information of Wiener Wohnen the cost-efficient operation of assisted living requires 10-20 connected apartments [10, 11]. For this aspect assisted living in small buildings is only realisable if the whole building is barrier-free designed. A requirement is an existing elevator or a subsequent installation. Assisted living only in apartments on the ground floor in small residential buildings without an elevator is realisable if the small residential buildings are located near a nursing institution.

4. Conclusion

In the presented research, a case-study of refurbishment strategies for a specific housing block of Red Vienna has been carried out and evaluated according to the criteria of sustainability. The study implies large potentials of existing stock for care at home, instead of much more cost intensive institutional care; reinforcing the value of stock as social capital. In terms of thermal refurbishment, due to the large energy consumption during the operation, the most preferred measure is the holistic refurbishment (complete envelope) through the highest energy and CO_2 saving potential. The façade-variants with low potential of heating demand reduction (without TIM, TIP) have, despite the positive sustainable performance concerning production and maintenance, high economic and ecological life-cycle impact (cumulated over 50 years), which cannot be neutralised by the positive evaluation concerning monument conservation.
In terms of lifecycle costs and achieved energy and CO_2 savings the ETICS EPS refurbishment variant shows the best performance over the period of 50 years, however is not compatible in terms of monument protection. As alternative, the interior insulation, causing higher ecological impact and higher skills in application, can be taken in account. The qualitative evaluation of the structural refurbishment and exploration of the potentials for providing the appropriate housing for aging society proves variant D as the optimal variant, both in terms of LCC as in social criteria for affordable housing (low heating costs and rent). Variant D disclaims the use of existing elevators, but instead installs the stair lifts and enables the barrier-free living of the ground floor and thus significantly lowers the LCC as well as the rents. However this simultaneously means a low owner´s rental income yield; which should not be primary concern for non-profit oriented social housing .associations.

Summary

This conference contribution presents a study tackling user behaviour and consumer aspects in highly energy efficient buildings taking into account social, ethnical, and especially gender-related aspects, and analyses the building design concept in comparison with the actual energy consumption. The interdisciplinary project team applies new socio-scientific methods to develop innovative solutions for influencing user behaviour, which undergo trial runs in selected buildings. Results will contribute to improving communication measures, design process and product development in order to tap the full potential of energy savings due to user behaviour.

Keywords: Gender mainstreaming; user behavior; planning tools; holistic planning approaches; highly energy efficient buildings

1. Introduction

According to the EU-project „BEHAVE“ (http://www.energy-behave.net/) more than 50% of energy savings are due to changes of energy consumption related user behaviour. The development towards plus-energy-buildings (buildings which produce more energy than what occupants consume) causes a change in the role of consumers: consumers turn to active stakeholders, because their way of using the building will be decisive whether the building actually achieves plus-energy status, or not. It is a precondition to fully understand the motivations and options for actions of consumers, in order to tap the full potential of energy savings related with user behaviour. In this regard, gender-specific aspects have not been considered so far. In order to meet the challenging reductions in greenhouse gas emissions behavioural change will be necessary along with technological innovations. Energy research and building technology in particular, are predominantly technology oriented fields. Gender aspects are so far still largely unresearched in both fields.

The ongoing research project *GINGER – The influence of gender on user behaviour in highly energy efficient buildings* (July 2012 – June 2014) tackles user behaviour and consumer aspects in highly energy efficient buildings taking into account social, ethnical, and especially gender-related aspects. This paper describes first assumptions about gender relevant aspects in energy research and in the concept of highly energy efficient buildings. In addition, the methodological approach applied in GINGER is presented: social, ethnical, and especially gender-related aspects are taken into account to analyse the building design concept in comparison with the actual energy consumption, user behaviour and consumer aspects.

2. Definitions: Gender, Doing Gender, Gender Mainstreaming

Modern science includes a gender perspective. Gender refers to the array of socially constructed roles and relations, personality traits, attitudes, behaviours, values, relative power and influence that society ascribes to women and men. Gender is an acquired identity that is learned, changes over time and varies widely within and across cultures, ethnicity, class and age etc.

"Doing gender" means how people construct and maintain gender through our actions and interactions. While gender can be done in repetitive ways it also can be undone or done differently. As Offenberger and Nentwich stated the research focus on gender and technology has shifted to the following three prepositions 1) from a single perspective on doing gender to a double perspective of doing and undoing, 2) from gender as a binary construction to multiple femininities and masculinities. [1]

3. Gender & Energy

Energy is recognized as a sector with an extremely low proportion of women in all its fields and at all levels. Therefore Gender mainstreaming plays an important role in enhancing the amount of influence afforded to women in energy planning and decision-making in production and in integrating gender expertise into planning as a whole to meet the different needs. Efficiency and effectiveness of energy technology development and energy policy instruments, could be increased by reflecting on gender implications and taking participatory approaches into account. [2]

Regular surveys on environmental awareness among the general public have shown that women are generally more environmentally aware and behave in a more environmentally compatible manner than men, even though they possess less specialist knowledge on the environment. Gender is also relevant in the field of energy. Great efforts must be undertaken to discover gender impacts in technology-orientated research because of lacking data and research. Gender aspects are to be found or can be assumed in access to energy technologies, perception of (risk) technologies, energy needs and use (e.g. energy needs are linked to gendered roles, responsibilities and identities as well. The question whether a new energy technology meets the needs and the interests only of those parts of societies who have power to define problems, design solutions and take decisions can be best solved by analytical approaches involving all stakeholders, including women and gender experts) and in particular in the very small share of women in energy technology-related areas, resulting in an inclusion of their perspectives in research and development. [3]

Different income levels of women and men, gender stereotypes and society's attribution of assignments in the field of energy technologies and energy use, and the low share of women in energy-related fields of work, in particular in technological professions are further reasons for inequalities in this field., but also the difference between countries of the North and countries of the South. Joy Clancy stated in an article on a "northern perspective" that e.g. more women than men are living below the poverty line. Poor women are disproportionately found as heads of households, either in single parent's families or, due to their greater longevity than men, living alone at pensionable age. Northern climates create the need for space heating and/or cooling for significant parts of the year. Young children and older people have special heating requirements to reduce their vulnerability to illness. Many women in the North are (were?) active in renewable energy e.g. running co-operatives like the Windfang women's wind energy cooperative in Germany Women have been leading activists in the anti-nuclear movement. [4]

4. Energy-efficient Building Concepts and User Experiences

A survey carried out with residents of four low energy building projects and four conventional residential buildings in the city of Salzburg showed that energy consumption of an apartment plays

no significant role in the residential choice of Austrians. [6] The main reasons to move into a new apartment are the size and the number of rooms followed by its attractive and quiet surroundings. As energy costs are hidden and hard to compare only a small share of respondents (25%) are aware of the main domestic energy cost factor for room heating and hot water (more than 50%).

When refurbishment projects of buildings are set up as effective measure for energy savings, possible rebound-effects have to be considered. Studies to date indicate that after the refurbishment not only expected energy reductions are hardly achieved but by a worst case scenario even an increased energy consumption for space heating is possible. Peter Biermayr examined measures for minimisation of rebound-effects concerning residential building renovation.[7] Within the framework of economical, structural and technical rebound effects he sees only limited opportunities for the reduction of rebound-effects when on the other hand higher demands on comfort and on living space is to be provided. Nevertheless, Biermayer suggests optimising the heating system or implementing an intelligent regulation system to reduce technical rebound-effects. Further research could be done to explore societal, social, ethnical, and especially gender-related aspects of different demands on comfort and how it could be restricted to a meaningful measure.

Gabriele Rohregger evaluated comfort, health and recreational value of passive houses. [8] Usually passive house concepts are not presented as “comfort houses” but as “highly energy-efficient buildings” or “houses without heating”. As such, potential customers tend to be sceptical about living in a house without a heating system to satisfy individual demands for thermal comfort. Her study stresses that different heating configurations in the buildings (pure heated supplied air, wall heating and pellet stove heating) were equally sensed objectively, via physiological measurements, and subjectively by questionnaires. However, all respondents stated that it would not be possible to heat the passive houses only by the air heating system. The customers’ desire for an additional heating system and individual temperature regulation is so far crucial for a success of the passive house building standard. Gender aspects or differences in the perception of comfort and convenience between men and women remained unobserved.

In most of the sociological studies on users’ acceptance one looks for the word „women” in vain. Men and women are summarized in their statements to „builder-owner” and their different interests are not brought up for discussion. And if attention is paid to gender related aspects, then as a problem making obstacle which has to be considered („space and cityplanning criteria: e.g. bicycle, women, kindergarten, social mixing, generation mixing, civil participation“, Rohracher and Ornetzeder 2008, p. 150) [9] or as „(married) wives“ and as such something which cannot be taken particularly serious („on the part of the wives there is partly a disputing from the belly“, respondent cit. in Rohracher et al. 2001, p. 122) [10].

5. Methods to Investigate Gender Related Aspects of User Behaviour in Energy Efficient Buildings

The research focuses specifically on large-volume multi-storey residential buildings (usable area > 5000m2), office and administration buildings (usable area > 3000m2) as well as larger school buildings and nursery schools which were constructed according to passive / plus-energy house standards or were upgraded to low-energy standards in the last five years. The entire proceedings – from the start of the planning process to the present operations of the building – will be taken into account. To ensure the best possible diversity among the research objects, the ranking of the selected objects was determined firstly by size and energy standards (heating requirement according to Passive House Planning Package PHPP less than 15kWh/m2a), followed by a selection of different locations, new buildings and renovations.

Research questions:

- How much knowledge does exist about the different technologies as well as the topic of energy efficiency
- Which motives and attitudes exist
- How are the technologies being used (operation, application)

- Which requirements and needs do the users have concerning the technologies/ the building/ the functionality?
- How and according to which factors can the users be segmented/ which user groups can be identified
- Do gender aspects have influence on user behaviour
- Are there differences in the perception of comfort/ convenience depending on lifestyle/ living standards/ values system
- Do various user groups have different needs for and behaviour towards obtaining information
- To which extent is the application of technology regarded as reasonable by the users? (affinity to technology)

5.1 Initial survey:

A plain user survey about their behaviour, habits, attitudes, motives and needs would only capture a superficial understanding of those. Many things that have become second nature (automated actions) or happen even unconsciously would therefore not be considered. [11] Therefore, in the first part of the initial survey a mix of methods of qualitative empirical social research is applied. Afterwards in the second part, the yielded results will be quantified by means of larger samples.
Qualitative pilot study: mixed methods, observation, ethnography, in-depth interviews
Quantitative questioning: in different target groups, by means of standardised questionnaire, large sample

It is the aim of this pilot to identify the range of existing attitudes, opinions, motives, behaviours and behavioural routines of the users of the researched buildings and understand their connections.
Especially when dealing with automated behavioural patterns, a lot is unconscious and would not be stated during an interview because it is regarded as obvious or self-evident. [11]
Through observation, these automated behaviours and habits as well as all behavioural routines can be surveyed and documented (e.g. filming, taking photos).
Additionally, ethnographic methods and in-depth interviews are used to add explanations by the users to the observed facts.
In so-called „focus blogs“, a small group of participants will be dealing with the topic for a limited period of time in a staged blog under the guidance a moderator. This method is similar to the conventional group discussion but is handled online. The participants will be asked questions and be given short tasks which will then have to be worked on and discussed in the blog. The advantage of this method is that the participants have an extensive amount of time to deal with the topic. Furthermore, they can upload self-made video and photo material and hence also provide non-verbal information. [12]

Webdiaries are arranged similarly to focus blogs but are more structured. The participants are provided with material they can work on by the moderator. Several rounds of tasks are carried out. The participants can also work on drafts or evaluate ideas and drafts, respectively. They can observe many aspects of their user behavior, illustrate and explain it, and develop new ideas and solutions. [13]

For the steps where social media methods are introduced, only users can be included who have internet access and are internet literate. However in 2010, 75% of Austrians used the internet and in 73% of households, internet access was available, with this figure set to increase in the future. [14] The stated social media methods are being utilized successfully in many areas of market research and innovation research, since they compensate for numerous disadvantages of conventional questioning – like limited time frames or little opportunity for the interviewee to contemplate or purely focusing on conscious verbal content. This contributes to a higher validity of the results. [11] For this purpose, they should render data in addition to the results from the qualitative one-on-one interviews by encouraging the researched users to more closely observe and analyse their behaviour. These additional methods will only be used for part of the participants, depending on their willingness and their possibility to work online. (access, „internet literacy“).

The sample is small, as is common for qualitative samples. It consists of different groups. These

are diversified according to lifestyle and other socio-demographic properties. The “Lebensphasenmodell” (Stage of Life Model), the socio-demographic structure of the Austrian population as well as models of lifestyle research will serve as a basis for this. Gender aspects are regarded separately.

Advantages of this extensive approach: a comprehensive and at the same time detailed image of the existing behaviours can be obtained attitudes and motives are identified and can be put into context from this, the needs of the users can be identified within the overall system to serve as a basis for the measures planned for step 2.

From the information collected in the pilot phase and from already existing studies, a structured questionnaire is developed which forms the basis for representative questioning. A sample consisting of a few hundred people will be recruited out of the users of the selected buildings. These interviews will be rendering representative data on behaviour, attitudes and motives of the users, which will then be assessed for significant differences in gender, diversity aspects, socio-demographic markers, lifestyle, values and many more. This phase allows to quantitatively acertain the acceptance of concepts and ideas developed in the qualitative phase.

As mentioned before, the research focuses on large-volume multi-storey residential buildings (usable area > 5000m2), office and administration buildings (usable area > 3000m2) as well as larger school buildings and nursery schools which were constructed according to passive / plus-energy house standards or were upgraded to low-energy standards in the last five years. Included will be

- 3 passive-house residential buildings,
- 3 passive-house office buildings and
- 3 passive-house school and nursery school buildings.

In the office buildings, the participants will be grouped according to various departments and a cluster sample will be drawn in order to produce a representative sample. In the schools and nursery schools, the entire teaching and childcare staff, the building service providers and technicians and the administrations will be contacted. Individual school classes will be chosen by means of cluster sampling and interviewed.

From the results of the initial survey, exact conclusions about behaviour, knowledge and attitudes of the users can be made, factors which determine user behaviour (ranked according to their intensity) can be identified, user profiles in the researched building types structured according to user groups can be created, differences in user behaviour between various user group according to gender and diversity aspects can be depicted (segmentation of users), the needs of the users can be deduced weighted by importance and degree of satisfaction, the influence of attitudes/ values/ lifestyles on user behaviour can be determined and existing differences of all aspects can be identified according to gender and diversity aspects.

5.2 Developing measures and solution strategies:

Based on the results of part 1, the most important factors to influence user behaviour will be analysed and measures and solution strategies will be conceived, e.g.

- information/ education and feedback measures for utilisation,
- different standards of regulation and supervision,
- „low tech“ solutions or
- incentives for employees (office buildings).

Special focus will be put on differences according to gender and diversity aspects.

5.3 Application in research units:

These measures will subsequently be implemented in a sample. The number of research units may vary according to the complexity of the proposed measures, e.g. the extent to which technology is used. Measures purely for information and education can be applied in larger groups rather than technically complex measures.
To be able to measure the effects of the strategies on user behavior (habit, routine), a time frame

of 4 to 6 months is calculated for this phase.

5.4 Evaluation of measures

For the final evaluation, the questionnaire created in the initial survey (step 1) will be utilised again to make the differences in behavior measurable.
All research units that participated in part 3 will be interviewed again.
This will provide an evaluation of the effects of the developed measures and solution strategies on user behavior by comparing the data before and after the changes were made.

6. Results

At the moment, the first qualitative part of the project has been concluded. The second phase of quantitative interviews in the test buildings are in the planning stages and will commence within the next month. A few aspects from the qualitative research could already be deduced that will be quantified in the subsequent questioning.

6.1 Motivations for moving into a passive house building:

The main motive for the residents that determined moving into the building complex was not so much the energy aspect but rather the good quality of living in the new and renovated apartments as well as the location. In the office and school buildings, the energy aspect is of more importance because the key staff (headmasters and headmistresses, office managers, CEOs) had already communicated about the advantages of a passive house building.

6.2 Level of knowledge and information:

The level of knowledge and information is small for most users in regard to functionality and the implementation of a passive house. Only few users feel sufficiently informed. If information material had been provided by the building owners or property management when the users moved in, the material was regarded as unappealing for the majority of users because it was too technical and incomprehensible.

6.3 Amenities of temperature and air quality:

The temperature regulation does not pose a problem for many users. For part of the interviewees it is problematic, however, to reach a comfortable room temperature. Depending on the seasons, the rooms are too cold during the winter and too hot in the summer. This user group refers to a badly functioning ventilation system. It is hard for this user group to regulate ventilation. It is often unknown how it works or is being used in the wrong way. Subsequently, the ventilation system is sometimes being rendered inoperative, for example by blocking the vent openings. It is considered as another possibility for regulating the room temperature to open the windows, although it is known that the windows should best remain closed.

This course of action is more common in the school and office buildings than in the residential buildings. Especially in the schools, the majority of teachers open the windows on a regular basis because the room appears too stuffy. Additionally, dry air is complained about. The students do not perceive this, however.

The users of the office buildings show similar behaviour. Many of them open the windows to let in better – not so dry – air. Some of the users complain about health problems as a consequence of the ventilation system. It has to be noted that this was solely mentioned by male employees.

6.4 Handling:

The control systems in the rooms are restricted to regulating the ventilation system and raising and lowering of the blinds. A part of the users perceives this as restricting, especially as the logic

behind it cannot be understood, e.g. why blinds are suddenly raised when the sun is shining on that particular side of the building.

6.5 Gender aspects:

Ecological aspects play a more and more important role in social community housing; residents in such buildings have a rather low level of education and small incomes. The role of women is a more traditional one. Therefore, they might spend more time at home and can/should serve as the main contact person for the technical facilities. Women make themselves responsible for many things in the household organization.

Women often consider issues in regard to their children. Social aspects play an important role for this. One starting point is to increasingly see them as addressees for environmental issues. At the same time, men who also fulfill their care responsibilities will be addressed with the same issues. Women should be encouraged where they doubt their technical abilities and understanding. Where they have no doubts, their competences can be further acknowledged.

In the quantitative study which will start shortly, the stated aspects will be transferred into a standardized questionnaire and will be quantified in an extensive sample. Only then can valid predictions about the emphasis of individual aspects be made.

Short Summary

Energy Efficiency in Buildings has been gaining increasing relevance in the past decades due to the raise of the energy consumption in the building sector as a consequence of the modern way of living with higher comfort patterns. In Europe, buildings are responsible for 40% of the energy consumption, which turns them into an important target for carbon emissions' reduction [1]. Energy efficiency should be a main concern not only in new buildings, but also in the existing ones, which have poor energy performances. In Portugal most of the building stock was built before 1990, date of entrance into force of the first thermal regulation. Therefore, most of these buildings need intervention to improve not only the living environment, but also their energy performances. To evaluate the best measures, that fulfil the minimum requirements established for the energy needs with the lowest costs, the European Commission released the Commission Delegated Regulation (EU) Nº 244/2012 that establishes a comparative methodology framework for calculating the cost-optimal level for minimum energy performance. In order to verify the renovation potential of these buildings, based on the Delegated Regulation methodology and taking advantage of a renovation process in course, a social housing neighbourhood called Rainha Dona Leonor was analysed. This analysis allowed obtaining the optimal levels for different renovations measures. The results show that it is not possible to establish a direct connection between the optimal level for the building envelope and the building as a whole, without considering the influence of the building systems.

Keywords: Buildings renovation, cost-optimal, energy savings, renovation measures

1. Introduction

Changes in the comfort patterns required by the buildings occupants and the buildings poor energy performance, led to excessive energy consumption in this sector, especially electricity [2].
In order to stop the increase in energy consumption and help the member states to keep up with their commitment towards the 2020 targets, the European Commission released the Directive 2010/31/EU (EPBD recast) to replace the previous one, dating from 16 December 2002. The new Directive states that after 2020 every new EU building must be a nearly zero energy building (nZEB). Besides this, every member state should create a methodology to establish minimum recommended requirements for buildings and building components to be integrated into the national legislation.
The minimum recommended requirements should be established to the buildings cost-optimal levels and also to their components [3].The cost-optimal level is the balance between the best energy performance achieved with the lowest cost during the buildings life cycle [4]. The costs

include initial investment, maintenance costs and energy costs.
Based on primary energy consumption and on the investment in each renovation solution, this methodology allows analysing different solutions. Usually the analysis starts with a basic solution and evolves to more efficient ones. When the analysis includes packages, instead of individual measures, it is possible to observe not only one cost-optimal level but a group of similar packages that form a range of cost-optimal solutions [5].
The combination of several measures can create a synergy that leads to better results compared to individual ones. Therefore, it is possible that despite the increase of the initial investment, the global cost may decrease because there is less energy costs associated to a certain measure or package. However, after a certain point, the increase in the initial investment will not be compensated by the reduction in energy costs [5].
This is an iterative process and the biggest challenge is to assure that the analysis doesn't become unbearable due to the numerous possibilities. Therefore, the analysis should be targeted to the lowest energy consumptions and lowest carbon emissions [5].
The cost-optimal analysis can follow two different perspectives: private perspective (microeconomic) and social perspective (macroeconomic). The social perspective considers the cost of the carbon emissions and excludes investment rates and discounts. The private perspective considers the discount rates and excludes the carbon emissions costs [5].
The methodology also advices choosing a reference building that can be either real or virtual. This building must be representative of the major part of the national building stock in order to have results that do not depend much on the buildings specific characteristics. In countries where the building stock has not been renovated, the age criteria may be very useful [5].
In Portugal the building sector is the second biggest energy consumer [6] after transports.
Despite this fact, there aren't yet many studies in accordance with these recommendations, so it is important to develop knowledge by applying the methodology to case studies.
Therefore, the present work aimed at studying a real building in which this methodology has been applied. The chosen building is part of the social housing Rainha Dona Leonor neighbourhood and it is located in Oporto city, Norwest of Portugal.

2. Methodology

The analysis followed the recommendations of the Delegated Regulation and the selected building is representative of the Portuguese building stock and is currently under a renovation intervention.
The analysis started with the energy characterization of the building. The determination of the energy needs followed the Portuguese regulation for thermal behaviour of the buildings (RCCTE, Decree-Law 80/2006) in accordance with ISO – 13790 [7]. The comfort temperatures considered were 20ºC for winter and 25º for summer.
After this characterization it was necessary to establish renovation measures able to promote energy efficiency in the building. The measures should affect the elements of the building with higher losses in winter and excessive gains in summer.
For this case study, the renovation measures intended to improve the insulation level in walls, roof, floor and windows. There were also some calculations related to the heating/cooling systems. The analysed systems (one for heating and another for cooling) were divided into three groups: first, electric heater and electric cooler; second, gas boiler with radiators for heating and electric air conditioned for cooling, third, a heat pump for both heating and cooling.

To evaluate the impact of the renovation measures it is necessary to calculate the heating and cooling needs and then the energy needs for all other usages. After that it is necessary to calculate the primary energy usage.
After calculating the energy needs for each measure or package it is necessary to calculate the global cost. The solution with the lowest global cost is the cost optimal solution. This global cost depends on the initial investment and on all the costs related to the measure during the life cycle of the building that was considered of 30 years. The costs were calculated according to the private perspective, so the carbon emissions costs weren't considered. The discount rate applied was 6% and it was considered an increase of the energy cost of 3% per year. The initial investment and maintenance costs were based on the Cype® software for generating prices.
With the primary energy consumption and the global cost of each renovation measure, it was

possible to determine the cost optimal measure. For this case, the primary energy included only the heating and cooling needs.
For an easier reading, the results were presented in graphics with the primary energy consumption on the x-axis and the global cost in the y-axis, for every tested measure. This way of presentation usually allows drawing a curve where the lowest point shows the optimal level for the selected building.

3. Case study characterization

The analysed building is part of a social housing neighbourhood built in 1953. It has two apartments with three bedrooms each with a total area of 110.54m² (55.27m² each apartment), divided in two floors. The building no longer comply with the current living patterns, therefore it will be transformed in two apartments, one in each floor and, instead of three small bedrooms, there will be only one bedroom with a bigger area, in each apartment. Besides these changes, the project also includes improvements in the building envelope. Figure 1 shows the building final horizontal plan and figure 2 shows how it looks like after renovation.
The building has single brick walls, light weight slabs, a wooden roof structure covered with fibre cement tiles and wooden windows frames with single glass. There is no insulation and the domestic hot water (DHW) is provided by an electric heater with a storage tank. The building doesn't have any heating or cooling system installed.

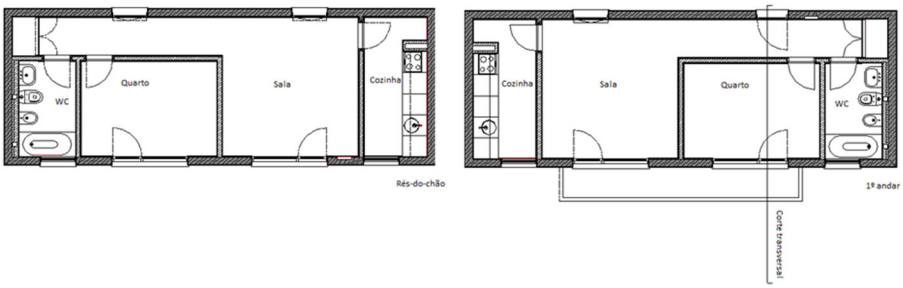

Fig. 1 Building horizontal plant after renovation

Fig. 2 Building front view, after renovation

3.1 Renovation measures

The intervention on the living space is a good opportunity to improve the energy performance of the building without increasing excessively the initial investment. However, it is important to study its impact before the final decision. Table 1 summarises the studied measures for this case study.

Table 1: Summary of the studied renovation measures per each building component

Element	Renovation Measure	Analysed Insulation type
Wall	*ETICS	*RW (thicknesses of 80, 100,120 and 140mm)
	Ventilated Façade	*EPS, *XPS and *MW (thicknesses of 60 and 80mm)
	Insulation in the inside	*EPS and *RW (thicknesses of 40, 60, 80, 100, 120 and 150mm)
Roof	Insulation above the slab	*EPS, *XPS and *RW (thicknesses of 60, 80, 100, and 120mm)
	Insulation above the roof' wooden structure	Sandwich panel with MW or XPS (thicknesses of 60, 80 and 100mm)
	Insulation above the existing fibrocement sheets	*GW and *RW (thicknesses of 80, 100, 120 and 140mm)
	Insulation between the wooden beams	*MW (thicknesses of 50 and 60mm)
Floor	Insulation above the floor slab	*XPS (thicknesses of 40, 60, 80 and 100mm)
	Insulation above the regularization concrete layer	*RW (thickness of 20mm)
	Insulation under the slab	*RW and *XPS (thicknesses of 40, 60, 80 and 100mm)
Window	New windows in PVC, Wood or Metal	Glass: 4+6+6 Low ε; 100% árgon
		Glass: 4+10+6 Low ε; 100% árgon
		Glass: 4+12+6 Low ε; 100% árgon
		Glass: 4+16+6 Low ε; 100% árgon
		Glass: 4+18+6 Low ε; 100% árgon
Heating and cooling Systems	Electric heater	
	Gas boiler	
	Heat pump	

*ETICS – External Thermal Insulation Composite System; XPS – Extruded polystyrene; EPS – Expanded polystyrene; MW – Mineral wool

4. Results

This section presents the cost optimal results obtained for the walls, roof, floor and windows considering the referred three heating and cooling systems for the analysed renovation measures. The purpose of the analysis was to find the cost-optimal solutions for each one of the building elements. Building renovation packages were not analysed. The reference solution (the starting point) included 60mm of EPS on the walls, 60mm of XPS on the roof and windows with wooden frames and double glass.

4.1 Wall

For the walls, the best solution consists in placing the insulation on the inside. This is due to the low investment needed to implement this solution. Figure 3 shows the results for different thicknesses of wall insulation and for the three heating/cooling systems analysed. The lowest point in each cloud of points is the cost optimal solution for that specific system.
Table 2 shows a summary of the best solutions per each one of the systems analysed. The best performance corresponds to 80mm of insulation on the wall when using heat pump for heating and cooling. This equipment may have a high initial cost but the energy savings along the building life cycle compensate the initial investment resulting in a lower global cost. For the other equipments

the cost optimal solution was obtained with higher insulation thicknesses.

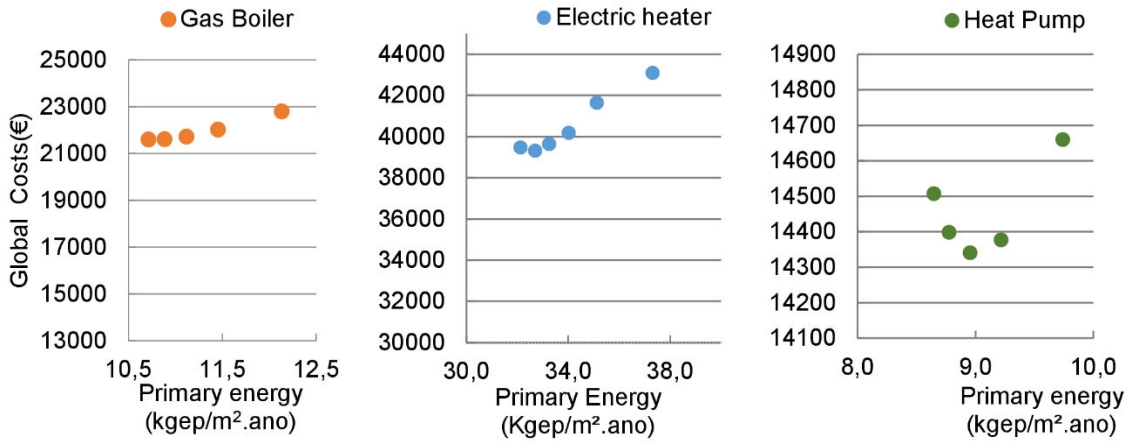

Fig. 3 Cost Optimal curves for the external walls for each of the three tested systems

Table 2: Cost optimal solutions for exterior walls per type of heating/cooling system

Equipment	Cost optimal	U-value (W/m².˚C)	Primary energy (kgep/m².year)	Costs (€)		
				Investment	Energy	Global
Electric heater and cooler	120mm *EPS	0,27	32,70	5593	33726	39320
Gas boiler	120mm *EPS	0,27	10,71	5593	16012	21605
Heat Pump	80mm *EPS	0,36	8,95	5108	9234	14342

*EPS – Expanded polystyrene

4.2 Roof

Among the measures analysed for the roof, the best solution corresponds to keeping the existing roof solution and applying insulation above it, placing asphalt shingle on top. Figure 4 shows the results for different thicknesses of roof insulation and for the three heating/cooling systems analysed. Per each system, the lower point represents the optimal solution which is placing rock wool with 80 to 120mm, depending on the heating/cooling system adopted, above the existing roof and cover it with shingle.

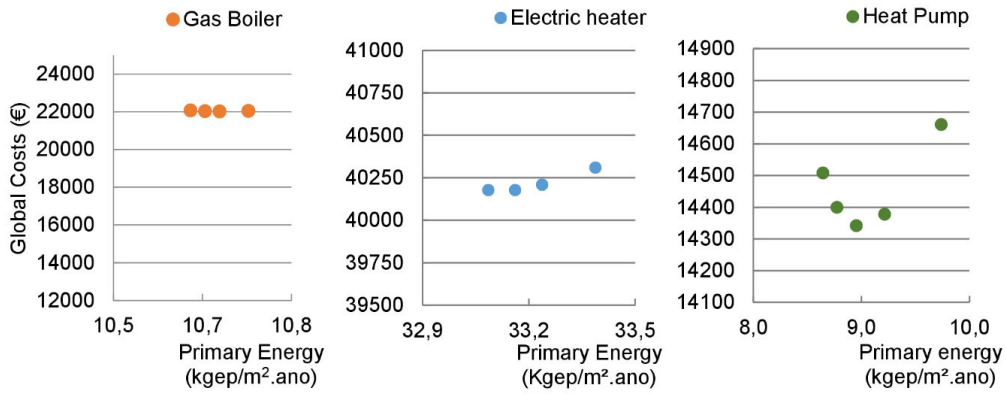

Fig. 4 Cost optimal solutions for the renovation measures in the roof per each of the tested systems

Table 3 summarises the results for the cost-optimal solutions with different heating/cooling systems. The heat pump is the equipment that combined with this solution requires the lowest roof insulation level.

Table 3: Cost optimal solutions for the Roof per type of heating/cooling system

Equipment	Cost optimal	U-value (W/m².˚C)	Ntc (kgep/m².year)	Costs (€)		
				Investment	Energy	Global
Electric heater and cooler	120mm *RW	0,17	33,16	5974	34205	40178
Gas boiler	100mm *RW	0,18	10,68	5927	16107	22034
Heat pump	80mm *GW	0,20	8,55	5871	8816	14687

* RW – Rock wool; GW – Glass wool

4.3 Windows

For the window frame type, PVC is the most cost effective. The changes come especially from the glass type. Figure 5 shows the results for the windows with PVC frames with different glass types. The best glass type is the 4+16+6 with argon or air inside the air gap.Table 4 summarises the cost-optimal solution for the windows with PVC frames, for the three systems analysed.

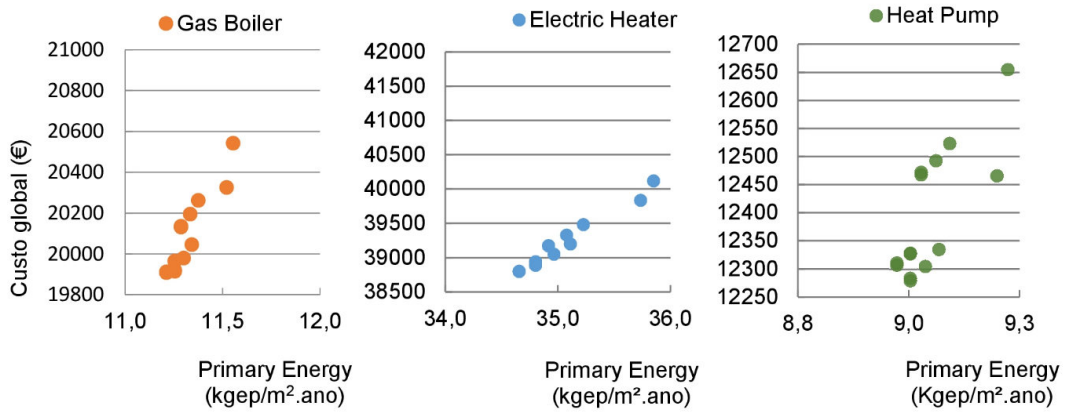

Fig. 5 Cost optimal solutions for the window renovation measures, for each one of the three analysed systems

Table 4: Cost optimal solutions for Windows with PVC frames with different systems

Equipment	Cost optimal	U_{glass}-$U_{frame.}$ (W/m².˚C)	Primary energy (kgep/m².year)	Costs (€)		
				Investment	Energy	Global
Electric heater	PVC + 4+16+6 100% Árgon	2,60-1,70	34,65	3052	35746	38798
Gas boiler	PVC + 4+16+6 100% Árgon	2,60-1,70	11,21	3052	16856	19908
Heat pump	PVC + 4+16+6	2,70-1,70	9,00	2993	9287	12280

4.4 Floor

For the floor, every solution was tested considering the creation of an air space underneath the floor slab. Taking this into account, the best solution was the application of rock wool under the slab. Figure 6 shows the results of different thicknesses combined with each one of the analysed systems. Table 5 has the compilation of the cost optimal results. The best result comes with the heat pump and with 40mm of rock wool insulation under the slab.

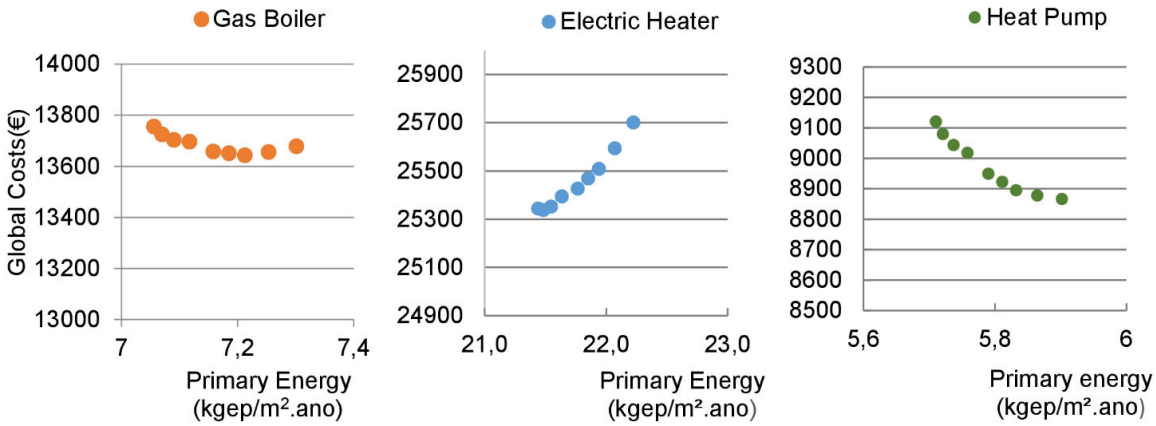

Fig. 6 Cost optimal solutions for the floor renovation measures, for each one of the three analysed systems

Table 5: Cost Optimal solution for the Floor per type of heating/cooling system

Equipment	Cost Optimal	U-value (W/m².˚C)	Primary energy (kgep/m².year)	Costs (€)		
				Investment	Energy	Global
Electric heater and cooler	140mm *RW	0,21	21,48	3180	22158	25338
Gas boiler	60mm *RW	0,42	7,21	2880	10764	13643
Heat pump	40mm *RW	0,55	5,90	2780	6087	8867

*RW – Rock wool

5. Conclusions

For each building component, the cost optimal solution depends on the efficiency of the heating/cooling equipment used. The more efficient the system the lower the level of insulation of the envelope needed. In this case, the heat pump allowed using a thinner layer of insulation to maintain the same comfort levels as the other systems.
In this particular case, the reference solution was already a good solution, considering the Portuguese patterns, unless for the floor. Therefore, the only renovation measures with significant impact on the building energy performance were those related to this building element. However, this conclusion cannot be generalized since this is not the common situation of the Portuguese existing buildings.

Short Summary

State-of-the-art studies indicate that the biggest energy saving potential in Serbia lies in the residential sector. These buildings mostly have poor thermal properties of building envelopes. We conduct our research to evaluate energy saving potential, cost-effectiveness and thermal comfort during the summer of three retrofit solutions for a representative house. A case study research is employed as a primary methodology, while simulation in relation to experimental research is the most dominant research tactic. The representative model of the detached house is located in Belgrade. Three retrofit solutions are evaluated through Euro-WAEBED and GEBA dynamic simulations. The results depict applied retrofit measures by annual savings, pay off period, and possible overheating in summer. Proposed retrofit strategies could be applied trough partial or comprehensive renovation for typical detached houses in Serbia.

Keywords: retrofit; building envelope; energy efficiency; overheating; house.

1. Introduction

Existing buildings significantly contribute to the high energy consumption in Serbia [2], where 38% of total energy consumption is due to the residential sector [3]. The First National Energy Efficiency Action Plan of the Republic of Serbia (NEEAP) point out that residential sector has the biggest cost-effective saving potential [4]. The average consumption for heating and domestic hot water preparation in households is approximated to 228 kWh/m^{2}a [2].

Around 70% of the population in Serbia lives in houses [5]. Most of the existing residential buildings in Serbia characterize poor thermal properties of building envelopes. Retrofit strategies that have been employed in recent years differ by the level of intervention from the value retention to the partial renovation [1]. In order to improve energy conservation, inner comfort and prevent summer overheating of the houses appropriate retrofit strategies have to be considered.

A growing body of literature has investigated the potential of building retrofit in Serbia. Main topics were renovations by passive and active measures. Energy efficiency in Serbian buildings was investigated by Sumarac [9]. For analysis of energy consumption in Belgrade, methodology was developed by B. Todorovic [10]. M. Todorovic investigated large scale residential RES integrated refurbishment [11] and refurbishment of existing multi-storey buildings in Belgrade [12]. She indicated that multi-storey housing in Belgrade has a massive energy saving potential. The work of Matic [13] analyzed renovation of multi-storey building to zero-energy and zero-carbon building. Stankovic and Nikolic [14] analyzed possible renewal of preschool facilities in Serbia trough green building technologies. Jovanovic [5] highlighted the importance of energy efficiency in single family

houses while investigated the model of energy-efficient house for the city of Nis. Stevanovic [15] analyzed the cost-effectiveness of active retrofit measures on a single-family house. Stevanovic found that investments were slow in paying off and announced that subsidies could increase retrofit rates. Bojic performed the study of refurbishment of old single family house in Belgrade [16] and described renovation scenarios for building envelope, heating system improvements and financial issues. He also investigated the impact of internal partitions on energy conservation. Bojic [17] stated that research efforts should be extended to cover multitude of interesting issues on energy conservation matching application of the envelope with better or worse thermal performances.

These refurbishments have mostly been studied in very specific case studies with focus on heating demands. The most of annual energy consumption in Serbia is due to the high heating demands. Since Serbia's average solar irradiation levels are 40% higher than the European average [7], the equal attention should be paid on the overheating during the summer months. Considering current findings and future necessities, retrofit solutions that we evaluate from the environmental/economical/social point of view, should be applicable to a bigger sample.

The goal of this paper is to evaluate building envelope retrofits by energy saving potential, cost-effectiveness, and thermal behaviour of buildings in summer. We conduct our research based on following research questions considering a common detached house in Serbia:

1) What is the energy saving potential of building envelope retrofits?
2) What is the cost-effectiveness of building envelope retrofits?
3) How do retrofits change inner comfort during the summer months?

For that purpose, we simulate one house in the initial condition and in three different retrofit scenarios. More information on methodology and our sampling procedure can be found in section below.

2. Methodology

2.1. Architectural research methods

The case study research [19] was employed as a primary methodology. We used experimental and simulation research tactics [19] to evaluate the effectiveness of the proposed retrofits regarding our research questions. Three retrofit scenarios were applied for the representative house. The proposed retrofit solutions improved thermal properties of building envelope by insulating external building components and by replacing old doors and windows.

2.2. Simulation software

Simulation software Euro-WAEBED [20] was used to estimate heating demands for the basic house and its three retrofit scenarios. GEBA simulation software [20] was used to predict thermal behaviour of the building in summer. These tools provide an appropriate accuracy of output data [21]. The tools were previously employed in research works published by Stieldorf and Krec [22-23] and other authors [24-25] to estimate energy performance of buildings.

2.3. Climate

The analyzed house was positioned in the city of Belgrade, the capital of Serbia, in Southeast Europe. To familiarize with the local climate, Figure 1 depicts mean temperatures in the city [26]. The climate data for Belgrade are used as input information for the simulations.

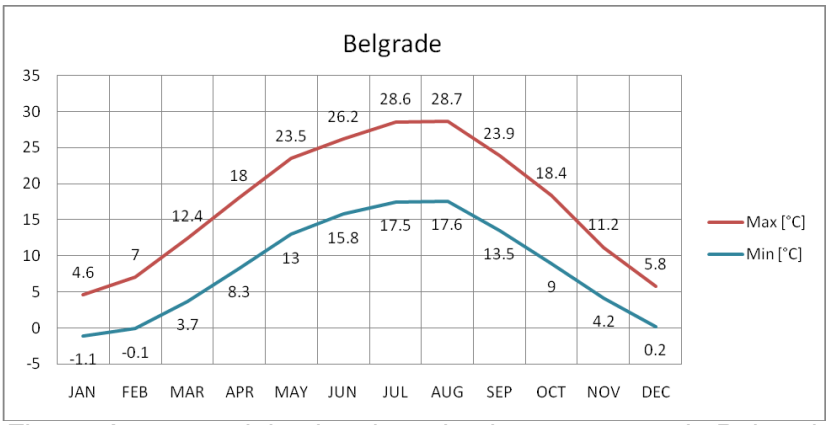

Fig. 1: Average minimal and maximal temperatures in Belgrade for the period 1981-2010 [26]

July and August are the hottest months in Serbia, while the Sun is at higher point in July. According to the Hydro-meteorological Service of Serbia, average maximal air temperature for July 2013 is expected to be 28.9°C [26].

2.4. Sampling procedure

The housing stock in Serbia was significantly enlarged during the period 1960-1990. About 1700000 housing units or 62% of total housing stock emerged within these 30 years [27]. These buildings characterize same concrete structure, brick-block walls, cement plaster and lack of thermal insulation [8]. We determined typical detached house from 1970's designed by architect Milisav Vojinovic to be the model for our simulations. The model was selected from the database of about 1300 typical housing designs from 70's and 80's in Serbia and other Ex-Yugoslavian Republics [29]. We used this selection procedure to enlarge the scope of application of our findings.

3. Simulation arrangement

3.1. Model description

The model for our investigation is a two-storey house with total floor area of 126 m^2. The ground floor has the area of 63 m^2 and the upper floor has the area of 63 m^2 as well. These two floors are heated zone. The attic is non-heated zone. A height of the building is 8.7 m and a total façade surface is 206.7 m^2. Total window area is 23.12 m^2, where 7.32 m^2 are south orientated. Entrance doors are 3 m^2.

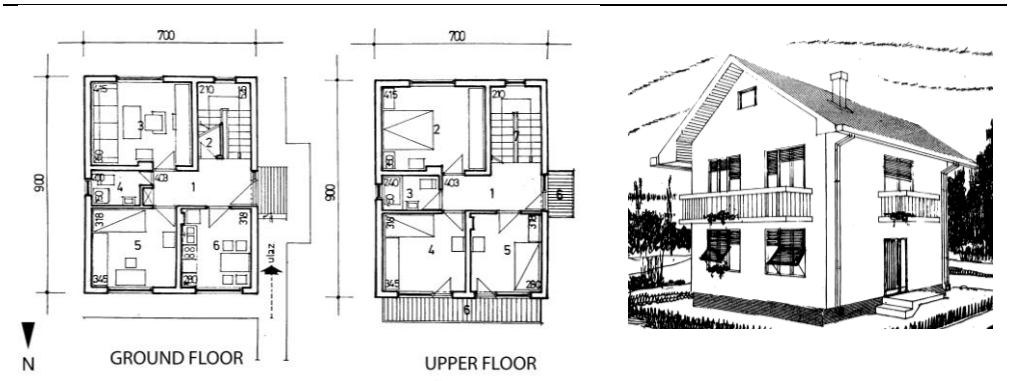

Fig. 2: Floor areas and perspective view of the representative house designed by architect Milisav Vojinovic [29]

The house is built in a concrete-skeleton construction with concrete foundations. External walls are built from brick-blocks with plaster finishing. The ceiling construction is semi-fabricated. The roof

has timber-frame construction with two slopes of 30 degrees. The roof covering are clay roof tiles. The windows are double glazed (80% of glass and 20% of wooden frames). The basic house is without any thermal insulation and has low energy performance. Thermal properties of the elements in building envelope are shown in Table I.

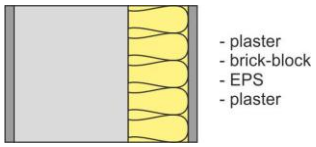

Table I. Properties of the building envelope for the basic house

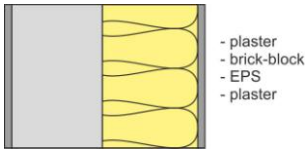
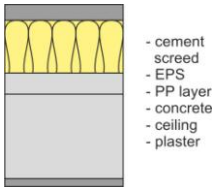
Building Element	Floor	Walls	Roof Ceiling	Windows	Frames	Doors
Thickness D [cm]	56.6	22	21.5	6-12-6 [mm]	22	4
U-Value [W/m^{2}k]	1.52	0.8	0.89	2.91	1.44	2.1

3.2. Retrofit scenarios



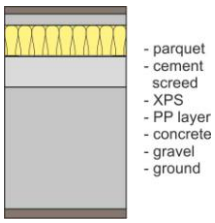


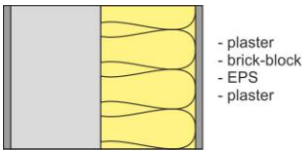
In the first retrofit scenario we improved the initial representative house by partial renovation. Improvements in this scenario considered the addition of the 10 cm polystyrene insulation (EPS) to all external walls. This investment in Belgrade cost 4600 EUR [43-46]. Structural and thermal properties of the insulated building components are stated in Table II.

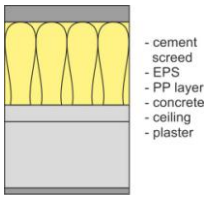
Table II. Details of building elements for the first retrofit scenario (R1)

External wall

Thickness, D=32 cm U=0. 22 W/m^{2}K







The second renovation scenario contained an addition of 20cm of EPS insulation to the external walls. Moreover, roof ceiling was upgraded with an addition of 10cm of EPS insulation and old doors and windows were replaced with double glazed PVC windows (4-12-4 mm) with shutters. This investment cost about 9800 EUR [43-50]. Improved thermal properties of the building components are shown in Table III.

Table III. Details of building elements for the second retrofit scenario (R2)

External wall	Ceiling construction	Windows with shutters
		
D=42 cm U=0.16 W/m^{2}K	D=36 cm U=0.26 W/m^{2}K	U_{frames}=1.1 W/m^{2}K U_{doors}=1.8 W/m^{2}K

The third scenario was a comprehensive renovation. The external walls were insulated with 20 cm of EPS insulation. The roof ceiling was insulated with 20 cm of EPS insulation and the floor on the ground was insulated with 10 cm of extruded polystyrene foam (XPS). Old doors and windows were replaced with triple glazed PVC windows (4-10-4-10-4 mm), while shutters for the windows were also installed. This investment in Belgrade cost about 15700 EUR [43-51]. Improved thermal properties of the building components are shown in Table IV.

Table IV. Details of the building components in the third retrofit scenario (R3)

Floor	External wall	Ceiling construction	Windows with shutters
			
D=66.6 cm U=0.33 W/m^{2}K	D=42 cm U=0.16 W/m^{2}K	D=45.5 cm U=0.18 W/m^{2}K	U $_{frames}$=1 W/m^{2}K U $_{doors}$=1.5 W/m^{2}K

Euro-WAEBED simulations took into account the presence of people, heat gains from the equipment, as well as air infiltration. For heating demands evaluation, the indoor temperature during the heating period was set to 20°C. These standard values were adopted from reference [30]. We assumed that the building was not shaded. For GEBA simulations, the south-oriented living room on the ground floor was potentially overheated space. The critical room was analyzed for the mid of July (Fig. 1).

The economical analyses were conducted by calculating the period of investment-return. For all economical analysis, mid-value of euro exchange rate of the National Bank of Serbia was taken, on the date 15.4.2013, 1 EUR= 111.73 RSD [34]. The value of the investment was determined as the average value from offers of three local construction companies. The average heat-energy price was calculated. Since single houses are not attached to the district heating system [8], the average local price of gas, wood and electricity in different tariffs was 5.11 €ct/kWh [35-38].

The applied passive retrofit measures considered energy conservation in the house. Our focus was to reduce annual heating demands of the building and to avoid the overheating in summer. According to these settings, the building envelope retrofits for the representative house provided output data that we further evaluated.

4. Results and discussion

Dynamic simulations were performed for the basic house and its three refurbishment scenarios. For each case, the paper reports the annual heating energy consumption, the annual savings, the investment return and the summer inner temperatures.

4.1. Energy efficiency

Our investigation showed that the annual heating consumption for the basic non-insulated house was 18646 kWh. Notice that the R2 scenario achieved the low-energy standard with the annual heating demands of 59 kWh/m^{2}a (Table V). The third retrofit reduced the annual consumption for 13326 kWh in total, although the passive house (PH) standard was far to be reached only through the building-envelope retrofit. To target the PH retrofit (i.e. annual heat demands of 15 kWh/m^{2}a) the additional measures including a ventilation system have to be analysed.

Table V. Annual heat energy consumption of the house

Scenario	Annual Heating Demands	Heating Demands Per m^2
Initial house	18 646 kWh	148 kWh/m^{2}a
R1	12 293 kWh	98 kWh/m^{2}a
R2	7484 kWh	59 kWh/m^{2}a
R3	5320 kWh	42 kWh/m^{2}a

The applied retrofit measures showed good energy saving potential. The output data pointed out that 34% of energy can be saved with the partial renovation. The second refurbishment scenario reduced heating demands of the building up to 60% while third scenario reduced them for 72%. Figure 3. describes the effectiveness of retrofit scenarios and the annual energy savings. Respectively to the energy savings, carbon-dioxide emissions from energy production were reduced. Therefore, proposed retrofits improved environmental impact of the building.

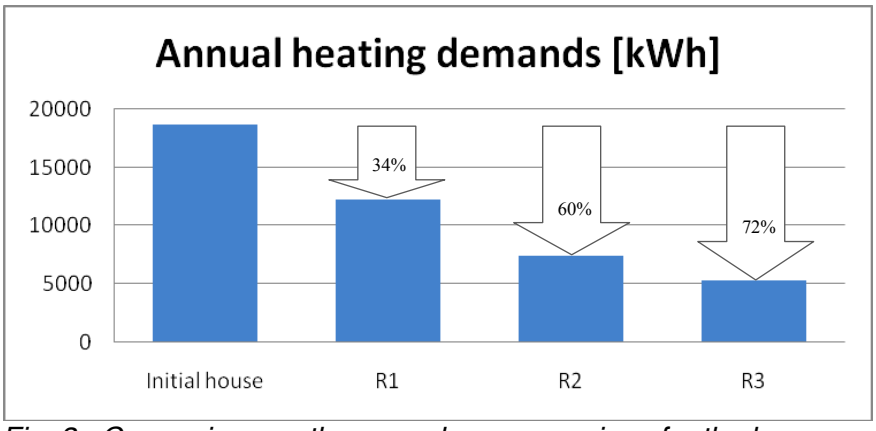


Fig. 3: Comparison on the annual energy savings for the house

4.2. Economical analysis

From the economical point of view, the partial renovation with the R1 was the most affordable option. The investment was the highest in the R3 scenario, for about 60% higher than in the R2 scenario. Despite the R1 showed the quickest financial return, the retrofit R2 demonstrated additional 26% of the energy savings (Table V). In 30 years estimation for Serbia, the R2 saved 144300 kWh more than the R1. The R2 scenario also showed better ratio of investment-return than the R3. Considering applied renovation measures, retrofit R2 was the most profitable solution.

Table VI. Value of the investments, annual savings and pay off period

Scenario	Investment	Annual heating cost*	Annual savings	Pay off **
Initial house	-	960 EUR	-	-
R1	4600 EUR	640 EUR	320 EUR	15
R2	9800 EUR	390 EUR	570 EUR	17
R3	15700 EUR	280 EUR	680 EUR	23

* Annual heating cost with average price for heating from gas, wood and electricity.
** Pay off period in a case of cash investment.

In a case of taking a renovation-loan, an offer from "*ProCredit bank*" on the date 15.4.2013 was used [39]. "*Energy efficiency loans*" have the repayment period of 5 years and an effective interest rate of 8.35%. This could prolong the calculated pay off periods for additional 6 years for the R1, 8 years for the R2 and even 10 years for the R3 scenario. Up to 15.4.2013, the renovation loans in Serbia were not favourable in comparison to other EU countries (e.g. Austria and Germany) [40].

A disparity of energy prices may be the source of impreciseness, because the financial return was calculated for the average energy price. Single prices of specific heat sources (e.g. gas and electricity) would induce quicker investment return. In our previous work, we elaborated differences in pay off period by every heating source in Serbia [8].

A trend of increasing energy prices in Serbia exist and it will also support quicker financial return. Latest increase of electricity price in Serbia took place in 2010 (10% on average) and afterwards in 2011 (15% on average) [41]. The price of gas in 2013 increased for 8.6% [42]. Recent information on future electricity prices show that increase from 10% to 12% is expected in 2013. Although the

precise data on the future prices are currently unavailable, the proposed retrofits will be more cost-effective in the years to come.

4.3. Summer conditions

The proposed retrofit measures on building envelope caused changes in the inner comfort. Regarding the retrofit solution R1, the south-oriented living room on the ground floor showed small decrease of inner temperatures during summer. The R2 with highly insulated walls, insulated roof ceiling and shuttered double glazed windows demonstrated the best results under critical summer conditions (Table VII). The house was cooled from the ground through the floor construction and protected from the excessive solar irradiation by window shutters. The inner temperatures were decreased up to 2°C in comparison to the initial case. This created more comfortable and healthier environment for living. For tenants, well-being is one of the important reasons to invest in retrofitting.

Table VII. Inner temperatures in the living room on 15. July

Temperature	Min [°C]	Mean [°C]	Max [°C]
External air	17.6	26.0	33.6
Initial house	25.0	27.5	29.5
R1	24.7	27.2	29.3
R2	23.8	25.8	27.4
R3	25.7	28.0	29.8

Interestingly, the R3 scenario influenced an increase of the inner temperatures. A combination of highly insulated walls, ceiling and floor with shuttered triple glazed windows failed to provide good inner comfort during summer months. The main reason for this was the floor insulation. In winter, insulated floor was effective to reduce heat loss where floor construction itself contributed with approximately 10% of heat demands reduction. On contrary, during summer the house was blocked to release the heat through the floor in order to be cooled down with ground temperature. Considering thermal comfort in summer months and healthy living environment, the R2 showed the best results with reduced inner temperatures (Fig. 4).

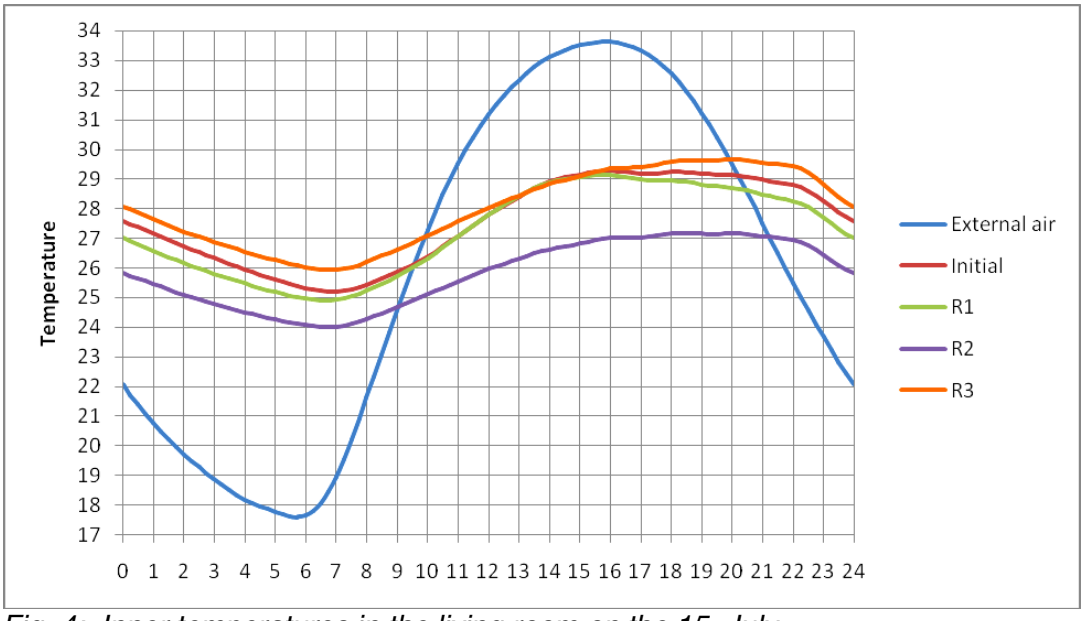

Fig. 4: Inner temperatures in the living room on the 15. July

The environmental, economical and social aspects of building envelope retrofits indicated pros and cons of the proposed solutions. We found that several refurbishments changed the building by

energy efficiency, financial benefit and inner comfort. For appropriate retrofitting in Serbia, beside the heating demands evaluation, thermal comfort and possible overheating have to be analyzed.

As we mentioned in Sampling procedure (Subheading 2.4), our chosen model regards numerous similar detached houses in Serbia. The survey of the outcomes could be used as a first step for refurbishment analysis of these houses. Dependently on the level of renovation, future investors will have an overview about retrofit saving potential.

5. Conclusion

In this paper, we evaluated the energy saving potential of the building envelope retrofits, the cost-effectiveness and the achieved thermal comfort during summer for the typical house in Serbia. The case studies and the simulation research were combined in our investigation. This drew the results that were used to assess benefits of three applied retrofits.

The current housing stock in Serbia has a great energy saving potential. With three variants of building envelope retrofits, we achieved the energy savings from 34% to 72%. The R3 scenario showed the biggest saving potential. However, the R2 scenario showed very competitive result, up to 60% of the savings (Fig. 3.).

Regarding a financial return of the investments, the R1 retrofit scenario showed the quickest pay off period and solid cost-effectiveness. The R3 scenario was the most expensive and less profitable. From the economical point of view, the second R2 scenario was the most profitable long-term solution (Table VI).

An effective retrofit for detached houses in Serbia has to take into account the critical summer conditions. Each building envelope retrofit should be carefully planned to prevent possible overheating. In our research, retrofit scenario R2 demonstrated the most beneficial result regarding inner comfort in summer (Fig. 4.).

The output data established criteria to compare the applied retrofit solutions. Three building-envelope retrofits were evaluated from the socio/economical/environmental point of view. Considering analyzed scenarios for detached houses in Serbia similar to our model, we propose the R2 scenario as the most appropriate solution.

We chose a very common house to be our model for the dynamic simulations (Fig. 2). Because of a similar economy, climate and housing stock, our findings may be used as a start point for the research on this issue in countries in the region. The findings could be helpful to learn how to retrofit the houses from 1970's and 1980's in the most suitable manner. We may recommend that for the refurbishment, house owners and planners do similar economical and non-economical assessment and chose appropriate retrofit measures for a particular house.

In our further work, we will analyse thermal behaviour of the building during summer. Further analysis should also include an equipment renovation and an effect of user behaviour on energy savings. A greater understanding of benefits of energy efficient homes could induce significant improvements in the building sector in the future.

Short summary

The building sector is a crucial sector for a sustainable development. It accounts for a large amount of land use, energy and water consumption, air pollution and impact on climate change. In order to reduce the energy consumption of existing buildings, the 'EFFINOV Bois' research program, a French National Research Agency (ANR) project, suggests to bring industrialised technological solutions using wood systems. These wood based multifunctional complexes can be used within the framework of retrofitting of facades.

The project aims to analyse the potentials of using a light framed wooden structure renovation technique on an existing heavy structured façade. To measure and to demonstrate the environmental progress obtained after the installation of the developed solutions, an environmental analysis has been conducted in a rigorous, quantitative, and comprehensive approach based on Life Cycle Assessment (LCA). LCA is a standardized methodology (ISO 14040 and 14044 standards) based on a quantified inventory of impacts sources such as material, water and energy consumption, waste generation and discharges of pollutants in water, air, and soil. From this inventory from cradle to grave, environmental impact indicators are computed according to NF P01-010, the French standard for environmental building products declaration.

In this study, environmental impacts of the building before and after renovation have been estimated with ELODIE, the building LCA tool developed by the French Building Institute CSTB. The environmental benefit of the renovation solutions has been calculated by making the difference between impacts of the building renovation solutions (materials production, transport, construction, use and end-of-life) and reduced impacts of lower energy consumption during the renovated building lifetime.

Four renovation solutions have been developed: low cost, high thermal performance (HTP), very high thermal performance (VHTP) and all-wood. To connect these solutions to the existing building, two types of support were considered: a facade connection (FC) or a ground connection (GC). All solutions have been adapted to an existing university building for simulation. Three types of building use have been considered for energy consumptions modelling: public assembly building (PAB), tertiary building and housing building.

The renovation solutions developed decrease the renewable energy consumption, non renewable energy consumption, water consumption, hazardous waste and climate change but increase non hazardous waste and inert waste. There is no significant gap between low cost, High Thermal Performance, Very high Thermal Performance, all-wood solutions, and between facade connection and ground connection.

Keywords: Life cycle assessment, wood, building rehabilitation, environmental impacts.

1. Introduction

The building sector is a crucial sector for a sustainable development. It accounts for a large amount of land use, energy and water consumption, air pollution and impact on climate change. In order to reduce the energy consumption of existing buildings, the 'EFFINOV Bois' research program suggests to bring industrialised technological solutions using wood systems. These wood based multifunctional complexes can be used within the framework of retrofitting of facades.

The project aims to analyse the potentials of using a light framed wooden structure renovation technique on an existing heavy structured facade. To measure and to demonstrate the environmental progress obtained after the installation of the developed solutions, an environmental analysis has been conducted in a rigorous, quantitative, and comprehensive approach based on Life Cycle Assessment (LCA).

LCA is a standardized methodology (ISO 14040 [1] and 14044 [2] standards) based on a quantified inventory of impacts sources such as material, water and energy consumption, waste generation and discharges of pollutants in water, air, and soil. In a practical way, LCA relies on the modelling of physical inflows and outflows at the product system boundaries at each step of the life cycle. It is necessary to do a mass and an energy balance.

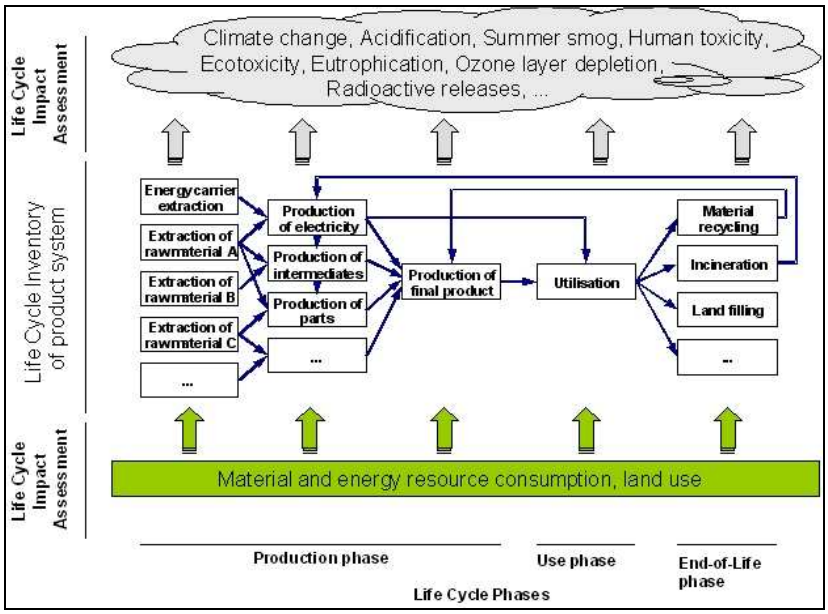

Fig. 1: Scheme of a product system's life cycle with data collection of product and waste flows and resources and emissions followed by the impact assessment of the emissions and resource consumption (source http://lca.jrc.ec.europa.eu/lcainfohub/introduction.vm)

From this inventory from cradle to grave, environmental impact indicators are computed according to NF P01-010 [3], the French standard for environmental building products declaration. Five life cycle stage are considered in NF P01-010: production, transport to construction site, construction, use and end-of-life.

2. Study description

2.1 Renovation solution description

Four renovation solutions have been developed: low cost, high thermal performance (HTP), very high thermal performance (VHTP) and all-wood. To connect these solutions to the existing building, two types of support were considered: a facade connection (FC) or a ground connection (GC). All solutions have been adapted to an existing university building for simulation. Three types of building use have been considered for energy consumptions modelling: public assembly building

(PAB), tertiary building and housing building.

In order to compare the impacts of renovation solutions developed with those of non renovated building, 27 cases have been studied:

Table 1: Studied cases

Building without renovation	BAP	Tertiary	Housing
Building after renovation, facade connection	BAP low cost	Tertiary low cost	Housing low cost
	BAP HTP	Tertiary HTP	Housing HTP
	BAP VHTP	Tertiary VHTP	Housing VHTP
	BAP All wood	Tertiary All wood	Housing All wood
Building after renovation, ground connection	BAP low cost	Tertiary low cost	Housing low cost
	BAP HTP	Tertiary HTP	Housing HTP
	BAP VHTP	Tertiary VHTP	Housing VHTP
	BAP All wood	Tertiary All wood	Housing All wood

For the buildings without renovation, the study is limited to the heating energy consumption for the building use for a period of 50 years. For renovation solutions, the assessment includes the heating energy consumption and the production, transport to pre-fabrication site, construction, use and end-of-life of the renovation materials.The renovated materials are:
- Precast wood walls with window,
- Connecting elements between the walls,
- Junction materials between wall and soil for the ground connection,
- Insulation of the floor and the roof.

The common elements between the existing buildings and the renovated buildings are not considered in this study.

The environmental impacts of the building before and after renovation have been estimated with ELODIE, the building LCA tool developed by the French Building Institute CSTB. ELODIE provides assistance for the design of environmentally friendly constructive solutions. It allows comparing several alternatives for the same building thanks to a LCA approach. The environmental benefit of the renovation solutions has been calculated by making the difference between impacts of the building renovation solutions and reduced impacts of lower energy consumption during the renovated building lifetime.

In this study, three main contributors may cause environmental impacts:
- Life cycle of renovation materials (production, transport to pre-fabrication site, construction, use and end-of-life),
- Assembling on the pre-fabrication site, transport and erection by crane,
- Energy consumption of the renovated building.

2.2 Functional unit

The functional unit is a quantitative performance which characterizes the studied product function. All the flows and impacts refer to this functional unit. The functional unit selected for this study is 1 square meter of net floor area of a building during the lifetime of 50 years.

3. Results and discussion

In this study, four key themes of the French “Grenelle of Environment” have been studied: energy, climate change, water and waste.

3.1 Energy

Regarding energy aspects in LCA according to NF P01-010 standard, there are two types of

energy:
- Consumed energy (burned) by the process (processing, transport, heating...) called fuel energy,
- Energy contained in the material called feedstock energy, which corresponds to a mobilization of a raw material with a calorific value.

These energies, whether feedstock or fuel may either come from renewable or from non renewable sources:
- Renewable energy comes from renewable resources like wind or biomass,
- Non renewable energy comes from fossil resources such as oil, uranium, coal or natural gas.

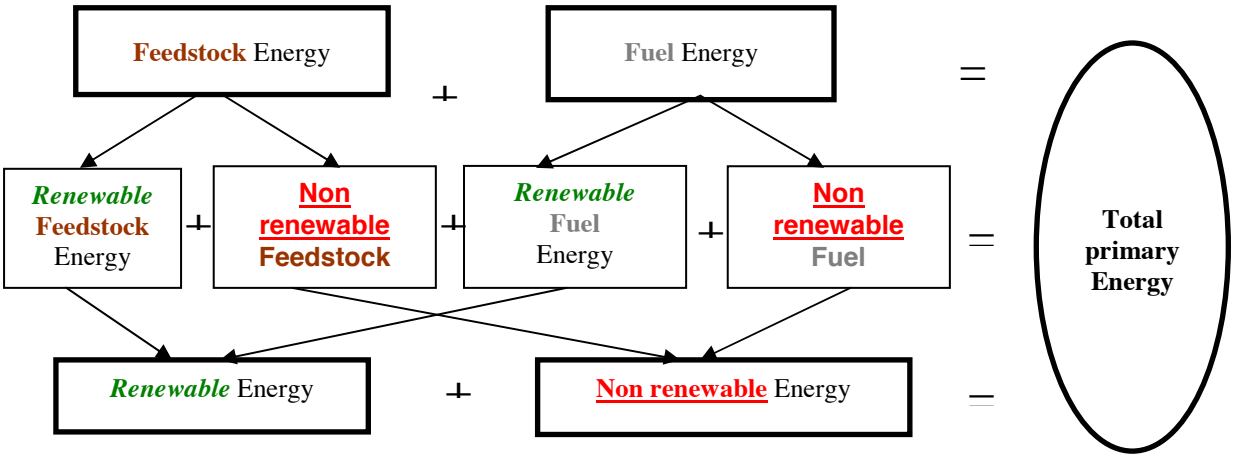

Fig. 2: Energy indicators

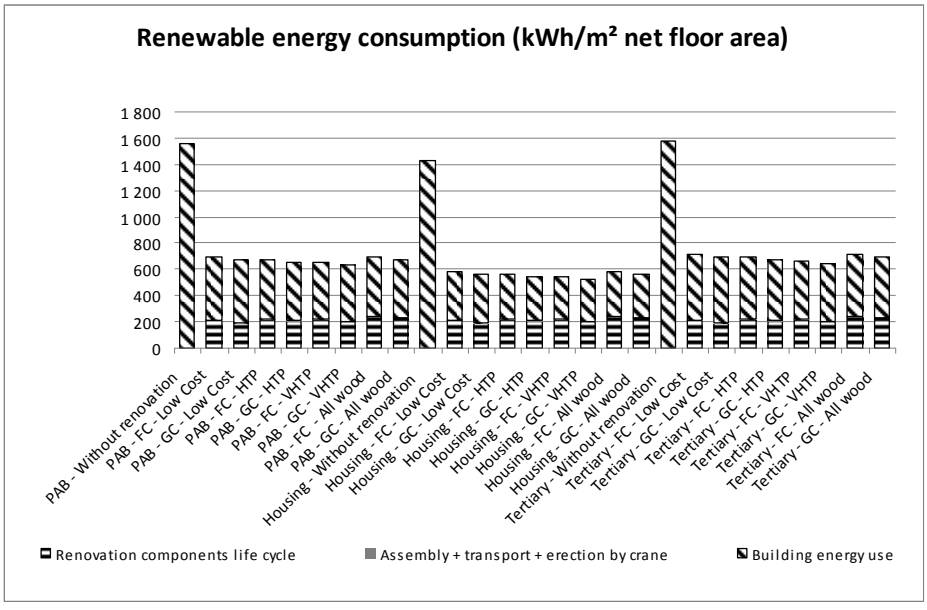

Fig. 3: Renewable energy consumption

The building renovation reduces the renewable energy consumption by 2 without significant difference between the different solutions. The renovation materials' renewable energy consumption is mainly due to the feedstock energy they contain.

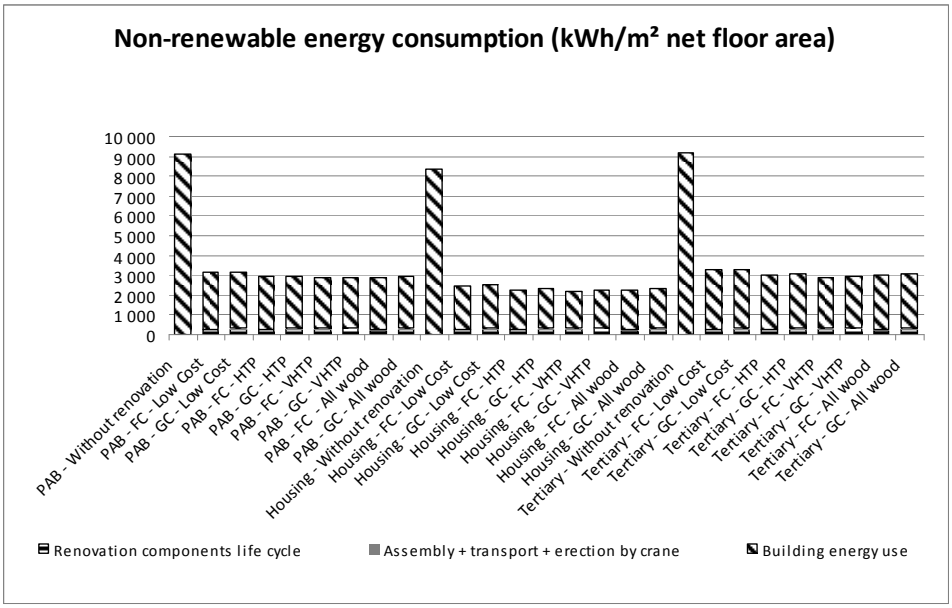

Fig. 4: Non-renewable energy consumption

The non-renewable energy consumption of the renovated building is three times lower than the non-renewable energy consumption of the existing building. The non-renewable energy of the renovation components life cycle, their assembly, transport and installation on site is low compared to the energy gain of the renovated building use whatever the chosen renovation solution.

3.2 Climate change

Contrary to minerals or fossil fuel based materials, wood molecules are the result of photosynthesis which is the transformation of carbon dioxide molecules into organic matter using solar energy. As a result, the growth of the tree captures carbon dioxide from the air. In the LCA methodology, this carbon uptake can correspond to an input or a negative emission. The uptake and emissions of carbon biomass were accounted for in this study, because the balance between uptake and emissions was not equal to zero. In the NF P01-010 standard, the reference scenario is landfilling. For wood, degradation in anaerobic conditions is incomplete and carbon contained in the product is stored for an indefinite time. A bibliographical review has been performed based on different publications including Barlaz study [4] and an average value has been found of 15% degradation rate for wood products.

The climate change indicator includes the greenhouse gases emissions from fossil origin and biomass origin. It is expressed in kg of carbon dioxide equivalent (CO_2).

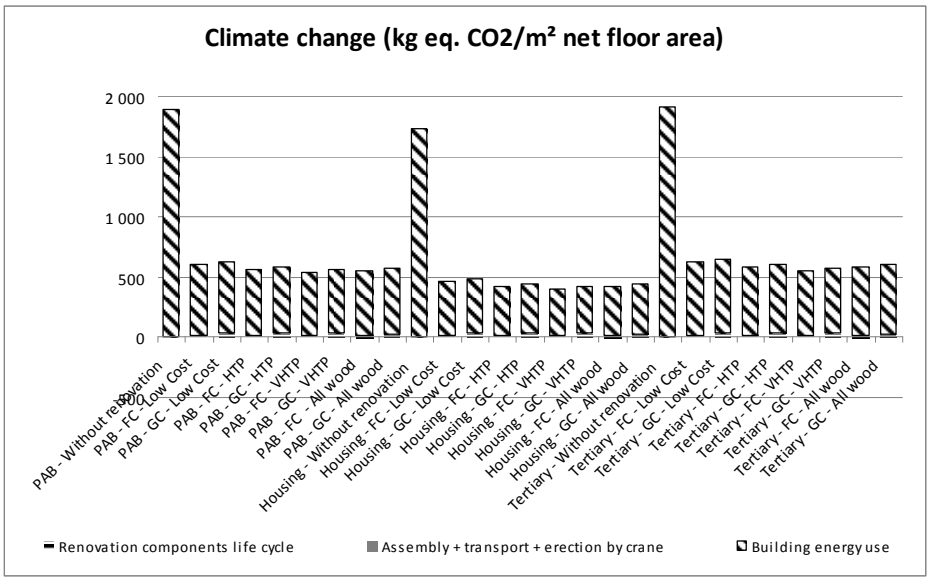

Fig. 5: Climate change

The studied solutions reduce by 3 the building impact on climate change. This reduction is achieved by low GHG balance of the materials used in the developed solutions and a significant reduction in building energy use due to the renovation. Low GHG balance of the materials system renovation is due to the fact that:
- A part of the energy used for the production of these materials comes from biomass with no impact on climate change,
- The end-of-life scenario of the wood components is the landfill. The hypothesis considered for wood is that 15% of the wood in landfill degrades to carbon dioxide (50%) and methane (50%), and 70% of the methane is burned. This scenario leads to a final storage of the carbon of a large part of the wood components, and a negative GHG balance of the wood components life cycle. This negative balance offsets the fossil GHG balance of the other components.

3.3 Water

The NF P 01-010 standard defines the indicator total water consumption as the sum of the consumption of water resources from the environment during the life cycle of the product (tap water, water from river, water from well, water from unspecified origin, except that used for cooling).

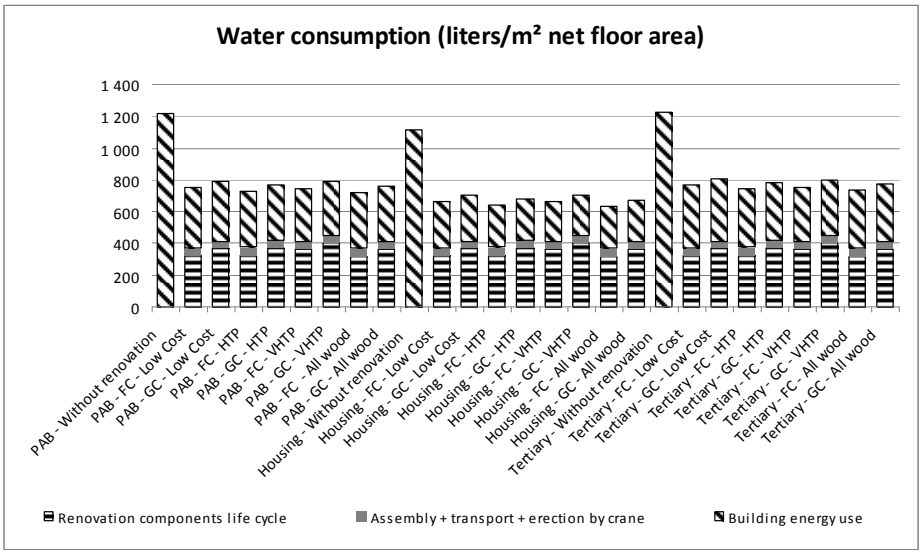

Fig. 6: Water consumption

All the developed renovation solutions reduce water consumption by 30% compared to the existing building. The water consumption evaluated in this figure is not the water consumed during the building use, considered to be identical between the exiting building and the renovated building, but the water consumption for the production of the building energy and the renovation components life cycle.

3.4 Waste

Waste indicators in NF P 01-010 standard are classified according to the European classification of waste: hazardous waste, non-hazardous waste and inert waste (nuclear waste is a special hazardous waste, it is not included in this study).

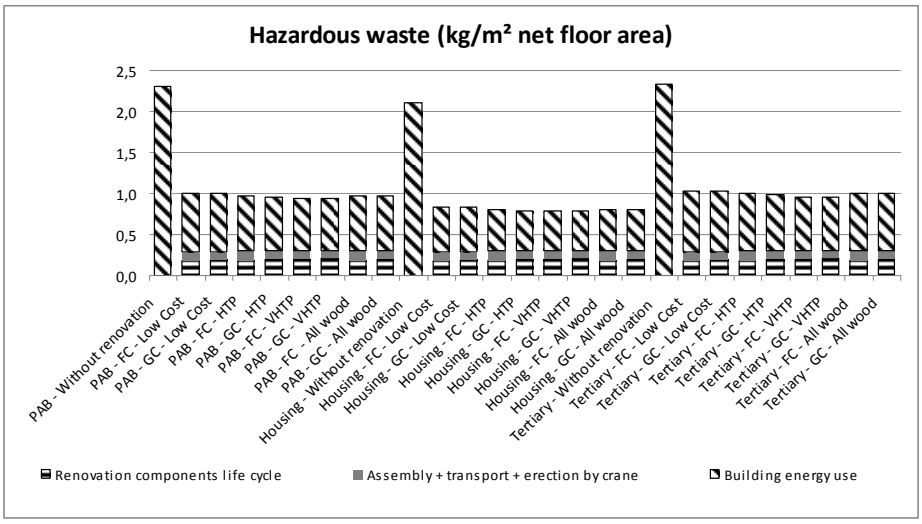

Fig. 7: Hazardous waste

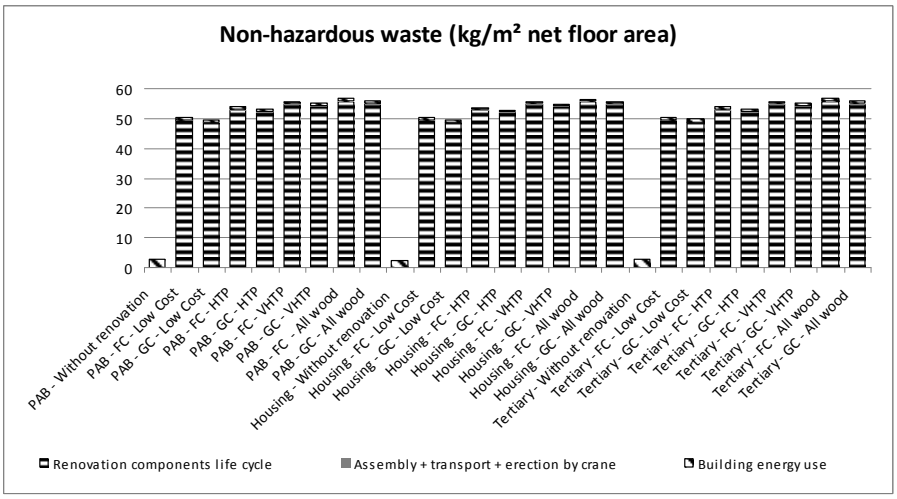

Fig. 8: Non-hazardous waste

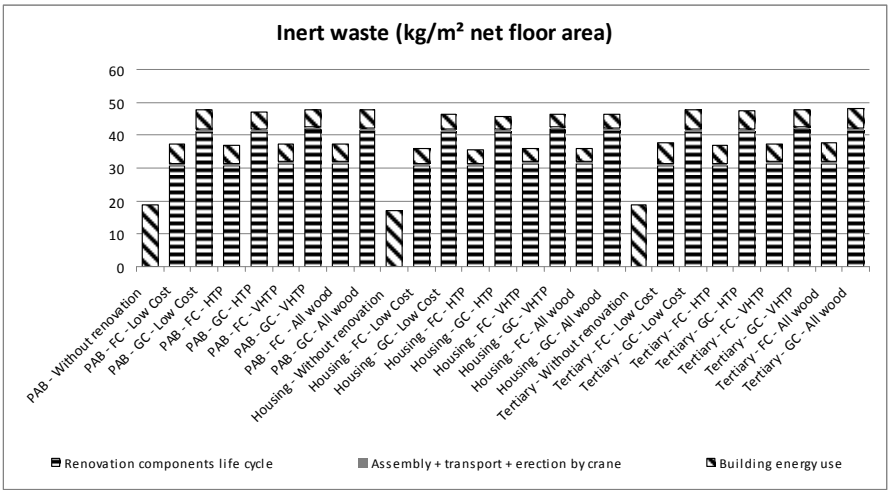

Fig. 9: Inert waste

The developed renovation solutions decrease hazardous waste, mainly due to energy production reduction, whereas they increase non-hazardous and inert waste, due to additional material disposal. The ground connection produces more inert waste than the facade connection. Nevertheless, the amount of renovation waste has to be relativized compared to waste of the whole existing building disposal, not considered here.

3.5 Discussion

Thanks to LCA methodology, this study showed that the impacts reduction due to energy saves is much more important than impacts of the facade components for most indicators, considering additional materials life cycle, assembling on the pre-fabrication site, transport to construction site, construction and energy consumption saves.

Indeed, the renovation solutions developed decrease renewable energy consumption, non-renewable energy consumption, climate change, water consumption and hazardous waste. However they increase non hazardous waste and inert waste, but the amount of renovation waste has to be relativized compared to waste of the whole existing building disposal, not considered here.

Moreover, for all the indicators, there is no significant gap between low cost, High Thermal Performance, Very high Thermal Performance and all-wood solutions, and between facade connection and ground connection, as it was already observed in thermal simulation. This is due to the too small differences in composition and thermal performance between the wooden solutions developed compared to the important energy saves of the building renovation.

Short Summary

The existing building stock encloses a huge potential for actions to deal with climate change and to move towards a sustainable economy, but the decision making process for its renovation keeps hampered by the evaluation of building renovation measures that only considers the direct costs, disregarding other relevant benefits and thus, significantly underestimating the full value of improvement and re-use of buildings, both in local and global economy.

The goal of this study was to identify a broader scope of effects that arise from building renovation and to propose a methodology for their quantification and integration in the decision making process in order to assist owners and promoters in the definition of the most appropriate renovation measures. These effects that arise from building renovation operations have been related with the different packages of renovation measures in order to allow comparing and ranking them through a tool developed for this purpose.

The application of the developed methodology and tool to a case study allowed to confirm the relevance of the non-financial benefits in the final evaluations, proving that not only economic criteria should support decisions in the field. An enormous influence of the categories related to the social aspects was demonstrated, as well as to the environmental parameters, clearly showing that these parameters can change the ranking between the tested renovation packages.

Keywords: Co-benefits; Sustainability; Building renovation; Multi-criteria analysis

1. Introduction

The renovation of the existing building stock is a relevant part of the actions to deal with climate change mitigation [1] and to move towards a sustainable relation with our planet [2]. This happens not only because of the reduction of greenhouse gas emissions that can be achieved by promoting the improvement of the overall energy performance of the built environment, but also by the reduction of resources depletion and minimization of waste production for which new construction is a major responsible.

Although existing buildings represent a huge potential in this areas [3], it has been found hard to fully exploit, mainly because of social and economic barriers that hamper owners and promoters in the decision making process, and mislead policy makers in the development of public support financial schemes and in the design of building directives. One of the common problems associated with the evaluation of building renovation measures is that only the energy savings and

the costs are considered, disregarding other relevant benefits and thus, significantly underestimating the full value of improvement and re-use of buildings at several levels of the economy [4].

In fact, building renovation has several side effects often yielding substantial benefits which can be felt not only at a financial level, but also at the environmental and social levels [5]. These side effects can be felt at the building level [6] by the building owner or user (like increased user comfort, fewer problems with building physics, improved aesthetics), but also at the society level [7] (like health effects, job creation, energy security, impact on climate change).

The goal of this study was the development of a methodology and a tool to support building renovation operations. This methodology should enable comparative analysis of different renovation alternatives in a holistic perspective in order to integrate the global benefits and co-benefits of building renovation in the decision process. The tool is intended to assist owners and promoters in the definition of the most appropriate renovation measures and allows the use of 34 different criteria that covers economic, environmental and social aspects, combined through the use of multi-criteria analysis.

The developed methodology and tool are strongly supported in several sustainability building rating systems such as SBTool – Sustainable Building Tool [8], LEED - Leadership in Energy and Environmental Design [9, 10], BREEAM - Building Research Establishment Environmental Assessment Method [11] and LiderA - Lead for the environment in search of sustainability construction [12] and have been applied to evaluate the renovation process of a social housing neighbourhood dated from the 1950's. This allowed to confirm that the inclusion of other effects besides saved energy and costs, clearly changes the hierarchy of the renovation solutions, and proves that a holistic perspective is necessary to reach sustainable building renovations.

2. The research methodology

The methodology for the integration of co-benefits in the decision making process and for the development of the tool to support the decision process occurred through the development of four essential steps, namely the identification of the benefits and co-benefits related to a building renovation, the assessment and quantification of each one of these benefits, their weighting and ranking, and finally the selection of the multi-criteria analysis tool.

The identification of benefits and co-benefits was performed based on the analysis of a set of methodologies for building sustainability certification [9, 10, 11, 12] and several studies on the evaluation of the benefits of existing buildings renovation [13, 14, 15]. The benefits were organized as evaluation criteria not only allowing their identification but also their evaluation and subsequent ranking. Were thus established 34 criteria for evaluating building renovation solutions, which were organized in 11 categories and by the three dimensions of sustainability: the economic, social and environmental, as described in Table 1.

For each criterion were given mechanisms for its quantification with reference to the different methodologies for sustainability assessment as well as for weighting its relative importance from the various stakeholders or beneficiaries of the building renovation perspectives (builder, designer, residents, promoters, community, etc.). To each criterion it was assigned a relative weight, so as to allow the subsequent weighting of the overall criteria in a single indicator.

Combination of the results of all the criteria to be evaluated was finally executed by multi-criteria analysis, specifically using the 'GREY Relational Analysis' [16] approach. The option was based on the non-limitation of the number of possible criteria to consider in the analysis and also for ease the entry of data. Besides this, results are provided even if not all the information is known. The approach is highly versatile allowing dealing with almost total lack of information to complete information availability. The introduction of data takes place through Excel sheets and the results are immediate allowing examining the various alternatives studied by introducing the values of each criterion and the appropriate relative weight.

Table 1: List of criteria for evaluation of building renovation alternatives

Dimension	Category	Criteria	Weigh (%)
Economic	Costs	Investment	9,0
		Maintenance	4,0
		Use	5,0
	Added Value	Real estate value	5,0
Social	Comfort	Thermal comfort	5,0
		Acoustic comfort	4,0
		Natural light	3,0
		Materials toxicity	1,0
		Air quality	3,0
		Inhabitants annoyance	4,0
	Functionality	Inclusive design	1,5
		Site management	2,0
		Interior layout adaptation	0,5
		Car parking	1,0
	Site integration	Territorial and landscape valorisation	2,5
		Awareness and education	0,5
		Surroundings regeneration	3,0
		Job creation	2,0
		Risk control	1,0
		Heritage values preservation	5,0
	Security	Fire	3,0
		Seismic	2,0
		Other risks	2,0
Environmental	Resources and materials	Materials recycling	1,0
		Materials durability	2,0
		Materials environmental impact	3,0
	Water	Water use	3,0
		Wastewater treatment	2,0
	Land use	Soil reuse	1,0
	Energy	Carbon intensity	5,0
		Renewables use	2,0
		Energy efficiency	6,0
	Waste	Waste treatment	2,0
		Waste production	4,0

3. Presentation and application of REHABILI-Tool to a study case

Based on the described methodology, a tool was developed to support the comparison of the building renovation solutions. The tool is performed based on Microsoft Excel and consists of 34 sheets for the criteria and 3 sheets in which is inserted information about the building, about the renovation alternatives and about the criteria under which the building will be evaluated. As final support to the decision making process, there are 2 sheets where comparative analysis are made out of the available data.

This chapter describes the work done before and after the introduction of data in the analysis tool, relying on the evaluation of a specific case study, namely a residential building located in Bairro Rainha D. Leonor located in Foz do Douro, Oporto.

The analyzed building is included in a renovation program of the Social Housing Neighborhood Rainha D. Leonor promoted and sponsored by the Municipality of Oporto and is presented in Figure 1 (before renovation) and Figure 2 (after renovation).

Figure 1: Building before renovation

Figure 2: Building after renovation (Base scenario)

In order to be possible to perform the calculation of each of the criterion in the tool and consequently compare different renovation scenarios, it is required the definition and characterization of each of the possible building renovation solutions by collecting data to allow the assessment of each criterion.

Once the data entry for each renovation solution is completed, the calculation is done for each criterion and the results are transferred to a multi-criteria analysis tool in order to proceed to the comparative analysis of the selected solutions. This analysis can be done overall or by sector, depending on the transposed criteria for multi-criteria analysis. Obtaining results from the multi-criteria tool is immediate and they can be analyzed both analytically and graphically by the user through specific sheets in REHABILI-Tool.

Within the present case study, three different scenarios for building renovation were evaluated:

- Base scenario: the renovation measures tested were the ones used in the recent renovation of the building. These correspond to the usual measures being used nowadays in current building renovations in Portugal;
- Best practice scenario: the package of measures used correspond to the best practice

currently available in the market, including the use of on-site renewables;
- Maintenance scenario: the original performance and characteristics of the building were kept and only maintenance and conservation measures were implemented;

For each of the alternatives for the building under study, each criterion has been quantified and the values were translated to the multi-criteria analysis tool. Once obtained the results of multi-criteria analysis for different alternatives of the building renovation, these were compared, analyzed and conclusions were found on the best solution for each dimension and still the best global solution through a rating between 0 and 1 which can be observed graphically in Figure 3 for the Base scenario, in Figure 4 for the Best practice scenario and in Figure 5 for the Maintenance scenario.

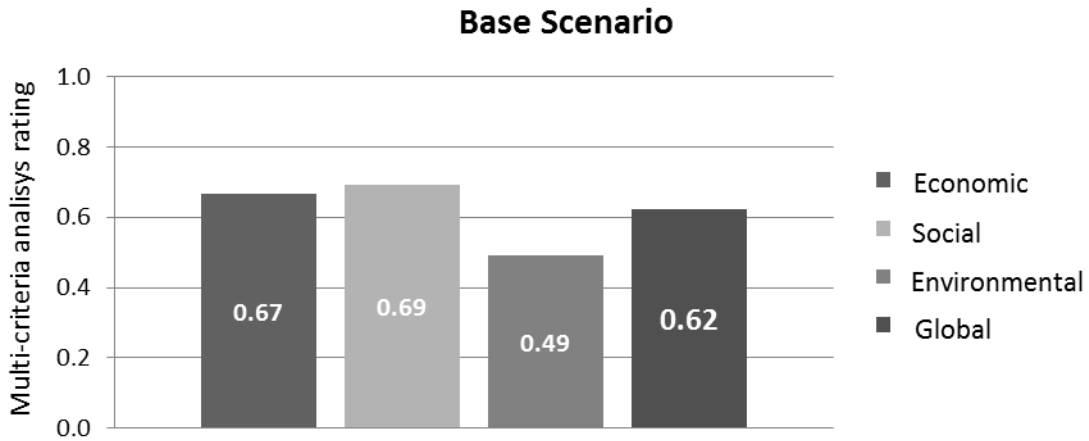

Figure 3: Results from multi-criteria evaluation for Base Scenario

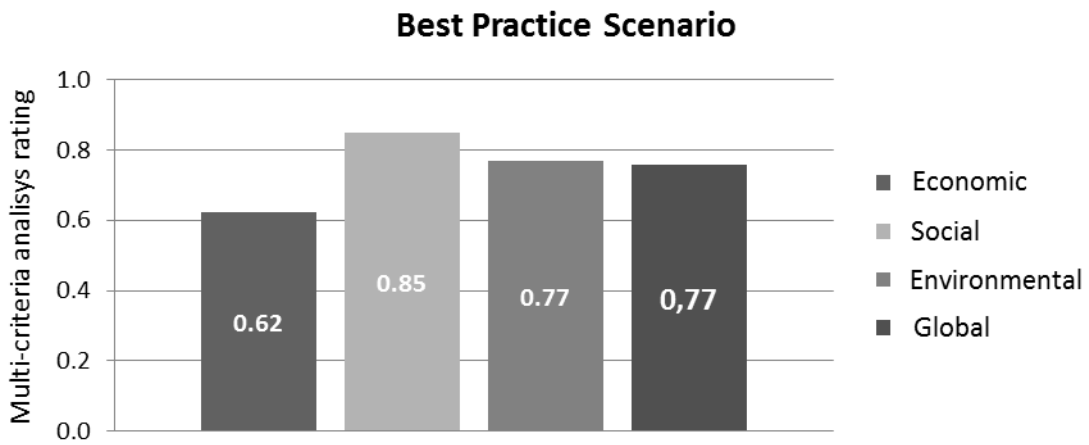

Figure 4: Results from multi-criteria evaluation for Best Practice Scenario

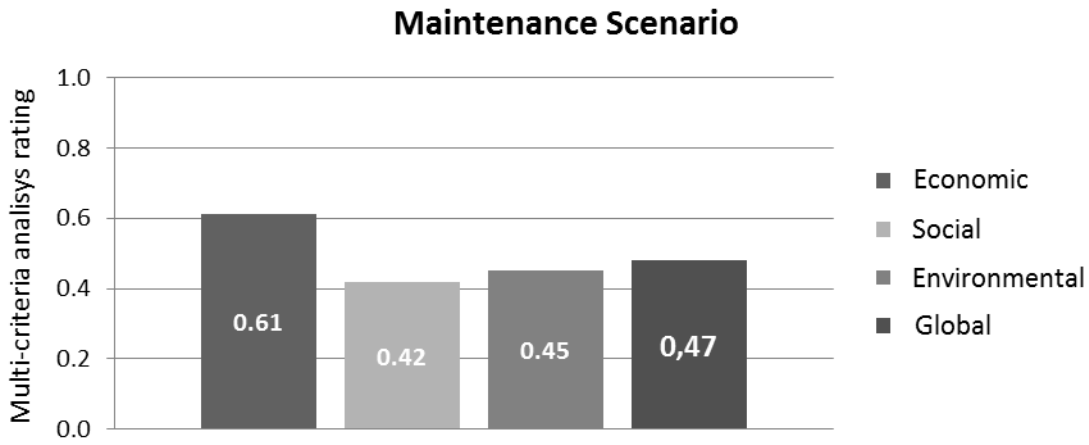

Figure 5: Results from multi-criteria evaluation for Maintenance Scenario

Comparative analyzes by sustainability dimensions held analogously to global analysis but only to the criteria of each dimension independently, allows a sectorial analysis, for the economic, social and environmental dimensions, so as to obtain a large number of perspectives and comparative data to aid in the decision making process.

Figures 6, 7 and 8 show the graphical analysis and comparison of the solutions for the different alternatives with the data of multi-criteria analysis tool for the three dimensions of sustainability.

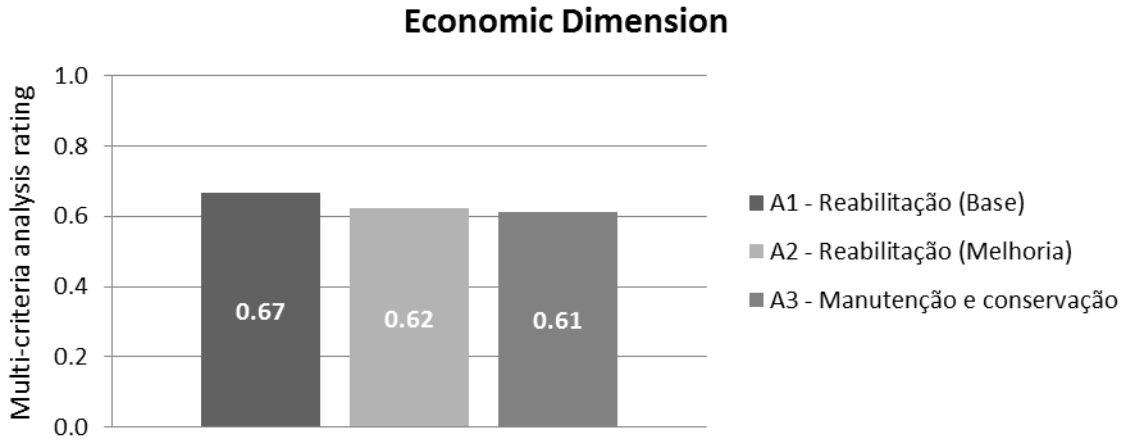

Figure 6: Results for Economic Dimension for the different renovation scenarios

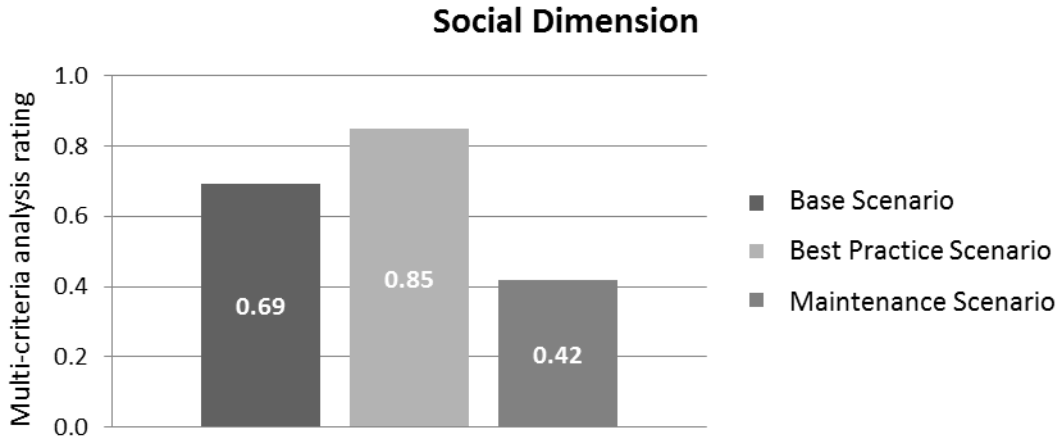

Figure 7: Results for Social Dimension for the different renovation scenarios

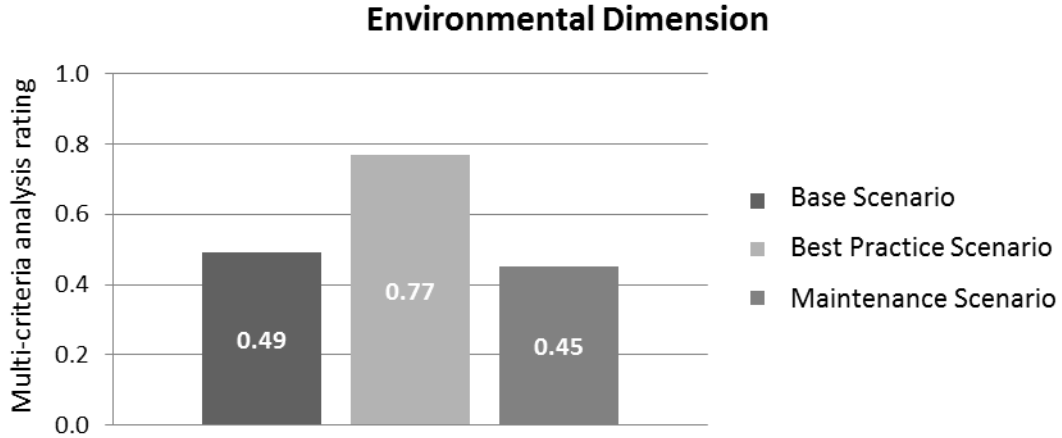

Figure 8: Results for Environmental Dimension for the different renovation scenarios

4. Discussion

From the results obtained and verified on the graphical analysis shown in Figure 9, as well as from previous Figures 3 to 8, it is obvious to conclude that the best studied alternative was the Best practice scenario. This evidence can be explained largely due to differences in classification obtained in the social and environmental aspects. This was the result of the application of the chosen constructive solutions allowing ensuring greater occupant comfort, improved equipment indoors and outdoors, higher level of security for occupants, lower energy costs, lower carbon emissions, lower water costs, lower environmental impact of the materials used and ultimately less production of non-reusable waste.

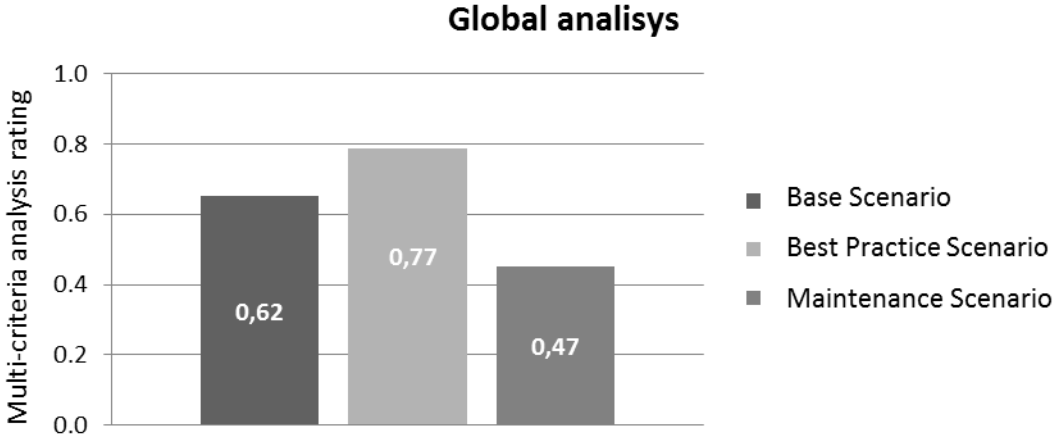

Figure 9: Results for Global analysis for the different renovation scenarios

Yet it is worth noting the slight superiority of Base scenario on the economic side, which is largely explained by the higher investment made in Best practice scenario, which still presents significant improvements in terms of running costs and real estate added value to the building.

Finally, it must be highlighted the poor results obtained with the Maintenance scenario. Despite having in its favor the extremely low value of the investment made, this turns out to be the worst alternative even in the economic dimension due to very high values of running costs and low real estate added value. In other dimensions the results with this scenario are even worse, which may be explained by the reduced intervention in a building that had clear deep intervention needs.

5. Conclusions

The primary objective of this study was the analysis of the co-benefits in building renovation and their integration into the decision making process. It was important to develop ways of helping decision-makers in choosing the best options during a building renovation process according to the particularities of the building under study, allowing that in this decision support process are considered various effects that are usually disregarded.

It was possible to present a method for integrating the benefits and co-benefits of building renovation in a decision process and it was recognized the ability of multi-criteria analysis in dealing with this type of assessment, essentially the ability to handle parameters with distinct magnitudes.

With regard to results, it must be emphasized the relevance of the co-benefits in the final evaluations, which proves that not only from an economic perspective the decisions should be taken, but also from perspectives indirectly related to the renovation measures or issues that do not affect to the same degree of importance different stakeholders. More specifically, it was evidenced the enormous influence of the categories related to the social and environmental aspects in the final standings of each alternative, more specifically in the Best practice scenario, that by adding its

rating in the environmental criteria enabled this to be the solution with the highest overall score. On the other hand, the weak ratings in the social and environmental criteria led the Maintenance scenario to be the solution with the by far worst rating.

These observations allow confirming that although sometimes a solution may not be the most attractive in economic terms can globally be the most effective and adjusted to the building under consideration. This occurs if the building renovation package meets determined criteria where quality of the constructive solutions and efficiency of equipment have great influence, thus allowing for better ratings in social and environmental aspects. This option for the quality of solutions and equipment will also lead to lower usage costs and higher property values after intervention that may justify higher initial investments. Lower affectation of the surroundings, lower resources depletion and less waste production are other relevant benefits that can be achieved with improved renovation packages.

It is intended that the analysis tool may become a practical and useful one for decision makers that through their use can build their opinion in the various building renovation solutions, and may thus decide and choose in a consistent manner, knowing the advantages and disadvantages of the different alternatives.

Short Summary

The new targets set by the EU for the building sector such as the EU-Directive on Energy Performance of Buildings (EPBD) open a new field for research and development activities which should focus on giving the best cost-effective innovative solutions in order to reduce the energy consumption in buildings. This contributes to an increase of the market potential for BIPV products and calls for a reduction of the energy needs for heating and cooling of the existing and new constructed buildings.

One approach to reduce costs in the building sector is the standardization of products, which helps improve the quality and reliability of the product. The goal of this project is to develop a Building Integrated Photovoltaics (BIPV) façade multifunctional product which could be used for both retrofitting and new construction. Simplicity of construction and cost-effectiveness are to be kept in focus. A first sketch and prototype of the module is to be developed. Studies are to be run regarding the most suitable measures of the product and the insulation material to be used taking into account costs and energy saving potential.

Keywords: Building Integrated Photovoltaics (BIPV); thermal insulation; industrial halls; cost-effectiveness; standard module; lifetime.

1. Introduction

In 2012 a PV capacity of more than 30 GW was installed worldwide, achieving a cumulated installed capacity of over 100 GW [1]. With this growing PV market, different studies do also state a growing potential of the BIPV market. A study run by EPIA estimates that 40% of the total energy demand in Europe could be supplied by roof and façade PV installations. This means an installed capacity of over 1500 GW with an annual electricity production of 1400 TWh [2].

Another factor that points out this potential is the idea of a future decentralized energy supply system. The Smart Cities idea deals with the integration of living, life, work, mobility, resources and energy concepts in the future cities. In this scenario, BIPV facades and roofs will play an important role in the local and direct energy supply (self-consumption).

Taking into account these numbers and perspectives the actual growth of the BIPV market is still too low. For example, in Germany, the installed BIPV capacity in 2009 was 1.5% of the PV capacity installed [3]. One of the barriers preventing this market to develop faster is the absence of standardized products as they are known and used in the building sector.

The actual building industry is based among other things on the standardization of products which

enable architects and designers to make faster decisions during the design phase. The standardization of dimensions and requirements for different materials allowed this industry to develop rapidly. For example, the existence of standard measures and requirements for the structural steel facilitates the designing process, ensures that a level of quality is met, and reduces the costs of the whole process. The regulation of BIPV products dimensions and requirements is expected to facilitate its implementation from the design phase to its installation.

In contrast to this idea, there are often seen custom made solutions for some buildings. In these cases, the aesthetical value is the most important factor of the design, leaving the yield to a second plane, thus, raising the costs of the manufacturing process and the installation. Both aesthetics and performance should ideally meet during the design of a BIPV product.

Fig. 1: Novartis Campus, F. O. Ghery, Basel, Switzerland.
Source: TRITEC

The actual needs of the building industry demand new PV products with integrated thermal insulation systems in order to lower the energy consumption of the building. Every type of building has different requirements and characteristics. With such a high diversified building market it is not possible to develop just one BIPV product for all buildings.

As a first approach to the development of standardized BIPV products, this project focuses on the design and construction of a standard product for a specific building category with particular dimensions and requirements. Non-residential buildings and especially industry halls with heating and cooling demand represent a large share of the potential market.

2. Industrial Halls

Factories, retail and warehouses belong to a building category where the integration of BIPV Modules in the façade is very attractive. Due to the simplicity of the architectural design and the large facade surface available, BIPV modules can be easily integrated in these buildings. Industrial halls represent a large potential BIPV market for both new building and retrofitting purposes. In most cases, these buildings have poor insulation and need refurbishment. This brings up the opportunity of adding more functions to the building material during the refurbishment phase such as higher thermal insulation and PV electricity production.

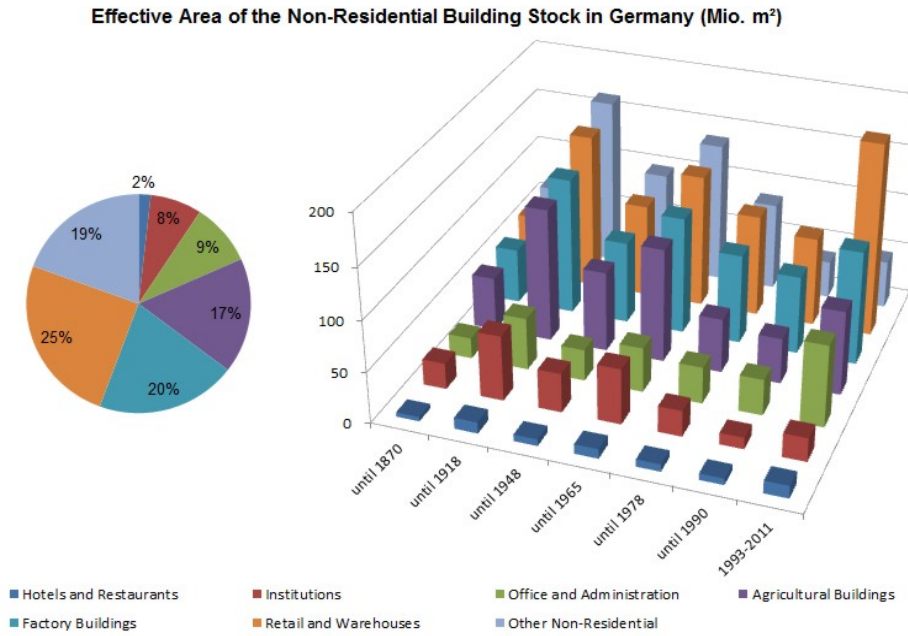

Fig. 2: Effective area of non-residential buildings in Germany [4], [5].

In Fig. 2 it is shown that these building categories represent a 45% of the effective area of the non-residential building stock in Germany. A recent study on energy efficiency in halls states that the usable net surface of heated hall buildings in Germany is estimated to be between 508 and 625 million m^2 for the building period 1960-2009 [6] (Fig. 3). As a first approach, the total façade surface can be estimated to be of around 400 million m^2 (based on a standard hall for South, East and West facades), which could mean a total installed capacity of 60.000 MWp. Due to shading and other issues, only a fraction of this area would be appropriate for BIPV.

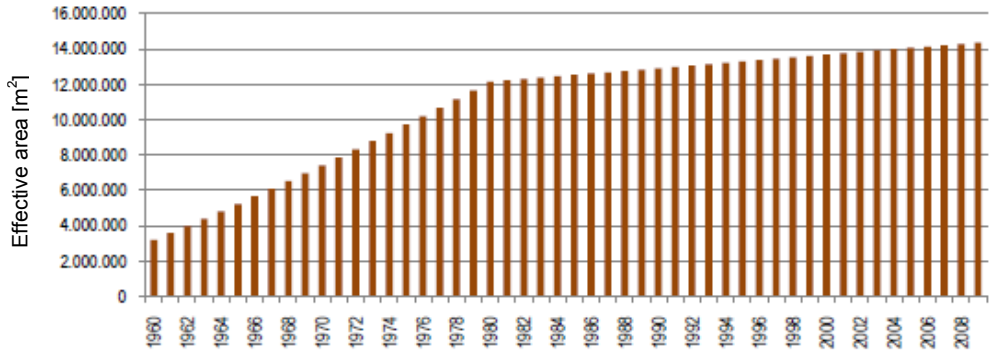

Fig. 3: Effective area distribution of heated industrial halls in Germany based on the construction year for the period 1960-2009 [6].

3. Module Design

3.1 Approach

Aim of this project is to develop a standard BIPV product with improved thermal insulation properties to be integrated in industrial halls facades. Water resistance, sealing and thermal bridges as well as the different building dimensions should be taken into account from the conception phase.

Whereas for PV roof installations there are already different solutions available in the market (75% of the expected BIPV products for 2014 are for roof integration [8]), the BIPV façade sector is not yet so far developed, and no standard solutions are available. The development of a standard module for BIPV is expected to widen the BIPV market, facilitating the acceptance from the

different actors in the building sector.

In relation to the development and study of new BIPV products for integration into steel elements for industrial halls, the first results of the research run within the NASTA project have been published [7]. Results are based on roof solutions and show that the maximum yield is obtained with standard modules, while the trapezoidal plates produce shadowing in the flexible PV elements, thus reducing the production. This kind of solution would result in a lower yield when installed in the façade due to potential shading. In contrast with the NASTA project, where the research is focused on the use of flexible modules, the approach followed in this case would be to maximize the yield by installing standard modules, thus reducing the losses due to shadowing.

A first sketch is shown in Fig. 4 with a trapezoidal plate as the core of the system, which will bring stability, ease of attachment, ventilation and a possible cabling space, while trying to limit the module weight. However, other structures are to be taken into account during the design process.

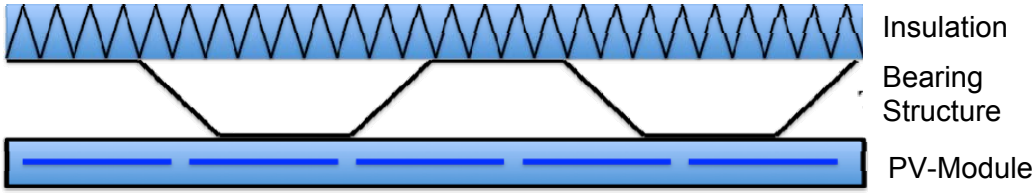

Fig. 4: First draft of a standard BIPV Module with thermal insulation

The development of a standard product provides a better quality control and a reduction of the failure rate. As the lifetime for façades should be in the range from 30-120 years, the building process becomes therefore of a great importance here.

3.2 Research tasks

3.2.1 Standard module dimensions

An important question is the standard dimensions of a PV product for the building industry. A first approach can be done through the analysis of the actual available in the market module dimensions. Fig. 5 represents the results of a market analysis of BIPV products, 79% of which are in the range of 1 – 2 m^2. A further step, in the case of crystalline modules, could be the analysis of cell and module dimensions derived from the different cell configurations, and a comparison of these with the available trapezoidal and insulation plates in the market.

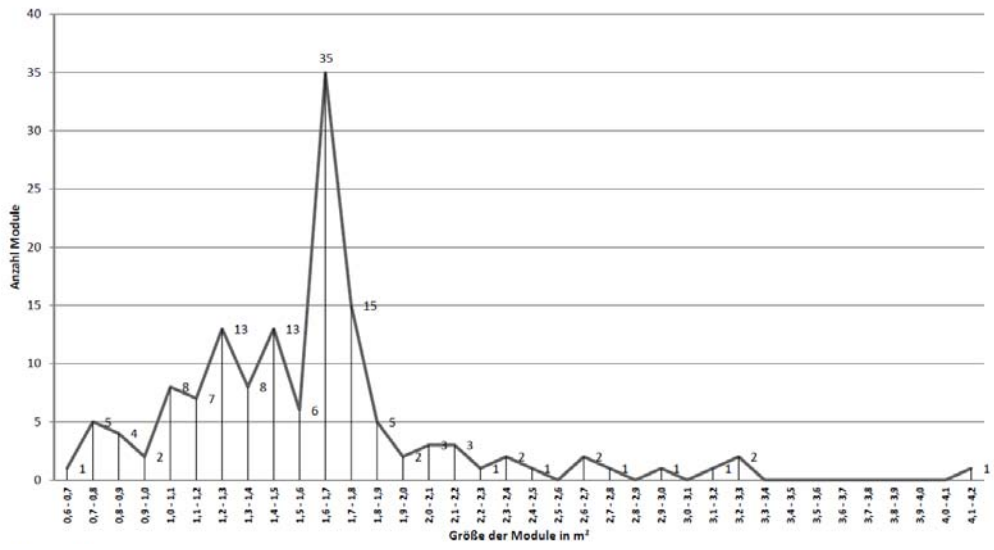

Fig. 5: Distribution of BIPV market module dimensions [8]

But the most important questions have to be answered with regard to the building typology. Therefore, a more detailed study is to be run taking into account façade products dimensions and configurations, available in the market façade systems for industrial halls, mounting systems and transport and handling best suited dimensions.

3.2.2 Insulation system

On the other side, there is the need to improve the thermal behaviour of the building stock, thus, reducing the cooling and heating demand. An analysis is to be done in this area regarding costs, thermal conductivity and lifetime of the different insulation systems. In the case of industrial buildings, where the effective surface is not as important in terms of costs as for residential buildings, a cost effective solution is to be expected.

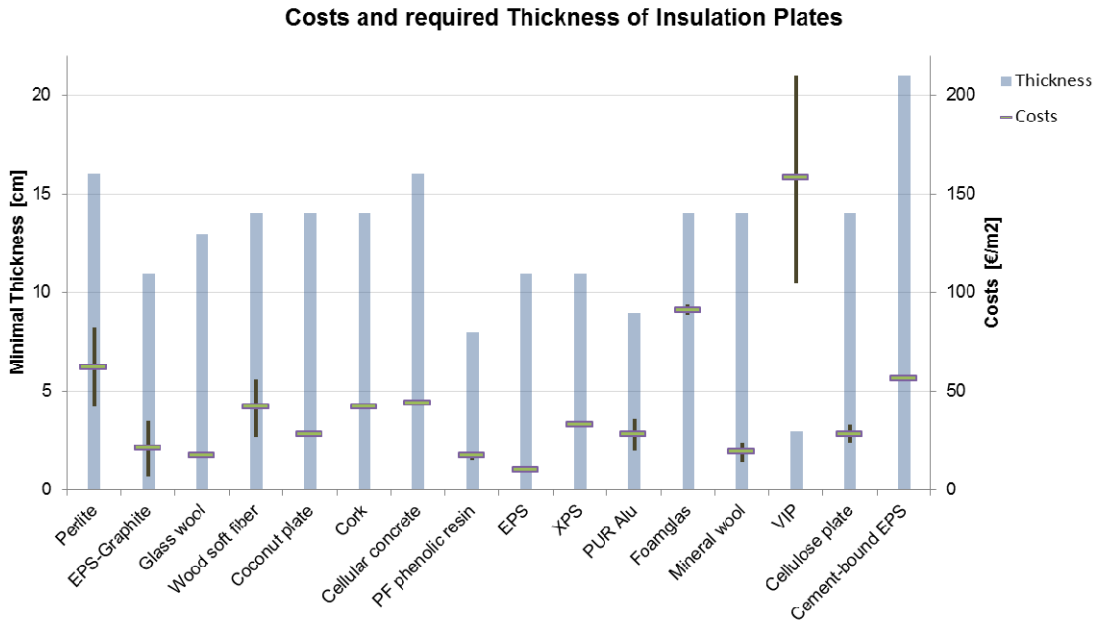

Fig. 6: Costs and required thickness of insulation plates based on a U-Value of 0.28 W/m2 K (EnEV 2009 back ventilated facade).

An analysis of the costs and thickness required by the actual regulations is shown in Fig. 6. This analysis is based on the German EnEV 2009 Standard for buildings, which requires a U-Value of 0.28 W/m^2K for back ventilated façade. Further requirements such as the Passive House Standards, are to be taken into account, and costs and energy savings in different scenarios are to be compared.

3.2.3 PV Module Configuration

Beyond the economic analysis, there are the technical issues (PV yield and thermal insulation. One yield related issue is the temperature of the PV module: a good ventilation of the back of the module is important in order to achieve good performances. At this point should be analysed whether the trapezoidal plate is the best solution or another structure would be more suitable. Further studies regarding the behaviour of the facade as a whole and the effects of the temperature gradient should be simulated and measured.

The thermal characteristics of the solution are directly related to a good design. The mounting system should minimize the thermal bridges, avoiding unnecessary thermal losses. Simulations of the different configurations are to be run in order to help in the decision making process. Analysis of the different photovoltaic technologies, their behaviour under diffuse radiation and high temperature are to be done.

In order to realize these measurements, one or more prototypes are to be built, and the selected

one is to be installed in a real façade, in order to analyse the characteristics and behaviour under real test conditions.

3.2.4 Lifetime stability

Table 1: Requirements, Standards and Tests for BIPV

Mechanical Loads			DIN EN 1991 / DIN 1055-4
PV	Mechanical Strength	3 Cycles, >5400 Pa, 1h	IEC 61215
Wind	Vibration-Resonance	--	
	Wind Pressure/Snow Load	Vacuum Cups Test	prEN 50583
		Air Chamber Test	prEN 50583
		Wind Channel	prEN 50583
	Curtain Wall – Resistance to wind load		DIN EN 12179
Fac.	Mech. Durability	5000-50000 Cycles (EN 12400)	DIN EN 1191
	Vertical load	200-800 N/Class 0-4 (EN 13115)	DIN EN 14608
	Torsion	200-350 N/Class 0-4 (EN 13115)	DIN EN 14609
Humidity			
PV	Humidity/Freeze	10 Cycles -40 to >85°C, 85%	IEC 61215
PV	Damp Heat	1000h, >85°C, 85%	IEC 61215
Facade	Curtain Wall - Water tightness		EN 13050
Temperature			
	Temperature Gradient	BIPV higher module temperature	
		Thermally induced glass breakage	
		Viscoelastic characteristics of encapsulates	
PV	Thermal Cycling	50-200 Cycles -40 to >85°C	IEC 61215
Fire IEC 61730			DIN EN 13501 / DIN 1055-4 / MBO
	Facade	GK 1-3 (<7m)	E d2 / B2
		GK 4-5 (7-22m)	C s3 d2 / B1
		*Special Buildings (>22m)	A2 s1 d0 / A2
Building Product	Non-combustibility	A1, A2	EN ISO 1182
	Heat of combustion test	A1, A2	EN ISO 1716
	Test SBI	A2, B, C, D	EN 13823
	Ignitability Test	B, C, D, E	EN ISO 11925

Lifetime stability analyses are as important as the technical or economical due to the high requirements of building products. It is important to keep in mind that building products require a much larger life time than the PV modules. Therefore, it is essential to guarantee the operability, not just of the PV Module but of the product as a whole. This will also secure the investment and ease the growth of the BIPV market.

Table 1 shows a summary of the tests and special requirements for BIVP modules. Due to the special conditions of facade integrated modules, different conditions apply. The action of wind over the whole surface of the façade exposes the buildings to different mechanical loads such as vibrations and resonance processes which can lead to cell breakage and damage of the cell connections. Higher level of humidity due to poor ventilation and high temperatures can be reached in building integrated products, thus, causing an alteration of the viscoelastic characteristics of the polymers. The behaviour of the product under these special conditions has to be analysed in the laboratory in order to guarantee the quality and lifetime of the module.

Another point of conflict is the fire safety requirements for building products. The minimum required in Germany is Class B2 (Class E as for European Standards) for buildings up to 7m. But for higher or special buildings the requirements are set in Class B1 or A2 (C and A2). Due to the higher heat of combustion value of the PV composite films and laminated glass a Class A2 cannot be achieved

[9]. Therefore, further development of BIPV Standards and test procedures is expected in the coming years in order to be able to expand the BIPV market.

4. First calculations - Costs

First calculations regarding the cost effectiveness of the solution have been performed. This analysis is done for the different insulating materials and the different types of heating energy consumed. The thickness of the insulation plate is calculated for the EnEV 2009 Standards. In order to estimate the costs and benefits, the energy savings are translated into costs depending on the heating energy used, with an estimation of the market price increase.

Table 2: Assumptions taken for the economic calculations

PV Production			Investment		
PV-Poly c-Si (15%)	150	Wp/m^2	Installed PV-Roof	1.751	€/Wp
Germany	1000	kWh/kWp.a	Insulation	Material dependent	
Façade E/W	50%		Trapezoidal plate	10	€/m^2
Façade S	70%		Module Assembly	5%	
Mean value	57%		FIT		
Façade system	85	Wp/m^2	From 01-01-2013	14.4	c€/kWh
Energy produced	85	kWh/m^2.a	Reduction	2.5%	pro year

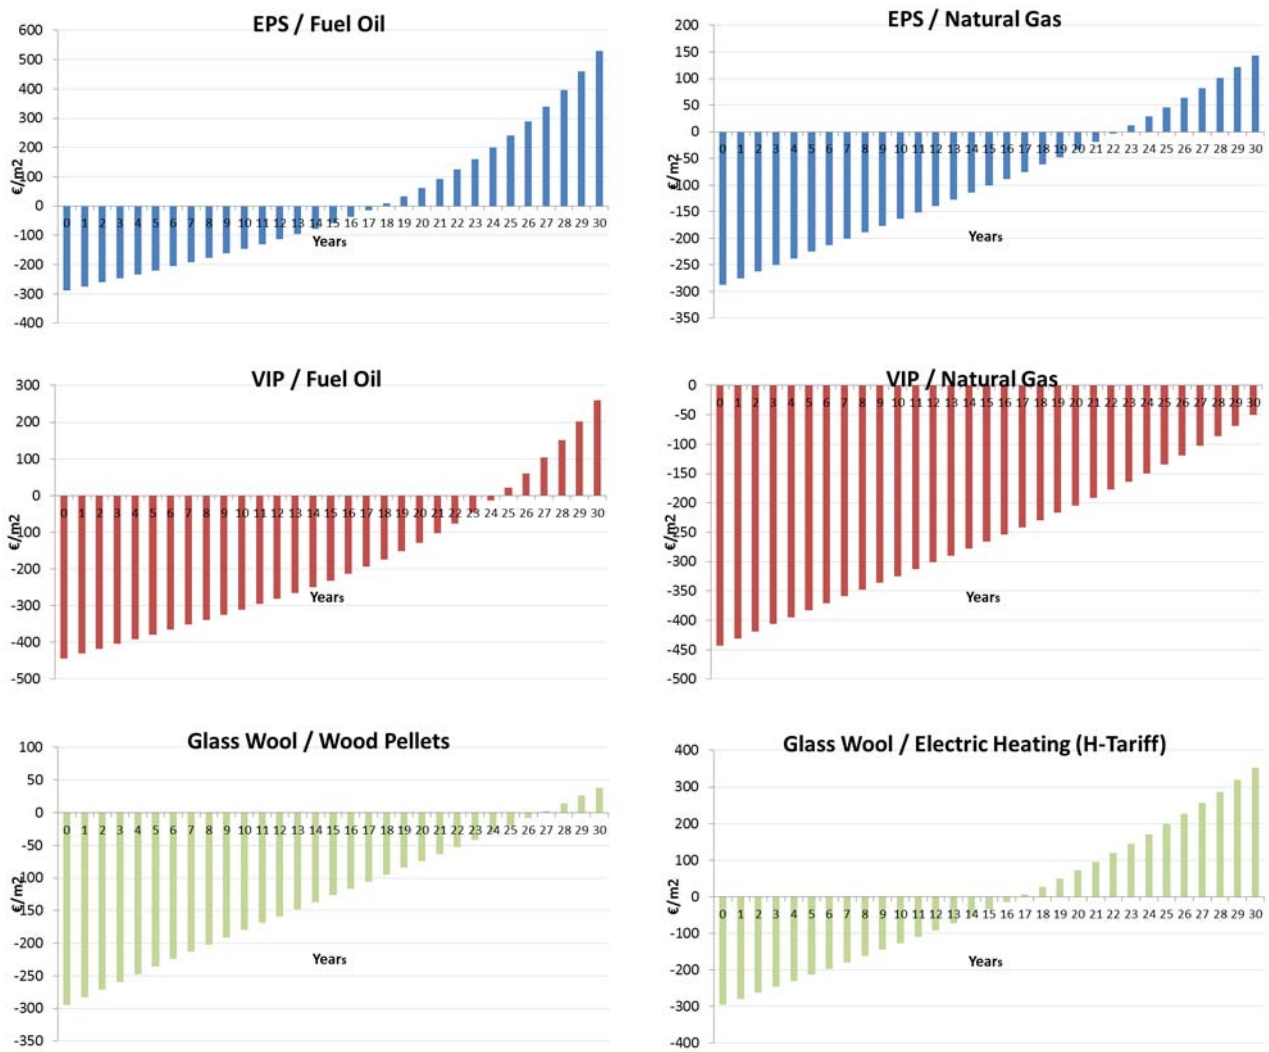

Fig. 7: Cash Flow comparison of different insulation materials and type of energy fuel used for heating of the buildings

Table 2 shows the assumptions done for the economic calculations. All estimations are done taking as a base a crystalline silicon PV module, and assuming that east, west and south facades will be used. Thus, a mean value of 57% is obtained for the whole façade system electric yield.

A deeper study should include more detailed information on costs increase per year, and maintenance cost of these installations which are expected to make the product more profitable. As a first overlook there are the graphs for selected materials and energy supply systems shown in Fig. 7. There can be seen how for standard installations where fuel oil or natural gas are used as fuel, the profitability for a common insulation system such as EPS can be high. Benefits are obtained after the 17th year when using fuel oil, or after the 22nd year when using natural gas.

All calculations are done assuming a minimum lifetime of the product of 30 years. On the other side, it is pointed out how high quality materials such as VIP would not be profitable in the case of use of natural gas due to the higher costs of the insulating material. The use of these kinds of materials could be profitable for households where the costs of the useful area per m^2 are higher and this would play an important role in the economic calculations.

5. Conclusions

The development of a standard product as well as the added thermal characteristics is expected to contribute to scale up the BIPV market. This is also supported by the increased demand on energy savings for buildings established by the EU- Directive on Energy Performance of Buildings (EPBD).

The standardization of products and regulations regarding BIPV plays an important role when trying to widen the market. Several problems have been pointed out in this paper, such as the absence of standard test for mechanical loads, or the impossibility to achieve the required Fire Class for some products. It is important to further invest in the research and development of these technologies due to their large potential.

Lifetime and feasibility of the products are another main factor, because of their expected longer lifetime. They require a big initial investment being profitable only in the long term. Therefore, analysis and tests that guarantee the operability of the systems are still needed.

Short Summary

In comparison to a demolition of existing buildings with severe technical deficits, usually the retrofitting of buildings is more effective in order to prepare them for low energy consumption and new necessities as communication and media connection or HVAC-installation (Heat, Ventilation and Air-Conditioning). Prefabricated retrofit solutions are developed throughout Europe to enable higher levels of industrialization in building envelope modernization and hence additionally improvements in energy efficiency. Five years of experience and a reasonable number of demonstrations done with timber-based element system (TES) facades show tendencies for best-practice building construction.
This paper focuses on the jointing between single façade elements and the connection of those elements to the existing building. Being a crucial construction detail within the TES-facade, the joint area shall meet various requirements and challenges, from load bearing over hygro-thermal to fire safety functionality. The results of in-depth construction detailing lay out the requirements and principles of the TES joint.

Keywords: Energy efficiency, refurbishment, façade construction, timber construction, prefabrication, fire safety, building envelope.

1. Introduction

Prefabrication – a well-known concept in new timber construction – still needs the implementation of proper detailing considering the different circumstances and assembly methods in refurbishment in order to apply it for retrofit projects. TES EnergyFacade and the follow-up smartTES, two international research consortia, work on this idea since 2008 [1]. Since then the TES facade elements for energy efficient retrofit of the building envelope with prefabricated timber based elements are demonstrated in several projects. A first milestone was the definition of an integrated work process starting from planning, digital survey, prefabrication and assembly [2]. A key feature was the development of horizontal and vertical joints of façade elements for certain assembly routines and structural properties. Further findings are dealing with fire safety, ecologic properties, thermal and moisture behaviour in specific climate conditions. This article shows the development of principles of detailing timber framework in refurbishment; analogy to existing systematics in timber construction, the requirements, and generic solutions.

2. Retrofit with prefabricated façades

Modern, prefabricated timber frame construction is highly developed as a building system for new construction. There is also no limit for small series or so-called pilot prefabrication [3][2]. Because

of the flexibility in the production planning and manufacturing, custom timber framed components can be produced without overhead [4]. This fact makes timber framed façade elements very interesting for the refurbishment of existing buildings, because individual elements are required for almost each building and project. Numerous pilot projects and demonstrators in the context of research projects have shown that the transferability of the principles of the timber framed building on a conceptual level is possible and useful [5][6][7]. But at the detail level numerous new developments and adjustments are necessary to meet the requirements of a reliable and economically feasible design.
The accurate measurement of the façade is a prerequisite for precise prefabrication and mounting Geometry data have to be combined with a thorough survey of the existing façade construction, assessing materials, detailing, load bearing capacity and if necessary building services und further in depth information from the existing substance [2].

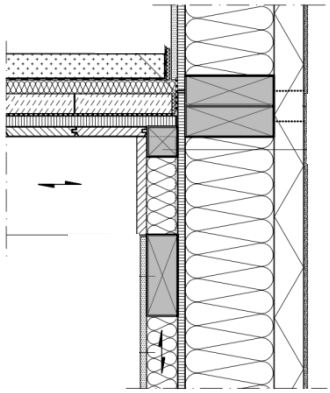

Figure 1: Vertical section of typical semi-balloon frame construction [9].

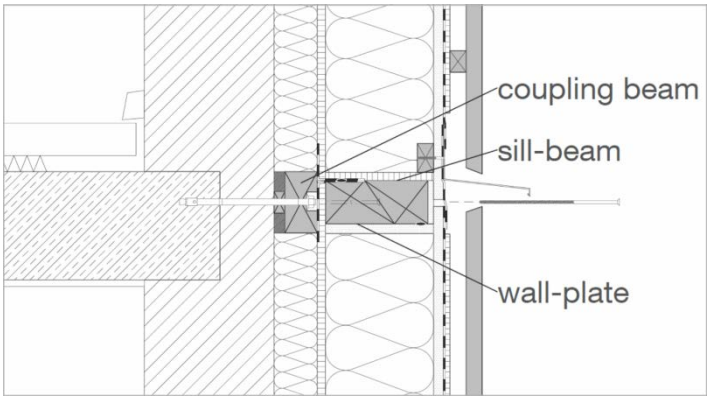

Figure 2: TES horizontal joint Vertical

3. Timber framed construction in refurbishment

3.1 Systematics of new-built timber framework and analogy

The three principles of timber frame construction are the platform frame construction, balloon frame, and the semi or virtual balloon-frame [8].
The virtual balloon-frame construction is the most suitable type as an analogy for a TES EnergyFacade element. The elements have storey-high size and are horizontally oriented; they can be produced in original upright position, put on the truck and handled on site the same way without changing orientation. All elements are stacked on top of each other and the dominant joint is the horizontal one. This has the advantage of a continuous façade layer or building skin, without interruptions and unbroken functional layers for air tightness, insulation or fire safety. In analogy to the ceiling support edge beam a so called coupling beam is introduced as a connection between the existing ceiling and the timber-framed wall. The coupling beam is adjusted exactly in height and depth. It has the additional advantage to assist horizontal alignment of TES elements. In contrast to new building in virtual retrofitting balloon-frame, no vertical forces are transferred to the coupling beam. The vertical loads are transferred only through the timber framed wall. The horizontal loads have to be induced into the existing ceiling plate. Hygrothermal exposure and wood protection of such a detailing solution can be solved in analogy to new building. The fire safety must be examined in depth because facades have a certain risk in the spread of fire and fire safety has always observed in relation with the boundary conditions of the existing building.

3.2 Definition of requirements

The number of parameters affecting the TES element and its details is large. Most influential are apart from structural issues, planning building physics of timber construction, correct production of multilayered elements and assembly on existing exterior walls. The main parameters about strengths and fixtures are derived from the load-bearing structure of the elements. As a result, they

are at the same time in conjunction with the materiality, manufacture, structural arrangement, aka. tectonics, and the assembly process. The other group of influences originates from building physics. They affect TES elements on the main inner and outer protection functions and therefore define the requirements for layering and details. In addition to the production, they are in interaction to the assembly, economy, ecology and technical building equipment and must be linked to the static requirements. These interactions take place not only within the TES system, but and above all, they are in interaction with the existing building. Some protective functions of the existing exterior wall are partially replaced by the TES, such as the thermal protection; they are fulfilled primarily by the TES envelope.

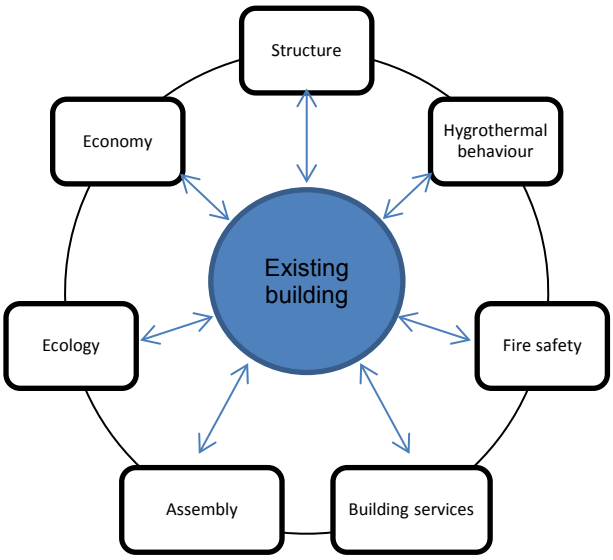

Figure 3: Parameters of a TES façade system.

3.3 Limitations of the analogy

The development of the retrofit construction system starts from the main structural influences and the appropriate way of tectonics of parts. The focus is on the area of the horizontal element joint. It is the connection of the existing exterior walls with the existing ceiling. The horizontal joint is the most relevant detail to solve from the technical and economic perspective, because it is the most frequent joint of a virtual balloon-frame. A 1950ies multi-story house with 8 apartments on four floors has a total length of basement and roof eaves joint line between circa 80 and 130 m. All other horizontal joints between the floors have a total length of approximately 240 and 390 m. The complete vertical joint length is around 65 to 75 m. It matches a ratio between vertical and horizontal joints from 1:5 to 1:7. The high deviation in this ratio clearly shows how important detailing of the horizontal joint has to be done. It influences assembly effort and costs to a large extent. The technical requirements and the effort in this area of the element have to be adjusted very carefully to avoid high costs or unforeseeable risk. The developed solutions have to be in line with the condition of efficiency. A robust solution of butt jointing two elements will reduce the risk of the construction system for failures. The detailed analysis of the construction principles on the applicability and specialties of the construction process with large-format element in refurbishment results in clear advantages for the balloon-frame principle. The requirements of the continuity of the insulation layer and the uninterrupted surface with defined axis of fixing, as alignment, and mounting aid for the façade elements are established as significant characteristics.
A further invention is the adaption layer between the uneven surface of the existing exterior wall and the plane back side of the TES element. The gap should be at least fifty millimetres wide for further filling with blown-in insulation material, preferably cellulose fibre. The process of blowing thermal insulation material in the gap has the advantage of adapting the thickness, where it is needed. Around penetrations of the exterior wall and the elements like windows, the gap should be stuffed with non-combustible mineral wool.

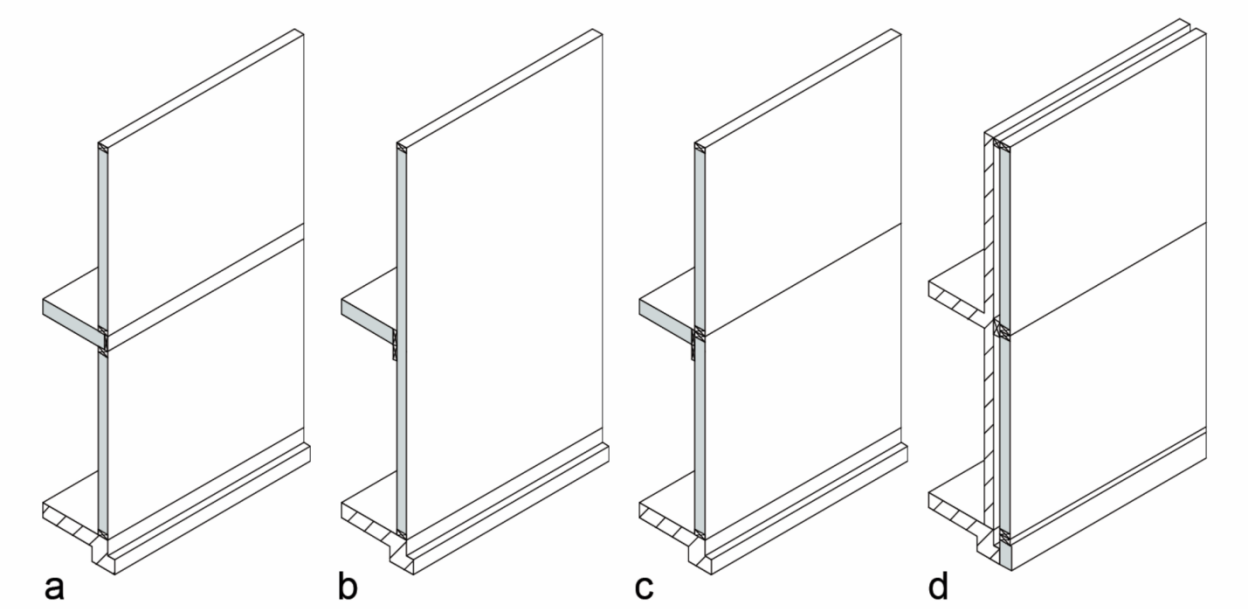

Figure 4: Development of platform frame, (a) balloon-, and semi balloon-frame (b-c) to TES (d) in analogy to (c).

4. Results in timber framework for refurbishment

4.1 Development of the horizontal construction joint

4.1.1 Principles of timber framing for refurbishment existing buildings

As in classic timber frame construction the solid wood studs are positioned in a span of 625 mm and butt-jointed perpendicular to sill-beam and wall-plate. On the element inside an OSB is applied and on the outside a gypsum fiber board. The cavities are filled with thermal insulation, e.g. cellulose fiber. Usually a timber-frame element measures about 12,0 x 3,2 m², limited by production facilities and transportation. [5]

Figure 5: Mounting a TES-Element [gumpp&maier]

While the TES-facade is built with a tolerance of +/-2 mm, the existing exterior wall deviates +/-40 mm in depth. This unevenness is leveled by the coupling beam, which is anchored into the existing wall and runs around the entire building horizontally on each floor level. Thus, while mounting, it's possible to align the façade elements to the coupling beam and fix it with self-drilling timber screws. The assembly of the elements happens horizontally row by row. The design of the element joint was inspired by the simple joining method of a tongue-and-groove connection and enhances the common butt-joint known from classic timber-frame constructions. The tongue consists of the upper element's sill-beam. The groove consists of wall-plate and the overlapping gypsum fiber

board of the lower element. That way the upper element is fitting precisely into the lower element, without any larger alignment work necessary and still guaranteeing a force-fitting connection. [5] The vertical connection is a butt-joint of two members without any further connection.

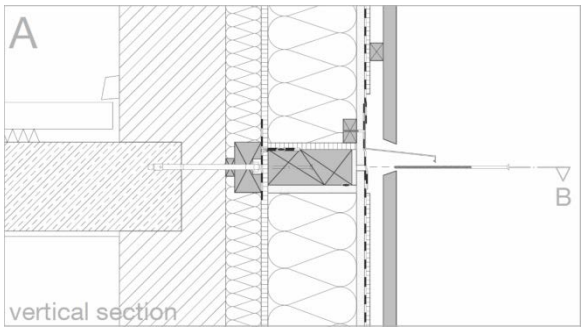

Figure 6: TES horizontal joint Vertical

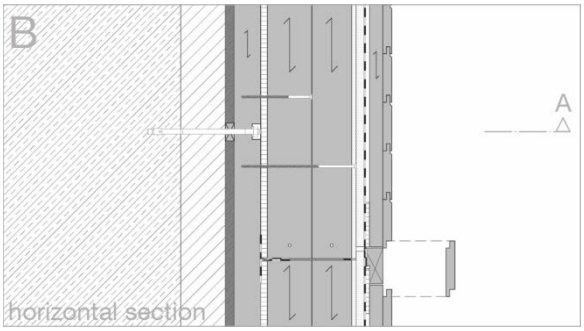

Figure 7: TES horizontal joint Horizontal

All facade components such as the window generally are integrated in the TES element, see Figure 7. This has the advantage of better manufacturing control and simplified construction site operations. The new window can be installed in different configurations as a replacement for the existing one. It can be integrated only as a supplementary window in the TES, which enhances the existing window and improves its thermal and acoustic properties. This solution is an important option for upgrading existing components of good quality, speeds up the construction process significantly and reduces disturbances of the residents.

The variety of applicable cladding materials is analog to new timber-frame buildings; however, retrofitting a larger multi-storey building, the options are strongly limited by fire safety requirements. In this paper the construction is given with a rear ventilated wooden façade.

4.1.2 Structural joint

Essentially there are two main loads (actions) on the TES-façade that have to be taken in to account constructing the loadbearing system: Self-weight and wind-load.
The self-weight of the given construction is with about 80 kg/m² (varying by thickness, thermal insulation material and cladding) comparably high. This is due to the extended timber loadbearing structure, the necessary fire safety boards, and a dense cellulose fibre thermal insulation. The vertical force caused by self-weight conducts all the way through the timber frame into a foundation system at the foot of the façade. As the vertical force accumulates over the building height, the horizontal joint between the elements is built as full form fit contact connector. (Fig. 8 No. 1)

The horizontal forces from the wind-load are induced shortest way into the next ceiling. To prevent unnecessary eccentricities the element joint is placed exactly at the height of the ceiling. So the element fixation with self-drilling screws should be horizontally in line with the ceiling anchorage. To connect both elements with the coupling beam, sill-beam of the top element and the wall-plate of the bottom element need to be on same height. This requirement is fulfilled by the tongue-and-groove connection. (Fig. 8 No. 2)

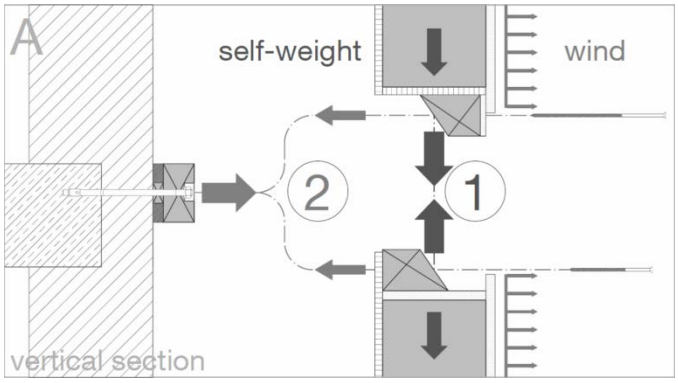

Figure 8: Force conduction

Another advantage of organising the connections in one spot is, in regard to high level prefabrication, a minimal necessary intervention from outside, which reduces onsite finish work on the cladding and thereby keeps the visual surface intact.

4.1.3 Hygrothermal behaviour of TES elements

The requirements, measures and design principles for moisture behaviour and safety of timber framed walls consist of three basic principles:

- No thermal bridges
- No convection
- Moisture management

The avoidance of thermal bridges is the first principle in detail development as no high heat-conductive material from the hot to the cold side goes through so that conduction of heat is minimised. Thus, the impact of material-related thermal bridges can be largely reduced by the use of wood or wood-based materials in the joint area. Geometry-related thermal bridges are not available on that part of the element; they are slightly more relevant at corners. They can be solved when the principle of an external insulation layer and sufficient layer thickness are taken into consideration. A flexible variation of the insulation layer thickness can be achieved by the adaptation of the depth of studs.

Moisture management also has to deal with diffusion safety of the TES layer. The back panelling of the element has to be vapour retardant. Diffusion open (to the outside) regular cross section of the element with a low s_d < 0,5m on the outside of the element and an s_d at least six times higher on the inside of the element is recommended.
Air and wind tightness of timber framed elements are one of the most important measures to stop convection of warm and moist air to the cold side of wooden parts. There are basic rules like the reduction of joints, airtight back panelling and sealing of clamped joints. Further all element joints have to be sealed with elastic rubber sealants. A proper airtight construction also improves fire safety and sound protection by overcoming leakages.
Airtightness is even more important than good diffusion properties, because through joints there is a higher risk for leakages. The horizontal and vertical TES joints have to be sealed for airtightness reasons to ensure the moisture performance and avoid heat conductivity through wet wood or insulation materials in the joint area.

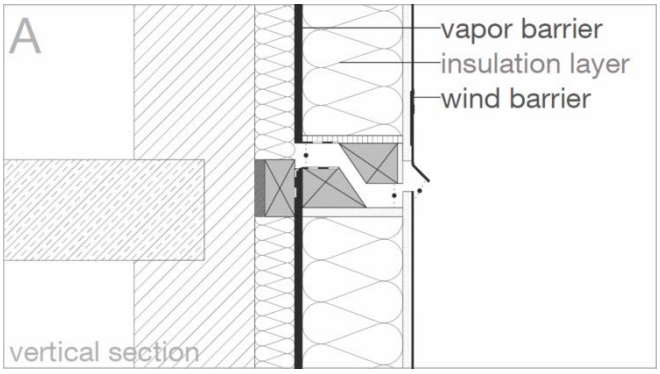

Figure 9: Hygrothermal Detail

Special attention is needed for window assembly. Penetrations offer a path for additional moisture intake into timber framework. Moisture protection from flanking/penetrating materials with high capillarity like brick wall could be a problem. An airtight closure of these penetrations is necessary. Window penetration in existing walls and TES elements requires the connection of window frame to airtight layer of the TES. Furthermore the airtightness of the gap has to be ensured especially for fire safety reasons. A closure with an airtight and fire proof box frame and sealing of the butt-joint between box frame and window frame is necessary. A window position in the existing wall is not allowed according the rules of thermal protection.
Wind tightness is provided by a wind barrier as an outer panelling or membrane of the closed TES element. The wind barrier has to be sealed at connection by tapes or clamped joints.
Besides construction material has to be dry, and elements are protected during construction by closed cavities and heavy weathering to minimize moisture intake. Diffusion open layering supports the drying capacity of elements. Hollow spaces between TES and existing walls have to be avoided and reduce the risk of uncontrolled convection. An appropriate measure is the filling of cavities with soft and dense insulation material during the assembly process. There is a good experience with blown-in cellulose fibre that has a sorption quality that can buffer the moisture from the existing exterior walls and reduces the moisture load on the wooden parts of TES.

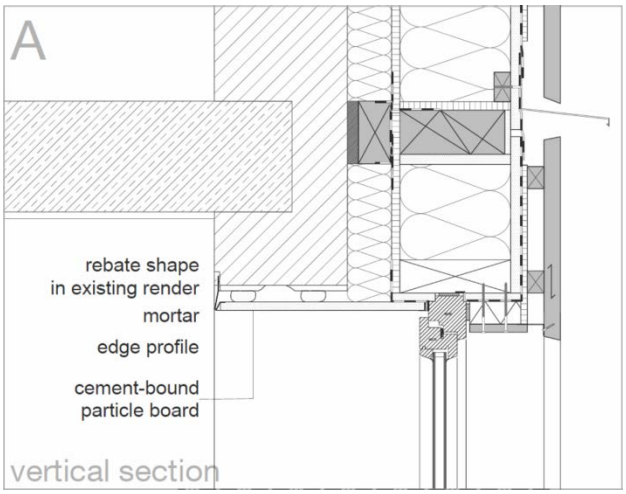

Figure 10: Detail Window

The existing wall and the window connection is very often permeable, warm and moist air is leaky into the gap, the coupling beam sits behind the insulation on the warm side and will not be damaged. See here the interrelation to other topics of building physics: hot pyrolysis gas, smoke, odors and airborne sound use same leaky paths. They will be stopped at TES element back side and at the coupling beam functioning as interruption at each floor. The window joint does not have to be fully closed, due to the second safety line described above.

The joints at the base and roof eaves as well as vertical edges are taped and sealed air-tight, what is non-trivial, since the ground from existing plaster or masonry will not show the best conditions. The elements and element joints are made air-tight with sealing stripes positioned between the elements and all paneling joints, thereby it is important that the inner sealing stripe is connected air-tightly with the OSB by sealing tape, see figure 9. This means, no warm and moist air can penetrate into the insulated compartments and reach the low-temperature side. There is no risk of condensation and moisture intake into the wood.

4.1.4 Wood protection and durability

The built-in wood and wood-based materials are sufficiently protected through compliance with the previously mentioned hygrothermal requirements and moisture management in closed timber frame components. Thus the TES elements fulfill the requirements of use class 0 [11].

4.1.5 Fire safety

Normally, the existing structure already fulfills the fire safety objectives. However the condition of the existing building has to be verified by a fire safety survey. [1] The TES-façade layer has to fulfill the requirements of the relevant building classes. In building classes 4 / 5, in which most of the potential TES-retrofitting objects are classified, or building ≥ 3 storeys, non-loadbearing exterior walls have to be at least fire-retardant (Fig. 11 No. 1) and difficult combustible cladding and insulation material of at least class C- or B-s2,d0 is required. Timber or other combustible façade materials are possible but need special construction and additional approval. Where combustible material and ventilated gaps are used the cladding must have a storey wise separation either by suitable fire stops or with a floor wise horizontal separating construction. (Fig. 11 No. 2) [1][13][14] The component requirements for the ceiling have to be taken in account especially if the existing wall is removed or quite thin. The spread of fire and smoke into the next storey in detour over the TES-façade has to be prevented. If the existing wall is removed, by definition, the TES-joint becomes part of the existing ceiling. (Fig. 11 No. 3)

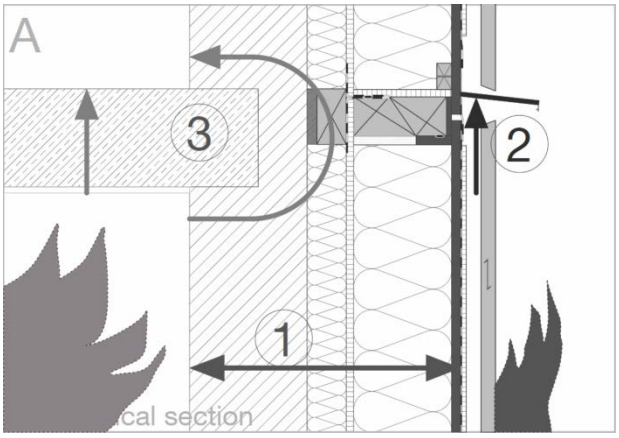

Figure 11: Fire safety detail

At the element joint closing the gypsum board layer is solved by backing the board with an additional stripe of gypsum fiber board and horizontally with another gypsum fiber board below the wall-plate.
(The fire barrier metal sheet is disposed slightly above the joint area in order not to obstruct the screwing of the sill-beam to the horizontal coupling beam.)

4.1.6 Mounting

An important difference to new building is the accessibility of the elements while mounting, because one side is blocked by the existing wall. The higher the prefabrication level the less work needs to be done on site. But, connection points will be harder to access this way. Especially if a visible cladding has been prefabricated, necessary works shall not leave any signs of destruction.

Pilot projects have shown that by sloping the cut between upper sill-beam and lower wall-plate and building a tough-and-groove connection the mounting of the elements is simplified a lot.
The screwing of the elements to the coupling beam offers a simple and uncomplicated solution.
(Before the prefabricated TES-Elements are mounted to the building, it's necessary to set the foot foundation, remove existing windows and building up surrounding scaffolding, if no elevating platform is used.)

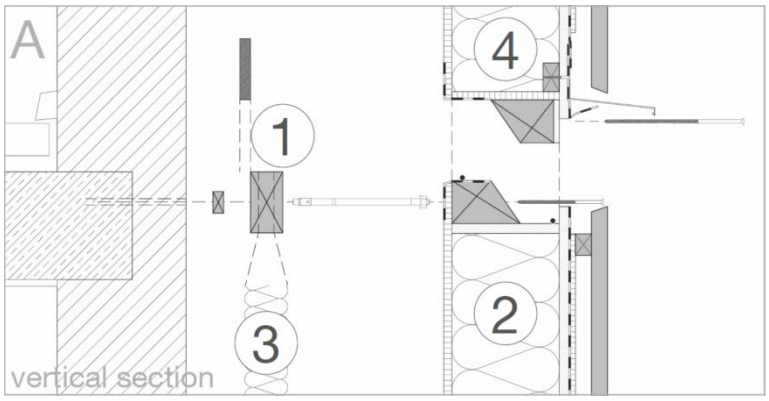

Figure 12: Mounting process

The mounting process is divided in four steps (Fig. 12):
(1) Fixing the coupling beam to the wall: For a fast mounting process and a clean plane stop for the elements the coupling beam is positioned by using a laser-assisted positioning system. The position points were taken during site measuring in the survey phase. With the help of computer-aided design a leveled plane is calculated onto the uneven surface of the existing building. The gap between existing wall and coupling beam is filled with swelling mortar.
(2) Placing the lower element, butting the wall-plate against the coupling beam, and fixing the connection with screws.
(3) Filling the adaption layer by blowing cellulose fiber through an opening in the coupling beam. (After the window reveal was made in a combination of out-run gypsum fiber board, foil and filler from the inside out)
(4) Placing the upper element into the lower element, screwing the sill-beam to the coupling beam, and closing the wind-barrier.

4.2 Principles of timber framed jointing in retrofit

For the structural connection of the TES-Façade to an existing building, the construction of the existing ceiling needs to be examined closely regarding stability and positioning. The pull-out strength of anchoring in to the floor slab needs to be determined. In some cases parts of the masonry work pass in front of the ceiling, this has an influence on the anchorage length. The self-weight of the façade needs be carried by the existing foundation. For the foundation system of the TES-Façade various solutions are available and should be chosen according to the existing laod-bearing capabilities.

The moisture management has to be dealt with like in new building. The claims for hygrothermal protection are airtightness of timber framed elements back-panelling and horizontal air stops in the vertical gap zone at each storey. The airtight sealing of the window remains a critical point. Convection and airborne sound might find also horizontal ways to neighbouring units through leakages around the box frame. Then this construction detailing can be improved from the inside after there are faults during assembly.

By adding the TES-Façade as wall part not only the fire safety of the wall as such has to be taken into account, but also the fire and smoke spread though gaps between new TES-Façade and existing structure.

5. Conclusion

Generally spoken the interface of the existing building envelope and the new timber-framed wrap around has to be planned very carefully. The building survey has to examine all types of exterior walls and junctions of existing ceilings with exterior walls. These are evident for structural jointing and critical routes for air, moisture, sound and fire propagation. In the early planning process it is prerequisite for risk mitigation. Timber framed elements for façade retrofit have no high risks as shown in the proposed robust solutions.

5.1 Outlook

The other principle details are examined in the further course of the project and published shortly in a final project report. Moreover, other variants to the positioning and improvement of the airtight layers and their connections in combination with sorptive insulation layers are tested. Another interesting issue is the capability of TES elements to provide the building envelope multifunctional properties with the integration of building service systems or dynamic energy saving concepts.
The timber-frame-system enables a self-bearing façade. Additionally loadbearing components like balconies, spatial extensions, or roof-top extensions can be built and integrated in the same system. Also HVAC-Systems can be included into TES. Research to potential topology and detailing is ongoing.

f.pomponi@brighton.ac.uk

Dr. Kenneth Ip, University of Brighton, UK, k.ip@brighton.ac.uk
Dr. Poorang Piroozfar, University of Brighton, UK, a.e.piroozfar@brighton.ac.uk

Short Summary

There is a growing tendency towards use of Double-Skin Façades (DSFs) for office buildings in Europe. The potentialities this technology has range from acting as thermal buffer to innovative application of natural ventilation. It is still a developing research field identifying what are the most determinant architectural parameters for optimal uses of DSF. This research focuses on applying DSFs to refurbishment of buildings, which has a bigger market than new builds. Knowledge on how to select suitable DSF systems for refurbishments is scarce due to the additional constraints of existing buildings thus narrowing the number of options.

This paper reports the initial findings of the first stage of a comprehensive research, with the aim to establish an assessment methodology and a tool to identify suitable DSF systems for the refurbishment of office buildings in the UK. The assessment methodology proposed here allows to determine a group of suitable DSF technologies for each of the UK office types identified. The tool has been tested with real refurbishments case studies, which showed coherent and consistent results.

Keywords: Double Skin Façade; Office Buildings; Refurbishment

1. Introduction

The major challenge for the UK government to meet the greenhouse gases (GHG) target is to reduce the emissions related to the energy consumption of existing buildings. More than 75% of non-domestic buildings in the UK were built before 1985 and about 60% of them will still exist in 2050 [1]. Because of the lifespan of elements and components, many of these buildings will need refurbishment. This is arguably a more sustainable option compared to full reconstruction or rebuild.

A building façade represents the physical barrier between the indoor and outdoor environments and its improvement has been shown to be one of the most effective ways to enhance the indoor environmental quality and to reduce energy consumption [2]. Most refurbishments involve the replacement of the existing façade with high performance windows and walls. However, there is a growing number of applications of an additional glazed façade to the existing one - what forms a Double Skin Façade (DSF). DSFs are mainly used as a means of improving a building's environmental performance, however, the influencing parameters are many and information on their design is scarce.

This paper reports on the findings of the first stage of a comprehensive research, with the aim to establish an assessment methodology and a tool to identify suitable DSF systems for the refurbishment of office buildings in the UK. Extensive literature review has been carried out to derive the key categories of office buildings in the UK of different age and their suitability to use

DSF. Basic principles of double skin façade technologies together with their performances in temperate climate have been investigated. The assessment methodology and the related tool are proposed and applied to identify suitable DSF systems for UK offices. The paper concludes with key findings and recommendations for future work.

2. UK office building stock

To assess the potential that Double Skin Façades have in improving the performances of existing buildings it is crucial to understand the current state of the UK office building stock. On new constructions it has been demonstrated that DSFs perform better than single skin façades and, although more expensive in capital cost, they are more cost-effective in the long term [2]. When the focus switches to the existing stock, the use of DSF has to take into consideration the buildings' constraints. Therefore, a critical analysis of existing office stock is necessary to project the potential and their suitability for DSFs.

2.1 The current state

Building energy use in the UK accounts for nearly half of the total national energy consumption and carbon dioxide emissions [3]. In cities like London, this figure raises up to 61%, which is substantially higher than the average in the EU (41%) and the US (36%) [4]. Non-domestic buildings tend to have greater energy consumption per m^2 of floor area compared to dwellings and, within them, offices have the highest energy consumptions as they account for over half of the total consumption in the non-domestic sector [5]. From the carbon dioxide (CO_2) emissions point of view, office buildings account for more than 20% of total UK emissions and technically there is the potential of cutting their carbon emissions up to 80% by implementing solutions which are already available today [1]. Only focusing on low and zero carbon new buildings will not solve the emission problem because whilst 1% of the building stock is built each year, 99% is already out there [6].

The higher figures in energy consumption - when compared to other countries – are due to the fairly old building stock in the UK. Around 80% of the office floor spaces, in all regions of the UK, were built before 1990 [7] with U-values double, if not triple, than current practice. Therefore, due to their age, their poor thermal performance and the different lifespans of elements and components (i.e. the load bearing structure and the façade) most of those buildings will be refurbished in the coming years. Additionally, future regulatory and occupier requirements will increase the pace for existing offices to be refurbished.

Refurbishments of existing buildings also offer advantages over new buildings in achieving environmental and economic sustainability [8]. Hence, to meet the GHG target of 80% reduction by 2050, energy-efficient refurbishments of office buildings deserve to be prioritised in research and development.

2.2 Office types

Office building forms have evolved over time and, within its historical infrastructure and culture, the UK presents a highly varied and complex scenario. A CIBSE [9] review on the energy use in offices has identified four office types mostly classified by means of the ventilation of the building, the floor area, the external façade and the characteristics of internal spaces, as shown in Table 1.

Table 1: Office types according to CIBSE review

Office	External Facade	Ventilation	Internal Layout	Floor Area
Type 1	Masonry Wall	Natural	Cellular space	From 100 m² to 3000 m²
Type 2	Curtain Wall/Brick and Glass facade	Natural	Open plan	From 500 m² to 4000 m²
Type 3	Fully glazed	Fully A/C	Standard Features	From 2000 m² to 8000 m²
Type 4	Fully glazed	Fully A/C	Prestige Features	From 4000 m² to 20000 m²

Although the CIBSE review mainly looks at energy consumption, the four types above also represent the evolution of the office building concept over the past decades. This study shows how the size of office buildings has increased continuously as well as the need to heavily rely on HVAC systems to balance the fully glazed single skin façade – main cause of overheating in summers and heat loss in winters.

In this study, the buildings to be considered are those belonging to the first three categories as the fourth mainly represents brand new buildings which will not be refurbished any time soon. The third category encompasses recent buildings that mostly are still in the middle of their operational life. Their fully glazed envelopes often represent an impediment to applying DSFs as the complete removal of the existing façade would be necessary. Therefore, type three is not included in the current study as the likelihood of refurbishing a recent building with a major intervention is relatively small.

Another study by Steadman *et al*. [10] focuses on office building forms addressing two main parameters: lighting (i.e. artificially or day-lit) and internal layout (cellular space, halls and open-plan space). Offices are further categorised by considering the building height as a parameter, distinguishing between buildings from 1 to 4 storeys and those with 5 storeys or more. An analysis [11] of their study highlights the different categories and their percentage share as shown in Table 2.

Table 2: Office categories from Steadman et al. (2000)

Categories	Office Description	Share of the stock
Category 1	Cellular offices between 1 and 4-storey high	33.9%
Category 2	Cellular offices with 5-storey or more	5.2%
Category 3	Cellular strips around some open-plan spaces	19.5%
Category 4	Open spaces artificially lit	5.5%
Category 5	Open spaces sidelit up to 4-storey high	0.9%
Category 6	Open spaces sidelit with 5-storey or more	2.0%
	Total	67.0%

From the figures and descriptions provided in this study, the first two categories match the Type 1 described in CIBSE [9] while the last four are very similar to the Type 2. The focus of this study will therefore be based on these more detailed categories – cellular offices and open spaces – and the reason is twofold. Firstly, they represent the vast majority – more than two thirds – of the existing office stock. Secondly, they are also the older among the existing offices, being *de facto* prospective candidates for sustainable refurbishments. Although available office studies date back to more than a decade ago, they are fully representative of the buildings this research aims to cover.

3. Double Skin Façades technologies

One of the first and probably most effective actions which can be taken to reduce energy consumption of a building is to improve on its external envelope, where the internal enclosure of the building comes in contact with its immediate external micro-climate. Although most refurbishments involve the replacement of the existing façade with high performance windows and walls, there are growing examples – especially in European office buildings – of applying an additional glazed façade to the building; which in combination with the main façade forms what is mainly known as Double Skin Façade (DSF).

Double Skin Façade technologies have greatly evolved over time and, nowadays, many options and configurations are possible. It is a growing research field to identify what the key architectural parameters are and to evaluate their influence on DSF performance. When being considered as an option in refurbishment, existing buildings impose their own limitations and impediments which require a methodology for identifying suitable double-skin façades for a specific building. The following sections give a brief review on double-skin technologies; it also outlines the known

performances in temperate climate to illustrate appropriate use can reduce the energy consumption in buildings and helps to achieve the 2050 CO_2 emissions target.

3.1 History and Definition

Although Double Skin Façades are a modern, complex and technological architectural phenomenon, their principles date back in the 19th century when Jean-Baptist Jobard theorised how hot air in winter and cold air in summer should circulate between two glazed surfaces [12]. DSFs started gaining momentum mainly in 1980s with many examples spreading all over Europe. From 1990s, they have experienced a continuous growth and development. Many authors have given definitions of Double Skin Façades. Oesterle et al. [13] describe them as a technology based on a multilayer principle which consists of an external skin, an intermediate space and an inner skin. Gratia and De Herde, looking from a different perspective, describe DSFs as an “architectural phenomenon driven by the aesthetic desire for an all-glass façade” [14].

Brunoro and Rinaldi [15], specifically focussing on refurbishments, defined double-skin façades as hybrid systems, formed by the existing façade of the building and a new glass skin. Other authors provided more technical definitions mentioning or highlighting thermal and ventilations properties, architectural parameters and shading devices to be placed in the cavity. By gathering these scientific contributions a glazed double skin façade referred in this paper can be defined as a heterogeneous system made of an external glass skin and the actual building façade. The two layers are separated by an air cavity which acts as a thermal buffer zone and as a natural/mechanical ventilation channel that may or may not accommodate shading devices.

3.2 Performance overview of Double Skin Façades in temperate climates

The literature on design and performance of double-skin façades in temperate climates are few and far in between. However, these technologies, when carefully designed, seem to have been capable of significantly improving the building performance. The double skin façade acts as a thermal buffer in winter thus decreases the heating loads while in summer allows use of natural ventilation resulting in less need for mechanical air conditioning.

However, it is not as simple as it seems as many parameters contribute together to determine whether a DSF is successful or not. Gratia and De Herde [16] investigated the energy consumption of buildings with DSF and established the influence the cooling strategies and the building insulation levels have. They conclude that, by using natural cooling strategies, the energy reduction ranges from 27% (for non-insulated buildings) to 67% (for those insulated). Cetiner and Ozkan [17] compare performance between single and double skin façades. Their findings show that DSFs are up to 34% more energy efficient than single skin façades. Other studies in northern Italy [15, 18] suggest a yearly energy reduction of 35%-40% when a double skin façade is used. A study in Germany [19] also concludes DSFs can reduce the heating loads by up to 30%. An investigation using the Turkish climate raises the reduction to nearly 50% under optimal conditions [20].

Whilst most researchers agree on the potential of DSFs to reduce heating loads in winters, performance over summer appears to be less agreed upon due to the risk of overheating. The possibility to exploit natural ventilation can result in significant reductions of the runtime of ventilators and air conditioning systems. Natural airflows can also be used for night-time ventilation in hot summer days to pre-cool the building without compromising its security when the second skin is added.

However, there are authors persuaded that overheating will occur without sunscreens. The use of shading devices has been widely investigated. A study on venetian blinds proves that they have a significant influence on the thermal performance of the façade [21]. Another study [22] looks at different aspects of shading devices (location, colour and opening of the DSF) concluding that nearly a 25% decrease in cooling loads can be achieved by using shading devices. A computational fluid dynamic (CFD) investigation [19] about the optimal position of sunscreen devices within the cavity suggests that they should be placed at a maximum distance from the

inner skin but not too close to the outer skin either – if the risk of overheating in summer is to be minimised.

In refurbishments, energy savings and reduction in environmental impacts can be obtained with the addition of a second skin. A case study of energy-efficient office refurbishment in Norway using dynamic computer simulation shows that the optimal configuration enables an energy reduction of 59% [23]. Among other additional benefits, it is possible to find a better protection for the shading devices in the cavity as well as a reduction of the wind pressure effects.

Double Skin Façades have some disadvantages. The main issue is the risk of overheating the air in the cavity during summer. On the operational side there is a risk of condensation in winter time which has to be carefully managed by correct choice of materials and ventilation strategies [23]. Besides, the space needed for the second skin generally reduces the net usable area of the building. From an economic point of view, the investment and maintenance costs are higher than those of single skin façades although the extra amount of money spent is usually justified by the energy savings and the increased productivity of the occupants [24].

4. DSF systems for refurbishments

Existing constraints such as location of the building, its conditions and characteristics, etc. make refurbishments more challenging than new constructions. In case of applying double-skin façades the difficulty is even higher due to the careful design this technology is required to exploit its full potentialities. Additionally, the huge number of possible DSF systems often confuses the making of optimal choice. This section describes the methodological approach proposed to identify suitable DSF systems for the chosen UK office types and its application by means of case studies.

4.1 Existing Classifications

Classifying DSFs is complex due to numerous parameters involved; for instance, the type of ventilation of the façade, its partitioning and the ventilation of the cavity are just to name a few. Oesterle *et al*. [13] provide a classification based on the types of façade construction, as illustrated in Figure 1, which are:

- Box Windows
- Corridor Façades
- Shaft-Box Façades
- Multi-Storey Façades

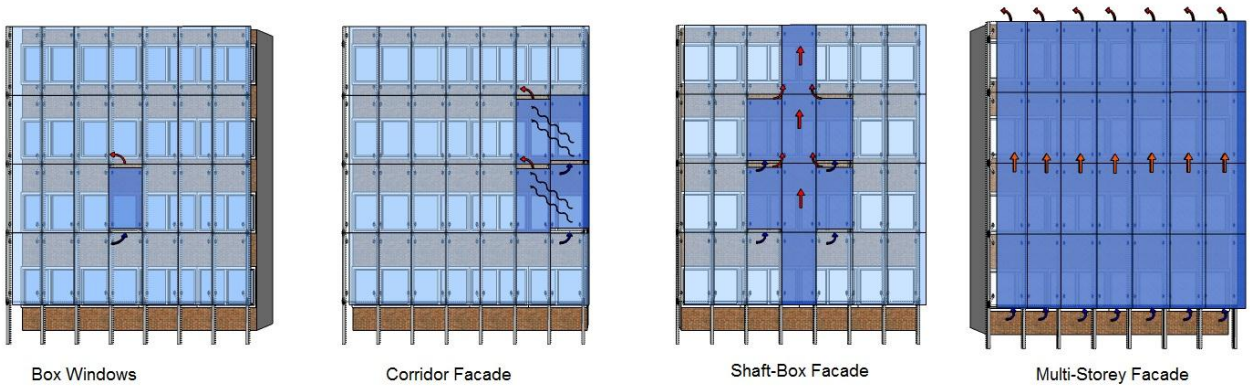

Fig. 1: DSF Construction Types

On top of these 4 types, the Belgian Building Research Institute (BBRI) [25] adds a fifth category, called the Louvers Façade. With this configuration the outer skin is composed of transparent rotating louvers that, when closed, are capable of a relatively fair airtightness. However, when opened, the ventilation is completely different from the types presented above. A well-known

example of this particular category is the Debis Headquarters building by Renzo Piano in Potsdamer Platz, Berlin.

Another classification by Arons [26] distinguishes between Primary and Secondary identifiers. In the first group, one can find Airflow Patterns and Building Height. The former represents the possible ventilation strategies – as shown in Fig. 2 – while the latter refers to the differences between low and mid-to-high-rise buildings.

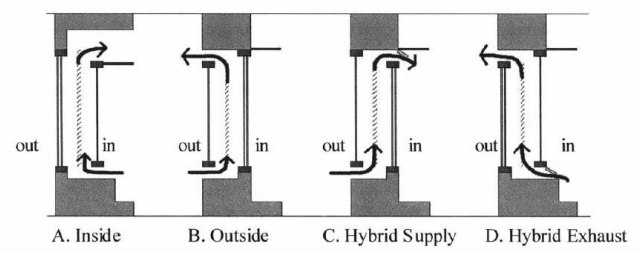

Fig. 2: Airflow Patterns for DSF (Arons, 2000)

Among the Secondary identifiers, Arons indicated more architectural parameters such as depth, width and vertical extent of the cavity, layering composition, materials and operability. Other classifications consider similar aspects and work on a three-tier approach [12, 28]. These are the façade compartmentalisation (construction types), the ventilation of the cavity and the airflow concepts. It is worth noting that the latter also includes the static air buffer behaviour which was overlooked by Arons [26]. Figure 3 shows an outline of the three-tier classification based on Haase *et al.* [27].

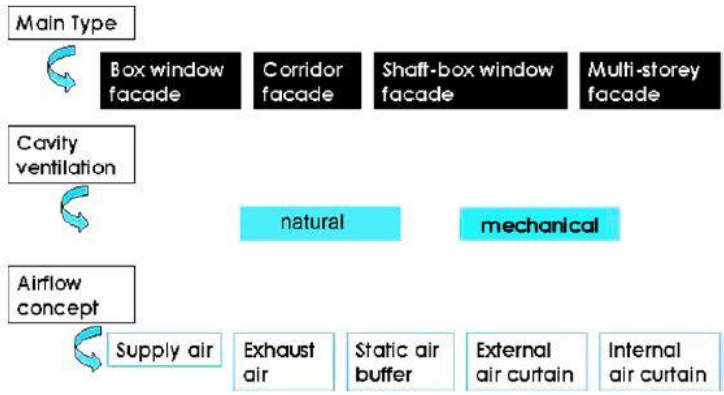

Fig. 3: Classification of Double Skin Façades by Haase et al., 2009 [27].

4.2 Proposed methodology to assess DSF systems in refurbishments

Existing classifications of DSF systems are based on design for new buildings and none of them encompasses all the key features, thus ignoring some of the possible combinations. For example, some do not address the fifth type (the louvers façade), nor do they consider the cavity width and the building height, which are crucial parameters in defining the ventilation of the double skin. Additionally, when it comes to refurbishments, they do not adequately help to identify what possible DSF systems should be used under specific circumstances.

In refurbishments, the existing building characteristics may impose impediments and limitations due to the building's structure and location as well as legal constraints etc. This is the reason why the building characteristics have to be established at the very beginning together with those associated with the double-skin façade. The diagram shown in Figure 4 is a proposed methodology to identify suitable DSF options for specific buildings based on their relevant constraints.

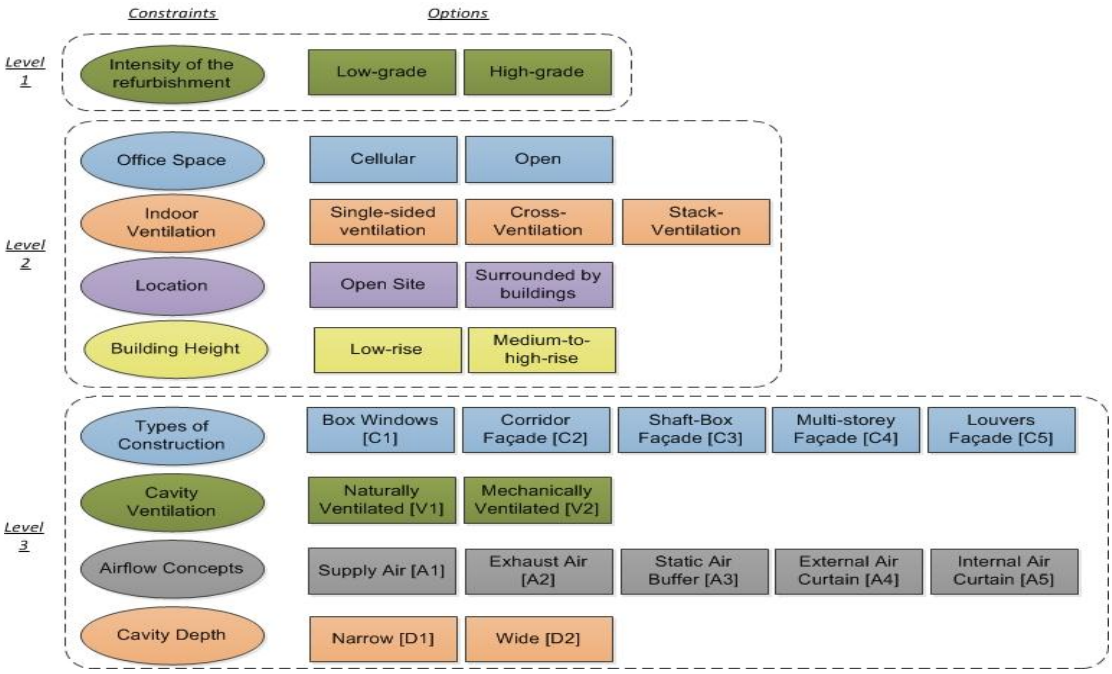

Fig. 4: Proposed methodology to assess Double-Skin Systems for Office Refurbishment

The proposed classification works on three levels, examining the intensity of the refurbishment, key parameters of the existing building and key parameters of the double-skin façade. First and foremost, the decision on the grade of refurbishment has to be taken as it influences all subsequent stages. For instance, a low-grade refurbishment is unlikely to replace all existing walls and windows, thus narrowing the suitable DSF options. Alternatively, a high-grade refurbishment may leave only the load bearing structure rebuilding all the rest from scratch and this greatly broadens the number of DSF systems that might be considered. The choice is mainly related to the available budget and the objectives the refurbishment aims for. In most circumstances, both options are possible and can reasonably be applied.

The second level takes consideration of elements related to the existing buildings. This does not include all the factors which are influential in refurbishment but only the determinants with an effect on the performance of the double-skin façade. For example, the load bearing structure is not considered as it is assumed that the existing building can sustain the weight of the second skin. The indoor ventilation of the office influences the airflow patterns of the future double-skin façade while the type of office space may point towards specific types of constructions rather than others. For instance, cellular offices provide a fair level of privacy, fire protection, and are a barrier to noise transmission. All these properties will vanish by installing some of the façades due to noise and fire transmission in the cavity.

Location and building height are often related. They mainly influence the cavity depth and, to some extent, the types of construction. Low-rise office buildings are often integrated in the urban fabric and, therefore, only the narrow cavity seems to be a viable option. High-rise office buildings, on the contrary, are generally located in a more open urban context, as a result of the architectural and design process, which often aims at communicating through the image of the building. For those then, a wide cavity is also a feasible solution.

The last level of the classification deals with key features of double-skin façades. While all the other constraints are quite straightforward, airflow patterns are worth further explanation. The supply air pattern, [A1], is the likeliest option considering the natural ventilation that a DSF allows for and also the lack of air conditioning systems that many of the offices which were examined for this study have had. The option [A4] is not realistic as the offices under examination allow for natural ventilation and a DSF designed just as an external air curtain may be jeopardised by

occupants opening internal windows. Also the static air buffer concept, [A3], may present the same issue. However, this specific airflow has to be considered as a hybrid solution within the refurbishment and not the only pattern available. Additionally, the thermal buffer behaviour of the façade is expected in winter where, generally, windows are closed.

The last two airflow patterns, [A2] and [A5], are both theoretically applicable but their feasibility has to be examined on a case-by-case basis as it might require implementing HVAC systems to mechanically achieve the desirable thermal behaviour of the façade and this aspect deals once again with the intensity of the refurbishment.

It is worth noting that the third level allows an easy classification of DSF systems. It also permits for classifying hybrid combinations, which represent growing examples in DSF installation – especially for the airflow patterns where different options may exist together within the same façade. The proposed classification is very easy to use. For instance, a façade coded as [C5].[V2].[A1].[D1] immediately describes all the different key features of its design. In case the same façade can also operate as a static thermal buffer (hybrid system), it will be possible to easily express it by using a different code such as [C5].[V2].[A1/A3].[D1].

This assessment procedure focuses on the UK offices and specifically – as described in Section 2 – on those categories that are mainly representative of the current office stock. Table 3 is an illustration of the possible combinations of DSF systems for low-grade refurbishments taking into consideration the office categories and the key features of DSF. This methodological approach, thence, enable practitioners and designers to identify the range of options for DSF technologies. Moreover, these options will form the basis of cases for use in the evaluation and optimisation studies.

Table 3: Examples of possible system combinations for low-grade refurbishments

Office Type	Ratio	Indoor Ventilation	Types of DSF	Cavity Ventilation	Airflow Concepts	Cavity Depth	Possible DSF Systems
Cellular up to 4 Storeys	50.60%	Single-sided	[C1], [C3]	[V1]	[A1], [A3]	[D1]	4
Cellular 5 or more Storeys	7.76%	Single-sided	[C1], [C3]	[V1], [V2]	[A1], [A3]	[D1], [D2]	16
Cellular - Open Plan (mixed)	29.10%	Single-sided/ Cross-ventilation	[C1], [C2], [C3], [C4], [C5]	[V1], [V2]	[A1], [A2], [A3]	[D1], [D2]	60
Open spaces artificially lit	8.21%	Cross-ventilation	[C2], [C3], [C4], [C5]	[V1], [V2]	[A1], [A2], [A3],	[D1], [D2]	48
Open spaces sidelit up to 4 Storeys	1.34%	Single-sided/ Cross-ventilation	[C2], [C3], [C4], [C5]	[V1]	[A1], [A2], [A3]	[D1]	12
Open spaces sidelit 5 Storeys or more	2.99%	Single-sided/ Cross-ventilation	[C2], [C3], [C4], [C5]	[V1], [V2]	[A1], [A2], [A3]	[D1], [D2]	48

Cellular low-rise office buildings, which form 50.60% of the stock under examination, only allow for four DSF systems. The small number is related to limited types of construction, the presence of surrounding buildings - which imply only a narrow cavity - and the single sided ventilation that limits the possible airflow patterns. Whereas in the case of mixed cellular open plan office sixty configurations are possible. This difference depends on the types of constructions, the choice on the cavity depth and the use of the DSF as a means to extract exhaust air. With sixty possible combinations to choose from, it is clear that an optimisation tool to determine the best option is

necessary. The use of stack-ventilation option has not been inserted in the table, as it is only possible if the building already has a central atrium, court or chimney. If that is the case, stack-ventilation should be a further option for each of the office types.

4.3 Case Studies

Case studies described in this section are used to illustrate the application of the proposed methodology and the assessment tool. Information on the state of the case study buildings before refurbishment has been gathered and prepared to establish the input data for the classification. By proceeding through the assessment tool, suitable DSF systems have been identified and compared, in the first two cases, with the actual system installed. The third case study building is yet to be refurbished but adopted for detailed analysis and optimisation studies in the next stage of the research.

4.3.1 GSW Headquarters – Germany

The authors have recently visited this building. Its refurbishment has been completed in 1999 as an extension of an office tower from the 1950s and the project design is by Sauerbruch Hutton Architects. This is a high-rise office building (22-storey) which consists of open plans and partitioned (cellular) offices. As explained in the assessment methodology, these buildings often have an open urban space surrounding them, which is the case for this building too.

GSW Headquarters has gone through a major refurbishment which allows for more flexibility and internal configurations. This building has been particularly designed around natural ventilation and this can be utilised approximately for 70% of the year with a 53% energy savings on heating and cooling [28]. It also has a building management system (BMS) that allows for automatic and manual operation of windows enabling optimal control options for occupants' comfort.

After the refurbishment, the building shows a shaft-box double-skin façade with a hybrid solution regarding the airflow patterns. Due to the presence of open spaces, cross-ventilation is possible acting both to supply and to extract the air. Additionally, in cold season, when the inner windows are closed the façade may act as a thermal buffer. The cavity is 90 cm deep and this has been possible because of the open site the building is located in. The cavity also allows for fair daylight without glare. However, the west-facing double skin façade is fully equipped with aluminium rotating louvers that can both be controlled automatically and manually. Due to their extreme flexibility, these louvers help to protect against morning, afternoon and low-angle winter sun. Hence the façade installed in this case after the refurbishment is a [C3].[V1].[A1/A2/A3].[D2] and it falls within those suggested by the proposed methodology for this kind of buildings as shown in Table 4.

Table 4: DSF option for Case Study #1

Office Type	Types of Construction	Cavity Ventilation	Airflow Concepts	Cavity Depth
Cellular - Open Plan (mixed)	[C1], [C2], **[C3]**, [C4], [C5]	**[V1]**, [V2]	**[A1]**, **[A2]**, **[A3]**	[D1], **[D2]**

4.3.2 Dorma Head Office - Germany

This building was completed in 1968 and then refurbished in 2002-2004, increasing its floor levels from 6 to 9. The refurbishment has been intense and the building has been completely remodelled removing the concrete units of the primary old façade and equipping it with new opening and well-insulated windows.

The building was originally designed for large open plan spaces and during the refurbishment floors had been cut out to allow more daylight to enter the building and to meet the current standards for workspaces. Considering the heavy refurbishment level of this building, the ventilation is both natural and mechanical, although the mechanical one is only used during the cooling season in south-east and south-west rooms and to extract exhaust air from the rooms when windows are open.

The key feature in this case is the airflow. This DSF is a multi-storey façade, which has structural glazed panes of the same dimensions mounted at different heights, creating thus a permanent and uncontrolled natural ventilation of the cavity. Although detailed information of the cavity depth is not available, from a reverse scaling process done on the pictures and drawings retrieved it seems it is a wide cavity and this is consistent with the open site where the building is located.

Table 5: DSF option for the Case Study #2

Office Type	Types of Construction	Cavity Ventilation	Airflow Concepts	Cavity Depth
Open Plan	[C2], [C3], **[C4]**, [C5]	**[V1]**, [V2]	**[A1]**, [A2], [A3]	[D1], **[D2]**

The double-skin façade installed is [C4].[V1].[A1].[D2], which correlates to the results from the proposed methodology as shown in Table 5

4.3.3 New England House – United Kingdom

New England House (NEH) is a 1960s building in central Brighton, UK that comprises over 11000 m² of net lettable space over eight floors and it is within a short walking distance from the central railway station. This particular building has been chosen as a key case study for the current research due to several reasons. Firstly, a report from 2004 concludes that it is structurally sound and it has substantial load bearing capacity as floors, walls and ceilings are cast and finished in concrete. Secondly, another report from 2010 identifies the poor thermal performances of the façade as the main issue. Taking all elements into consideration, including the commissioning of a business case report by the Brighton & Hove City Council, the refurbishment will take place in the near future.

Figure 5: NEH, Aerial view from South (http://newenglandhouse.org.uk)

Despite its uniform shape (see Figure 5), space distribution varies from floor to floor and also within the same floor. The result is a mix of cellular and open space offices, unevenly distributed on a floor and also throughout different floors. Although the building is centrally located, it still has enough space in its surroundings and already has a light well that can act as an airshaft. The office layout is made around the corridors in the courtyard, giving each office space the access to windows for daylighting and natural ventilation.

Table 6: DSF option for New England House

Office Type	Types of Construction	Cavity Ventilation	Airflow Concepts	Cavity Depth	Possible combinations
Cellular - Open Plan (mixed)	[C2], [C3], [C4], [C5]	[V1], [V2]	[A1], [A2]	[D1], [D2]	32

Unfortunately, the depth of the offices and the size of the whole building do not allow for a cross-ventilation strategy according to the rules of thumb described in literature [28]. By applying the proposed methodology to NEH the result is a total of 32 possible DSF configurations as shown in Table 6. It is important to clarify once again on what this result means. Thirty-two are the DSF systems suitable for NEH considering the constraints related to the building itself, such as the location, the height and the possible indoor ventilation strategies. This number represents the starting point to identify which configurations need to be further investigated to ascertain an optimum selection.

5. Conclusion and future work

Double Skin Façade is a developing technology and, when suitably applied, has the potential to offer greater environmental sustainability than the single skin facade. Current research in this field chiefly focuses on new developments yet the greatest environmental impact lies in the refurbishment of existing buildings. This research has reviewed the current state of the office stock in the UK and indicated that the majority of them are naturally ventilated with cellular or open plan format, which are suitable for the application of Double Skin Façades.

The first step towards accessing the environmental sustainability of DSF is to identify suitable systems for the refurbishment of offices in the UK. In the absence of existing knowledge, an assessment methodology based on parameters identified in the literature review has been successfully developed. This assessment tool takes into account the characteristics and functionalities of DSF systems, and more importantly, the constraints imposed by existing office buildings.

Initial tests of the proposed tool on two completed projects indicated coherent and consistent results but further refinements, additional parameters and a decision flow chart are some of the improvements already identified to be implemented. The third building, New England House in Brighton, which is going to be used as a live case study to demonstrate the true environmental sustainability of DSF through life cycle assessments, was also tested using the proposed methodology to identify the number of viable DSF strategies. This on-going research will not only evaluate the life cycle impact of the possible systems identified by the tool developed in the current study, but will also compare these impacts with the alternative generic façade systems commonly used.

This research has contributed towards the deeper understanding of DSF in the context of their application in office refurbishments. The assessment tool developed to identify the system options, although basic in its current form, is a stepping-stone towards the building up of a knowledge base to support the wider and more appropriate use of DSF for sustainable refurbishments of offices in the UK.

Short Summary

We are in the process of developing an energy assessment tool for residential property within the framework of the SHERIFF (Hybrid and Economic System for the Flexible Comprehensive Rehabilitation of Facades) Research Project, funded by the Spanish Ministry of Economy and Competitiveness and part of the INNPACTO Program. This tool will help to make decisions about how to rehabilitate buildings in Spain. For its development, we have studied the following topics: typologies of existing enclosures, weather conditions and the most appropriate improvement actions to apply on the facade.

First of all, based on previous studies, [1, 2] this research is limited to the period between 1950 and 1980 in the Community of Madrid, Spain. A selection of neighbourhoods has been made based on the amount of buildings built during that time and their state of conservation. The most representative type of residential buildings of each neighbourhood has been chosen and building information for each property has been requested to the relevant administrative entities. A two hundred independent building inventory has been created, collecting information about multiple building enclosure typologies. This inventory has been summarised into the following typologies:

- Six different classes of opaque enclosure construction
- Two types of window construction and
- Three different sun protection typologies.

Secondly, weather conditions, guidelines and representative sections of the city street have been studied, allowing the appropriate action's definition appropriate action as (previously) defined to be applied on the enclosure. The facade has been divided into four specific areas:

- Null zone, where no solar radiation is received during the year.
- Sun protection zone, which must be protected from excessive solar radiation.
- Solar gain zone, which can take advantage of the solar collection strategy.
- Flexible zone, which requires both solar gain and sun protection.

Finally, the summarized inventory has been verified according to both the new draft and the existing Spanish regulation document (CTE).

Keywords: Rehabilitation, Assessment, Facade, Method, and Bioclimatic.

1. Introduction

The energy rehabilitation of facades in buildings has been recognized as the most efficient mechanism for the reduction of energy consumption and CO2 emissions associated with the

construction sector. To comply the objectives of energy efficiency and CO2 emissions in the framework of the European Union by 2050, Spain should increase the rehabilitation rate annual of 400,000 homes (1.5% of the existing housing stock). Which represents an increment of 1.2% more than the current rate 0.3%.[3] Moreover, at this time, the available free land in cities is practically nil, and rehabilitation is seen as the most significant construction activity for the future. This is why the SHERIFF "Hybrid and Economic System for the Flexible Comprehensive Rehabilitation of Facades" Research Project, has among its main goals to optimize the energy rehabilitation phases, starting with the energy performance of the existing facade.

The SHERIFF Research Project contains six different work packages. The first package, "Characterization and construction and energy assessment of building(s)," is in turn divided into four tasks: *E1.1. Cataloguing of the building systems's facade enclosures according to their energy behaviour. E1.2. Energy performance classification for the facades considered. E1.3. Benchmarking of the facade's energy performance before and after rehabilitation. And E1.4. Energy rehabilitation measures tool based on the previous assessment.* This document only refers to part of the work for the first two tasks, because the others are currently in development.

E1.1. Cataloguing of the building systems's facade enclosures according to their energy behaviour. The objective of this task is to define the different types of facade cladding occurring in a given period in Spain. A detailed study has been carried out in several neighbourhoods of Madrid; this methodology will be extrapolated to the whole country. To carry out this task, it has been necessary to develop a preliminary work defining the study period and the selection of the neighbourhoods. Subsequently, building files in which the information concerning the construction composition of the enclosure is gathered have been consulted. With this information, a classification of the types of opaque facade and openings has been developed.

E1.2.Energy performance classification for the facades considered. In this phase, the minimum requirements requested by the Spanish Technical Building Code (CTE) for facade enclosures and the actions that are necessary in order to reach these values were determined.
In order to classify the energy performance of the facades considered and to propose improvements, it was necessary to take the following steps:

- Study the weather conditions influencing the hygrothermal behaviour of the building.
- Determine the needs of the building envelope by using tools for studying the weather conditions of the location.
- Verify the compliance of the enclosure under study with the CTE's minimum requirements.
- Establish the annual bioclimatic strategies that comply with the CTE's provisions according to region and typology.

It is noteworthy that the study of the weather conditions was made for 25 cities, however in this document the city of Madrid has been taken as an example.

2. Cataloguing of the building systems's facade enclosures according to their energy behaviour

2.1 Determination of the study period

Between 1950 and 1980 there was a massive housing construction that resulted in more than 8.5 millions of households, representing more than 35% of the national total. During these years the construction procedures for the housing developments throughout the country were very similar. During this period, commonly known in Spain as “Desarrollismo” (Developmentalis) there was a great demand for housings in the major cities, due among other things to the mass exodus that occurred from the countryside to the city. In those years, buildings were constructed quickly and with precarious means across the country, using the same materials everywhere without any legislation in force to regulate the thermal performance of buildings and therefore the indoor thermal comfort of the homes built. All the housings built during this period have a great potential to be rehabilitated.

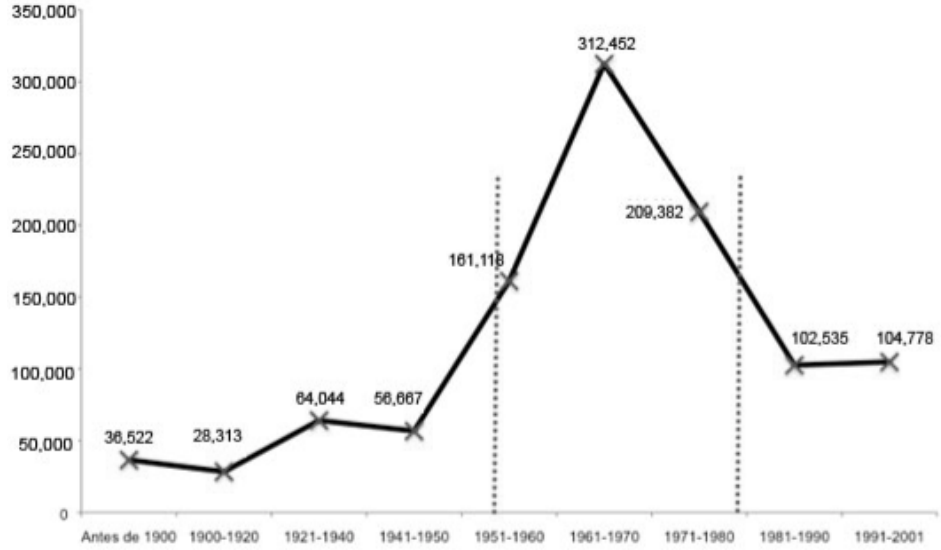

Fig. 1: Family dwellings by date of construction in the city of Madrid

2.2 Selection of neighbourhoods and constructive typologies to study

Once the study period was defined, a selection of the neighbourhoods in Madrid was made with the highest number of houses built in the chosen period.[4, 5] Then, a thorough study for the selection of facade's types in every neighbourhood was developed, considering the most representative ones. Subsequently, building information was requested from the Public Administrations (Archivo de la Villa, Gerencia de Urbanismo, Archivo Central del Ministerio de Fomento and Archivo Regional de la Comunidad de Madrid).

Table 1: Neighbourhoods with over 10,000 housings built in the period between 1951 and 1980 in Madrid

Districts	Neighbourhoods	Homes Built
Hortaleza	Pinar del Rey	17,584
	Canillas	10,668
Villaverde	Los Ángeles	10,115
Salamanca	Guindalera	11,320
Chamartín	Prosperidad	10,219
Fuencarral	El Pilar	18,669
La latina	Puerta del Ángel	12,362
	Lucero	10,850
	Aluche	25,245
	Las Águilas	17,813
Carabanchel	Vista Alegre	13,895
Ciudad lineal	Ventas	17,177
	Pueblo Nuevo	17,310

2.3 Cataloguing of facade enclosures

The information found in the documents consulted has allowed to summarise and categorise facade enclosures in the following types:

- F.1.1. One-foot-thick solid face brick wall
- F.1.2. One-foot-thick double hollow brick wall + rendering
- F.2.1.b One-foot-thick solid face brick wall + 5cm air chamber + 4cm hollow brick

- F.3.1. Half-foot-thick solid face brick wall + 5cm air chamber + 4cm hollow brick
- F.3.2. Half-foot-thick solid face brick wall + 5cm air chamber + double hollow brick
- F.4.1. Half-foot-thick solid sand-lime face brick wall + 5cm air chamber + 4cm hollow brick

The predominant constructive configurations were firstly Half-foot-thick solid face brick wall + 5cm air chamber + 4cm hollow brick and secondly One-foot-thick solid face brick wall.

Frames are classified into two groups:

- C.1.1. Wood frames
- C.2.1. Metal frames

The conclusion is that in this period houses were built mainly with metal frames and rarely with woodworks, and in both cases without thermal break.

Glazing are classified into two groups:

- V.1.1. Single glazing
- V.2.1. Double glazing (4-6-4)

Most of the glasses found were double glazing.

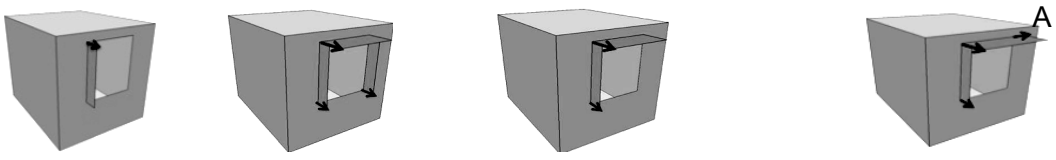
Solar protections are classified into three groups:

- PS.1.1. Blinds
- PS.2.1. Slats
- PS.3.1. Lattices

The solar protections identified were mainly blinds.

3. Preliminary studies for the definition of the actions on the façade.

3.1 Weather conditions



For the evaluation of the energy performance of the facades, the monthly averages of climate data have been taken from the Spanish State Meteorological Agency for the 1971-2000 period. Twenty five cities of the climatic zones established by the Spanish Technical Building Code have been selected. For each one of these cities, all the weather conditions influencing the hygrothermal behaviour of the building (temperature, precipitation, relative humidity, sun exposure and wind) have been studied. This research has been used to assess the housing needs of the twenty five cities, such as window shading or solar incidence on vertical surfaces depending on the proportion of the streets.

3.2 Need for shading in the openings

The shading and sunlight needs for a 1.20 x 1.20 m window opening in the relevant orientations (north, south, east and south-east) [6] were studied. When selecting the sizes of the solar protections, the need for shade in the summer and for sunlight in the winter has been taken into account.

Table 2: Solar protection dimensions required in Madrid (latitude 40°) for each orientation.

Zone	North	South		East		South-east		
D3	Vertical	Horizontal	Vertical	Horizontal	Vertical	Horizontal (A)	Vertical	Horizontal
	0.75	1.24	0.44	0.69	0.44	0.26	0.78	0.51

Note: Sizes are measured in meters

3.3 Solar incidence on vertical surfaces according to the orientation

In the study of solar incidence on vertical surfaces, the Vertical Shading Angle (VSA) was calculated according to the season and two important aspects; first, the angle between 10am and 2pm, when the solar incidence is at its highest; secondly, the solar protection and solar collection needs studied in the weather conditions.

The VSAs obtained have been drawn in order to apply them in the study of the proportions of the street section and in the actions on the facade to improve the energy performance of the building.

3.4 Proportion of Madrid's street sections

To classify the streets of Madrid, a study of street proportions has been carried out, in which the influence of the shadow of the nearby buildings on the facade has been evaluated, including the width of the section of the street and the VSA. For this task, a previous research done by Prof. Agustín Hernández Aja has been taken as a starting point.[7]

Once the results obtained, a classification of six different sections has been taken the average value of each proportion has been taken, that is to say:

- Section 01, proportion of street width and height between 0.3 and 0.5
- Section 02, proportion of street width and height between 0.6 and 0.8
- Section 03, proportion of street width and height between 0.9 and 1.2
- Section 04, proportion of street width and height between 1.3 and 1.6
- Section 05, proportion of street width and height between 1.7 and 2.0
- Section 06, proportion of street width and height >2.1

4. Actions on the envelope

4.1 Strategies to improve the energy performance in the facade according to latitude

A graphic study of solar incidence on the facade for each orientation has been carried out. The different types of street section and the AVS previously selected have been necessary for it. This work has resulted in the division of the facade into four zones depending on the most appropriate actions for improving their thermal behaviour.

These zones are:

- Z01 (Zone 01), Shadow is on this facade area. Solar gain is impossible.
- Z02 (Zone 02), Sun protections are needed to prevent solar gains (overhangs, louvres, blinds, slats, etc.).
- Z03 (Zone 03), Solar gain and prevention of heat loss are needed (greenhouse, trombe wall, thermal inertia, etc.).
- Z04 (Zone 04), Flexible zone, solar gain and sun protection are required (for example moveable sun protections).

Figure 2 shows the percentage of facade for each zone type, for the 6 types of street sections. In this case, we have studied Madrid's east and west orientations. In the sections Type T01, T02 and T03, the solar gain area (Z03) increases up to 82% when the street section grows in width. This area is 100% in the remaining street sections. When the street section is the narrowest, like Type T01, solar gain is impossible in this area (Z01), which in this case is 25% of the facade.

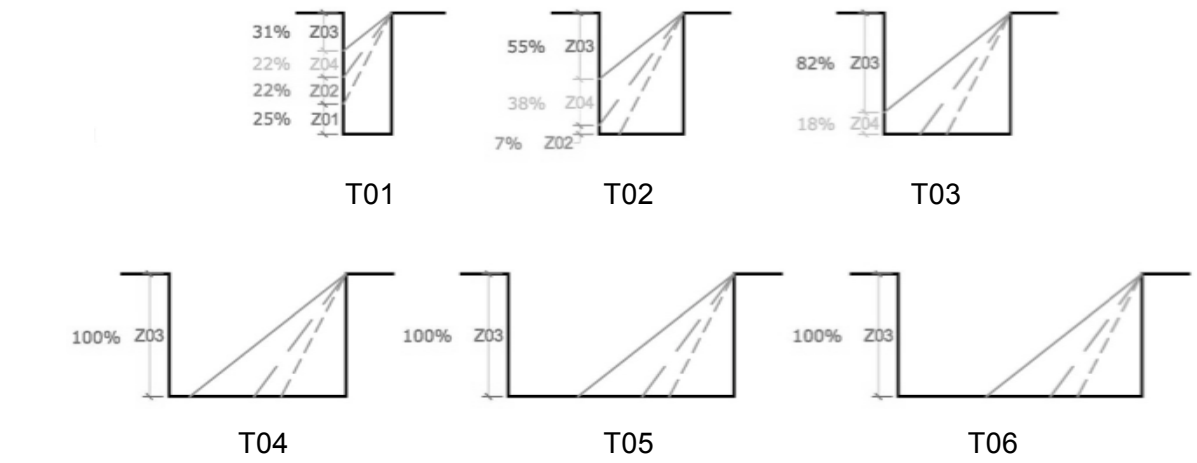


Fig. 2: Example of determining the most appropriate actions on the facade, latitude 40 ° Madrid, east orientation.

Legend:

4.2 Action requirement according to the Spanish Technical Building Code (CTE)

We have compared the theoretical transmittance of facades previously catalogued with the transmittances required by the CTE 2006 (still in effect), the CTE 2013 (draft document) and a proposal for improvement of the latter by 25%. These last data have been made taking into account that the European Standards are already establishing the steps that will be needed to get zero energy buildings.

Table 3: Transmittance comparisons: theoretical transmittance, CTE 2006 transmittance and CTE 2013 transmittance.

	Region D			
	Thermal transmittance of the facades (W/m2 K)			
Cataloguing summary	Theoretical	CTE 2006	CTE 2013	Improvement proposal by 25%
F.1.1	2.21	0.86	0.66	0.50
F.1.2	1.05			
F.2.1.b	1.22			
F.3.1	1.49			
F.3.2	1.30			
F.4.1	1.56			
	Thermal transmittance of the frames (W/m2 K)			
C.1.1	2.00	3.50	2.70	2.03
C.2.1	5.70			
	Thermal transmittance of the glazing (W/m2 K)			
V.1.1	5.70	3.50	2.70	2.03
V.2.1	3.30			

The purpose of this comparison was to evaluate the requirements needed for each type of facade according to its corresponding climate zone. Although this comparison has been made for all the areas of Spain established in the CTE, this study only shows region D, corresponding to Madrid.

5. Conclusions

The selection of the study period and neighbourhoods has allowed us to develop a detailed analysis in order to catalogue the most common facade types. The procedure used could be extrapolated to any other period that might be studied.

Knowing the composition of the facades and their cataloguing allows the thermal behaviour of the building to be established in order to make a proposal to improve according to the existing buildings.

Studying the weather conditions has allowed the identification of the specific rehabilitation actions for each CTE climate zone, namely:

- For the windows (the openings), the appropriate dimensions and location of the sun protection have been defined, which could be adapted to most of the existing openings and would be a non-intrusive installation.
- For the facade enclosures catalogued (the opaque part), which do not comply with the Spanish legislation (the current one and the one that is about to be published), a comprehensive study to evaluate the thickness of the insulation needed for each type of facade in order to comply with the legislation has been initiated/started.

6. Acknowledgements

The authors wish to thank the ABIO Research Group and the Department of Construction and Technology in Architecture, Technical University of Madrid (Universidad Politécnica de Madrid, UPM) Spain. We would also like to thank the SHERIFF Project and the Public Administrations (Archivo de la Villa, Gerencia de Urbanismo, Archivo Central del Ministerio de Fomento and Archivo Regional de la Comunidad de Madrid) for allowing us the use of their facilities and access to their archives. And finally thanks to Pablo Velez for helping us in developing this paper.

Short Summary

We are in the process of developing an energy assessment tool for residential property within the framework of the SHERIFF (Hybrid and Economic System for the Flexible Comprehensive Rehabilitation of Facades) Research Project, funded by the Spanish Ministry of Economy and Competitiveness and part of the INNPACTO Program. This tool will help to make decisions about how to rehabilitate buildings in Spain. For its development, we have studied the following topics: typologies of existing enclosures, weather conditions and the most appropriate improvement actions to apply on the facade.

First of all, based on previous studies, [1, 2] this research is limited to the period between 1950 and 1980 in the Community of Madrid, Spain. A selection of neighbourhoods has been made based on the amount of buildings built during that time and their state of conservation. The most representative type of residential buildings of each neighbourhood has been chosen and building information for each property has been requested to the relevant administrative entities. A two hundred independent building inventory has been created, collecting information about multiple building enclosure typologies. This inventory has been summarised into the following typologies:

- Six different classes of opaque enclosure construction
- Two types of window construction and
- Three different sun protection typologies.

Secondly, weather conditions, guidelines and representative sections of the city street have been studied, allowing the appropriate action's definition appropriate action as (previously) defined to be applied on the enclosure. The facade has been divided into four specific areas:

- Null zone, where no solar radiation is received during the year.
- Sun protection zone, which must be protected from excessive solar radiation.
- Solar gain zone, which can take advantage of the solar collection strategy.
- Flexible zone, which requires both solar gain and sun protection.

Finally, the summarized inventory has been verified according to both the new draft and the existing Spanish regulation document (CTE).

Keywords: Rehabilitation, Assessment, Facade, Method, and Bioclimatic.

1. Introduction

The energy rehabilitation of facades in buildings has been recognized as the most efficient mechanism for the reduction of energy consumption and CO2 emissions associated with the

construction sector. To comply the objectives of energy efficiency and CO2 emissions in the framework of the European Union by 2050, Spain should increase the rehabilitation rate annual of 400,000 homes (1.5% of the existing housing stock). Which represents an increment of 1.2% more than the current rate 0.3%.[3] Moreover, at this time, the available free land in cities is practically nil, and rehabilitation is seen as the most significant construction activity for the future. This is why the SHERIFF "Hybrid and Economic System for the Flexible Comprehensive Rehabilitation of Facades" Research Project, has among its main goals to optimize the energy rehabilitation phases, starting with the energy performance of the existing facade.

The SHERIFF Research Project contains six different work packages. The first package, "Characterization and construction and energy assessment of building(s)," is in turn divided into four tasks: *E1.1. Cataloguing of the building systems's facade enclosures according to their energy behaviour. E1.2. Energy performance classification for the facades considered. E1.3. Benchmarking of the facade's energy performance before and after rehabilitation. And E1.4. Energy rehabilitation measures tool based on the previous assessment.* This document only refers to part of the work for the first two tasks, because the others are currently in development.

E1.1. Cataloguing of the building systems's facade enclosures according to their energy behaviour. The objective of this task is to define the different types of facade cladding occurring in a given period in Spain. A detailed study has been carried out in several neighbourhoods of Madrid; this methodology will be extrapolated to the whole country. To carry out this task, it has been necessary to develop a preliminary work defining the study period and the selection of the neighbourhoods. Subsequently, building files in which the information concerning the construction composition of the enclosure is gathered have been consulted. With this information, a classification of the types of opaque facade and openings has been developed.

E1.2.Energy performance classification for the facades considered. In this phase, the minimum requirements requested by the Spanish Technical Building Code (CTE) for facade enclosures and the actions that are necessary in order to reach these values were determined.
In order to classify the energy performance of the facades considered and to propose improvements, it was necessary to take the following steps:

- Study the weather conditions influencing the hygrothermal behaviour of the building.
- Determine the needs of the building envelope by using tools for studying the weather conditions of the location.
- Verify the compliance of the enclosure under study with the CTE's minimum requirements.
- Establish the annual bioclimatic strategies that comply with the CTE's provisions according to region and typology.

It is noteworthy that the study of the weather conditions was made for 25 cities, however in this document the city of Madrid has been taken as an example.

2. Cataloguing of the building systems's facade enclosures according to their energy behaviour

2.1 Determination of the study period

Between 1950 and 1980 there was a massive housing construction that resulted in more than 8.5 millions of households, representing more than 35% of the national total. During these years the construction procedures for the housing developments throughout the country were very similar. During this period, commonly known in Spain as “Desarrollismo” (Developmentalis) there was a great demand for housings in the major cities, due among other things to the mass exodus that occurred from the countryside to the city. In those years, buildings were constructed quickly and with precarious means across the country, using the same materials everywhere without any legislation in force to regulate the thermal performance of buildings and therefore the indoor thermal comfort of the homes built. All the housings built during this period have a great potential to be rehabilitated.

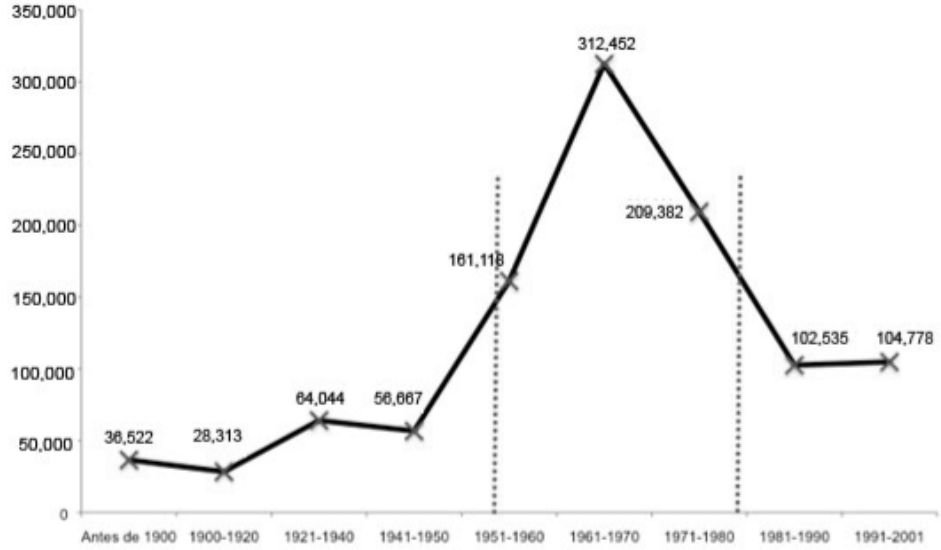

Fig. 1: Family dwellings by date of construction in the city of Madrid

2.2 Selection of neighbourhoods and constructive typologies to study

Once the study period was defined, a selection of the neighbourhoods in Madrid was made with the highest number of houses built in the chosen period.[4, 5] Then, a thorough study for the selection of facade's types in every neighbourhood was developed, considering the most representative ones. Subsequently, building information was requested from the Public Administrations (Archivo de la Villa, Gerencia de Urbanismo, Archivo Central del Ministerio de Fomento and Archivo Regional de la Comunidad de Madrid).

Table 1: Neighbourhoods with over 10,000 housings built in the period between 1951 and 1980 in Madrid

Districts	Neighbourhoods	Homes Built
Hortaleza	Pinar del Rey	17,584
	Canillas	10,668
Villaverde	Los Ángeles	10,115
Salamanca	Guindalera	11,320
Chamartín	Prosperidad	10,219
Fuencarral	El Pilar	18,669
La latina	Puerta del Ángel	12,362
	Lucero	10,850
	Aluche	25,245
	Las Águilas	17,813
Carabanchel	Vista Alegre	13,895
Ciudad lineal	Ventas	17,177
	Pueblo Nuevo	17,310

2.3 Cataloguing of facade enclosures

The information found in the documents consulted has allowed to summarise and categorise facade enclosures in the following types:

- F.1.1. One-foot-thick solid face brick wall
- F.1.2. One-foot-thick double hollow brick wall + rendering
- F.2.1.b One-foot-thick solid face brick wall + 5cm air chamber + 4cm hollow brick

- F.3.1. Half-foot-thick solid face brick wall + 5cm air chamber + 4cm hollow brick
- F.3.2. Half-foot-thick solid face brick wall + 5cm air chamber + double hollow brick
- F.4.1. Half-foot-thick solid sand-lime face brick wall + 5cm air chamber + 4cm hollow brick

The predominant constructive configurations were firstly Half-foot-thick solid face brick wall + 5cm air chamber + 4cm hollow brick and secondly One-foot-thick solid face brick wall.

Frames are classified into two groups:

- C.1.1. Wood frames
- C.2.1. Metal frames

The conclusion is that in this period houses were built mainly with metal frames and rarely with woodworks, and in both cases without thermal break.

Glazing are classified into two groups:

- V.1.1. Single glazing
- V.2.1. Double glazing (4-6-4)

Most of the glasses found were double glazing.

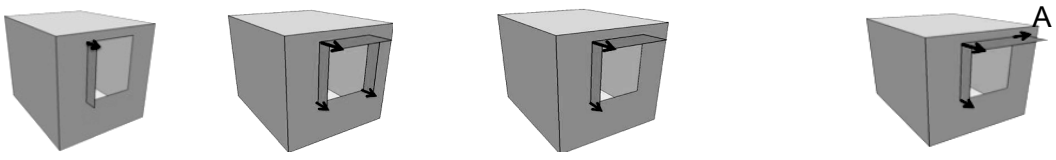
Solar protections are classified into three groups:

- PS.1.1. Blinds
- PS.2.1. Slats
- PS.3.1. Lattices

The solar protections identified were mainly blinds.

3. Preliminary studies for the definition of the actions on the façade.

3.1 Weather conditions



For the evaluation of the energy performance of the facades, the monthly averages of climate data have been taken from the Spanish State Meteorological Agency for the 1971-2000 period. Twenty five cities of the climatic zones established by the Spanish Technical Building Code have been selected. For each one of these cities, all the weather conditions influencing the hygrothermal behaviour of the building (temperature, precipitation, relative humidity, sun exposure and wind) have been studied. This research has been used to assess the housing needs of the twenty five cities, such as window shading or solar incidence on vertical surfaces depending on the proportion of the streets.

3.2 Need for shading in the openings

The shading and sunlight needs for a 1.20 x 1.20 m window opening in the relevant orientations (north, south, east and south-east) [6] were studied. When selecting the sizes of the solar protections, the need for shade in the summer and for sunlight in the winter has been taken into account.

Table 2: Solar protection dimensions required in Madrid (latitude 40°) for each orientation.

Zone	North	South		East		South-east		
D3	Vertical	Horizontal	Vertical	Horizontal	Vertical	Horizontal (A)	Vertical	Horizontal
	0.75	1.24	0.44	0.69	0.44	0.26	0.78	0.51

Note: Sizes are measured in meters

3.3 Solar incidence on vertical surfaces according to the orientation

In the study of solar incidence on vertical surfaces, the Vertical Shading Angle (VSA) was calculated according to the season and two important aspects; first, the angle between 10am and 2pm, when the solar incidence is at its highest; secondly, the solar protection and solar collection needs studied in the weather conditions.

The VSAs obtained have been drawn in order to apply them in the study of the proportions of the street section and in the actions on the facade to improve the energy performance of the building.

3.4 Proportion of Madrid's street sections

To classify the streets of Madrid, a study of street proportions has been carried out, in which the influence of the shadow of the nearby buildings on the facade has been evaluated, including the width of the section of the street and the VSA. For this task, a previous research done by Prof. Agustín Hernández Aja has been taken as a starting point.[7]

Once the results obtained, a classification of six different sections has been taken the average value of each proportion has been taken, that is to say:

- Section 01, proportion of street width and height between 0.3 and 0.5
- Section 02, proportion of street width and height between 0.6 and 0.8
- Section 03, proportion of street width and height between 0.9 and 1.2
- Section 04, proportion of street width and height between 1.3 and 1.6
- Section 05, proportion of street width and height between 1.7 and 2.0
- Section 06, proportion of street width and height >2.1

4. Actions on the envelope

4.1 Strategies to improve the energy performance in the facade according to latitude

A graphic study of solar incidence on the facade for each orientation has been carried out. The different types of street section and the AVS previously selected have been necessary for it. This work has resulted in the division of the facade into four zones depending on the most appropriate actions for improving their thermal behaviour.

These zones are:

- Z01 (Zone 01), Shadow is on this facade area. Solar gain is impossible.
- Z02 (Zone 02), Sun protections are needed to prevent solar gains (overhangs, louvres, blinds, slats, etc.).
- Z03 (Zone 03), Solar gain and prevention of heat loss are needed (greenhouse, trombe wall, thermal inertia, etc.).
- Z04 (Zone 04), Flexible zone, solar gain and sun protection are required (for example moveable sun protections).

Figure 2 shows the percentage of facade for each zone type, for the 6 types of street sections. In this case, we have studied Madrid's east and west orientations. In the sections Type T01, T02 and T03, the solar gain area (Z03) increases up to 82% when the street section grows in width. This area is 100% in the remaining street sections. When the street section is the narrowest, like Type T01, solar gain is impossible in this area (Z01), which in this case is 25% of the facade.

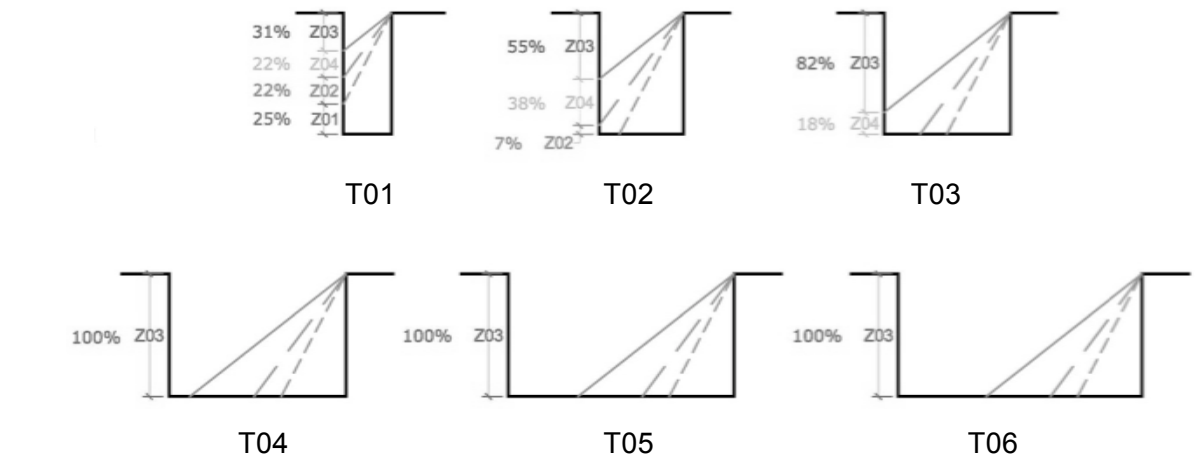


Fig. 2: Example of determining the most appropriate actions on the facade, latitude 40 ° Madrid, east orientation.

Legend:

4.2 Action requirement according to the Spanish Technical Building Code (CTE)

We have compared the theoretical transmittance of facades previously catalogued with the transmittances required by the CTE 2006 (still in effect), the CTE 2013 (draft document) and a proposal for improvement of the latter by 25%. These last data have been made taking into account that the European Standards are already establishing the steps that will be needed to get zero energy buildings.

Table 3: Transmittance comparisons: theoretical transmittance, CTE 2006 transmittance and CTE 2013 transmittance.

	Region D			
	Thermal transmittance of the facades (W/m2 K)			
Cataloguing summary	Theoretical	CTE 2006	CTE 2013	Improvement proposal by 25%
F.1.1	2.21	0.86	0.66	0.50
F.1.2	1.05			
F.2.1.b	1.22			
F.3.1	1.49			
F.3.2	1.30			
F.4.1	1.56			
	Thermal transmittance of the frames (W/m2 K)			
C.1.1	2.00	3.50	2.70	2.03
C.2.1	5.70			
	Thermal transmittance of the glazing (W/m2 K)			
V.1.1	5.70	3.50	2.70	2.03
V.2.1	3.30			

The purpose of this comparison was to evaluate the requirements needed for each type of facade according to its corresponding climate zone. Although this comparison has been made for all the areas of Spain established in the CTE, this study only shows region D, corresponding to Madrid.

5. Conclusions

The selection of the study period and neighbourhoods has allowed us to develop a detailed analysis in order to catalogue the most common facade types. The procedure used could be extrapolated to any other period that might be studied.

Knowing the composition of the facades and their cataloguing allows the thermal behaviour of the building to be established in order to make a proposal to improve according to the existing buildings.

Studying the weather conditions has allowed the identification of the specific rehabilitation actions for each CTE climate zone, namely:

- For the windows (the openings), the appropriate dimensions and location of the sun protection have been defined, which could be adapted to most of the existing openings and would be a non-intrusive installation.
- For the facade enclosures catalogued (the opaque part), which do not comply with the Spanish legislation (the current one and the one that is about to be published), a comprehensive study to evaluate the thickness of the insulation needed for each type of facade in order to comply with the legislation has been initiated/started.

6. Acknowledgements

The authors wish to thank the ABIO Research Group and the Department of Construction and Technology in Architecture, Technical University of Madrid (Universidad Politécnica de Madrid, UPM) Spain. We would also like to thank the SHERIFF Project and the Public Administrations (Archivo de la Villa, Gerencia de Urbanismo, Archivo Central del Ministerio de Fomento and Archivo Regional de la Comunidad de Madrid) for allowing us the use of their facilities and access to their archives. And finally thanks to Pablo Velez for helping us in developing this paper.

Short Summary

A saleable software was created for the evaluation of built-in windows and the savings effect to be attained by building in new windows. With the help of the program Uwin the energy savings can be prognosticated in case of refurbishing by consultations with suppliers of windows, facades and glazing.

The program starts with guideline values which can be adjusted and refined step by step. The calculated energy savings are indicated in kWh/m² as final energy (as QE in kWh/m²a). According to the operation of the rapid access field the result can be issued with or without heat loss by airing as well as with or without solar gain.

The program anticipates that the window is protected from insolation by lateral and horizontal components. It also anticipates that there is a building opposite. The linked Ug-value measuring tool was tested by appropriate procedures and the results were evaluated.

The software Uwin is available in German only on the project website www.fenstercheck.info.

Keywords: window; refurbishment; energy savings potential; energy-efficient buildings.

1. Introduction

Windows are an energy sensitive part of the building façade. In case of a planned window refurbishment however, it is often difficult to evaluate the energy savings potential of such a measure, especially if no product information about the built-in glazing and frame is available.

Within the frame of the project „Development of a new evaluation tool to determine the energy savings potential of window refurbishment including effects of glazing, frame and connection“ [1], a saleable software was created for the evaluation of built-in windows and the savings effect to be attained by building in new windows. With the help of the program Uwin the energy savings can be prognosticated in case of refurbishing by consultations with suppliers of windows, facades and glazing.

The program starts with guideline values which can be adjusted and refined step by step. The calculated energy savings are indicated in kWh/m² as final energy (as QE in kWh/m²a). According to the operation of the rapid access field the result can be issued with or without heat loss by airing

as well as with or without solar gain.

The program anticipates that the window is protected from insolation by lateral and horizontal components. It also anticipates that there is a building opposite. The linked Ug-value measuring tool was tested by appropriate procedures and the results were evaluated.

2. Results

As a basis for the project, Kurz und Fischer GmbH have compiled the results of their business experience gained by acting as consulting engineers in the field of building physics. With reference to windows and glazing it is

- knowledge of the ageing process of windows and glazing of several typical objects
- knowledge of typical processes of planning and decision-making, depending on structures, i.e. private ownership, condominiums, property of building societies, municipal buildings etc.
- requirements referring to analysis instruments, i.e. the measuring system and the software for analysing and consulting.

On this basis a definition was found to differentiate between characteristics to be gained by in-situ measuring of the base and by appearance and comparison with data supplied. The development of a measuring tool is concentrated to glazing (not to the whole window), and, because of the considerable dependence on geometrical facts, to collect the influence factors of the other components by a calculation software to be developed.

The structure consists of about twenty input masks that are to be operated alternatively depending on the task (selection, multiple selection or manual input). The select buttons were as detailed as possible illustrated by symbols, so that the program can be operated intuitively. In addition input routines were structured to make it possible from the beginning to receive return data fast and easy to explain and, in the course of further input, more and more precise.

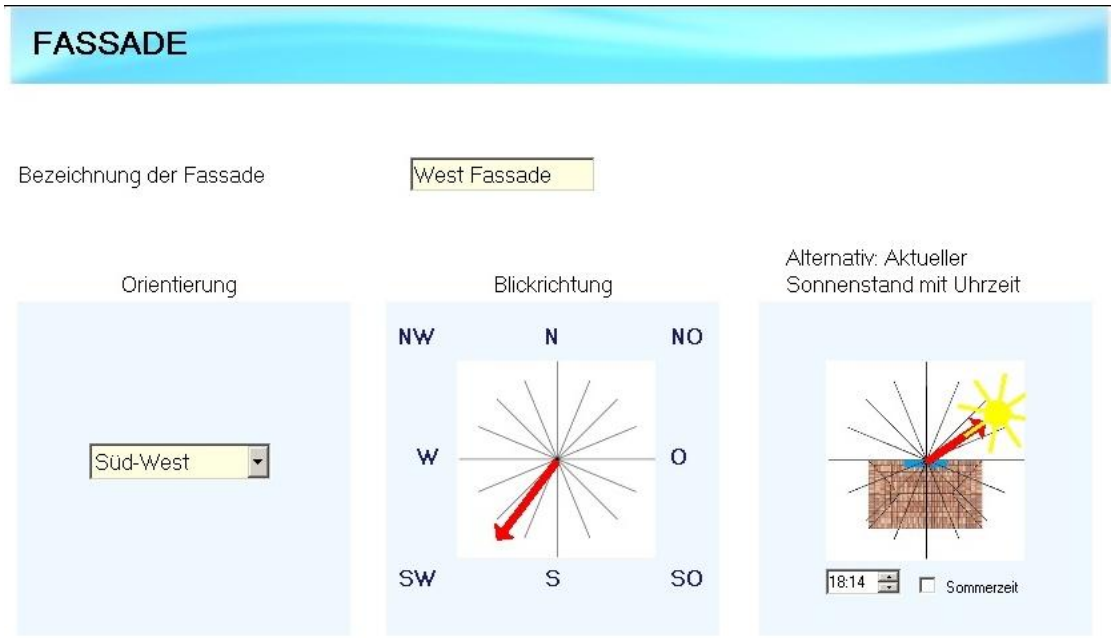

Figure 1: Example of an intuitively operable input screen for selecting the façade orientation.

The evaluation of the market data and the material data of glazing delivered results that indicate in which way data of the built-in windows can be collected and where, above all, measuring is appropriate.

The report function was created to achieve a preliminary evaluation with little input. It is, however, connected to a graphic design that indicates the probability of the result. A description of the program and an operating manual were worked out. The most important functions of the program were provided with tool tip texts.

In the course of the project a saleable full version (Uwin) was programmed well in time taking into consideration suggestions for optimizing. The program was tested by several users, among them the Hochschule für Technik und Wirtschaft in Berlin. The results of the test were commented. After examination some of the suggestions were realized in the final version.

The Ug-value measuring tool was tested by appropriate procedures and the results were evaluated. The software offers an opportunity to calculate the solar gain and the heat losses caused by airing.

With the help of the program Uwin the energy savings can be prognosticated in case of refurbishing by consultations with suppliers of windows, facades and glazing. Additional functions are included in the program. According to the type of problem and the motivations the program offers to the user either a prompt result or a more precise calculation in a particular case. Therefore, the program starts with guideline values. They can be adjusted and refined step by step. If the input referring to a built-in window can be specified the result of the calculation can be improved considerably.

The user is enabled to define in advance standard values of the project and of the types of windows available. For consultations the data of several types of windows available can be put in before and selected accordingly. Windows for comparison can be imported and managed continually.

In addition to the mere indication of energy savings a range of additional information will be registered for internal use. That can deliver important data for working out an offer. At the same time the program can be used for recording the results of the investigation. If several windows have been recorded the results refer to the total outcome, that means an average U-value for the whole window surface will be calculated. In the same way the energy savings refer to the number of all windows, if necessary with various formats, different orientation etc.

The calculated energy savings are indicated in kWh/m² as final energy (as QE in kWh/m²a). According to the operation of the rapid access field the result can be issued with or without heat loss by airing as well as with or without solar gain.

Access to the internet enables to fill in missing local data and procures information on the respective state of the Federal Republic, region of summer climate, year of test reference (region), altitude above sea level, wind zone, wind speed, heavy rain region, estimated rainfall per year.

Even without internet an approaching definition of additional input is possible. There is a map of Germany and by clicking the respective siting with the arrow to the object the data will be transferred to the program. For verification latitude and longitude appear on top right as GPS coordinate. Direct input is possible too, provided a GPS set is at the object consultant´s disposal.

To evaluate the exposure of a building to wind photographs have been used to show the wind situation symbolically.

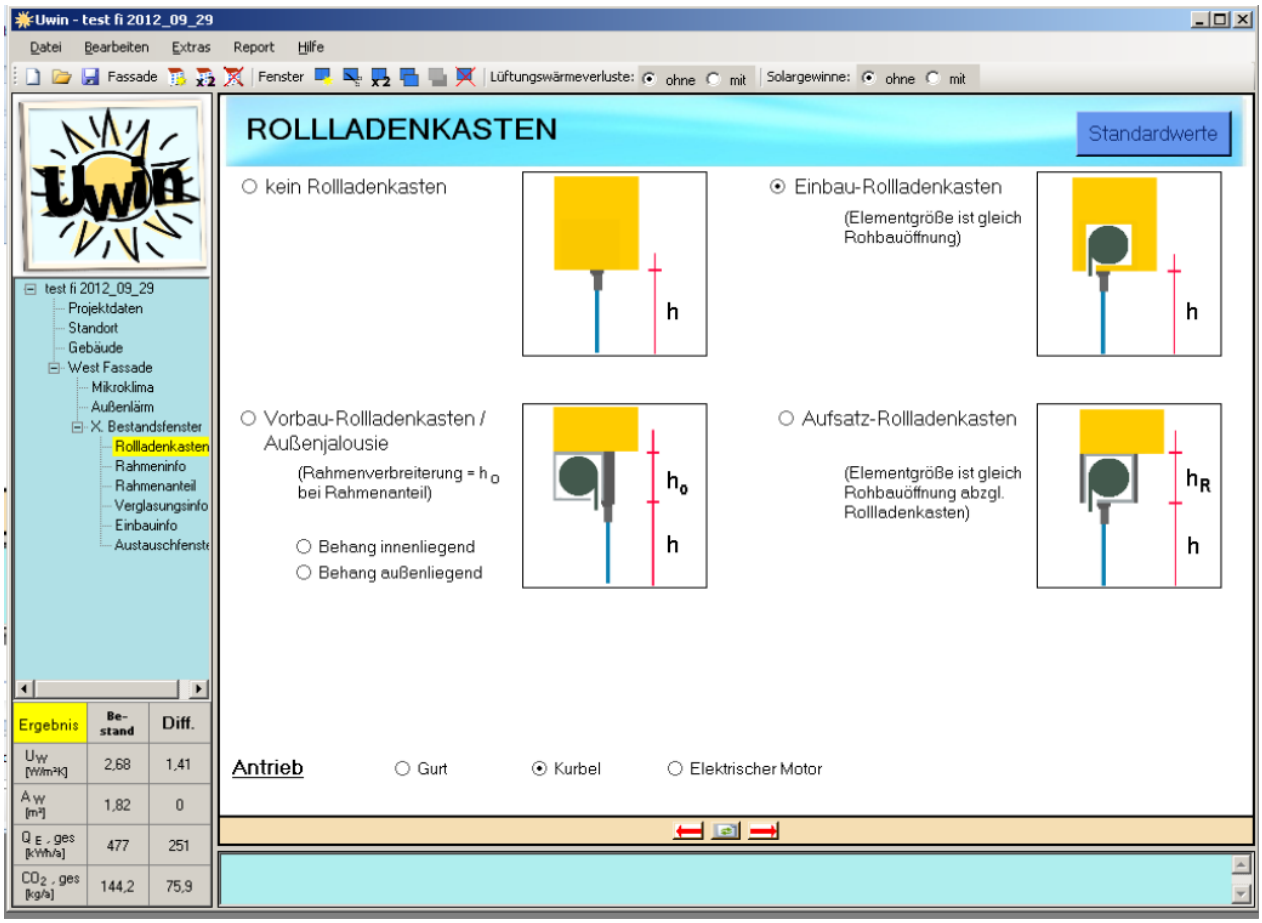

Figure 2: The software works with user-defined default values for a quick first result but quite many details can be added for an increased accurateness.

Knowledge of the openings of a building under construction is important for finding out the surface and the length of the respective share of frame, glazing, shutter, panelling, the length of sealing and the factor of loss by thermal bridges. The program allows the entry of the essential types of shutters. According to that the implemented methods of calculation are adjusted.

2.1 Shading

The program allows to anticipate the protection of window from insolation by lateral and horizontal components. It also anticipates that there is a building opposite.

The program calculates the solar gain of the window on base of the quantity of radiation depending on orientation and shading. It is to be taken into consideration that the degree of utility of the solar gain per year is generally at 1. In practice solar gain can be realised only partly, depending on the share of window surface, kind of utility, solidity of the building and the heating system.

2.2 Fringe information

It is possible to register the constructions characteristics depending on the respective age and with regard to the type of frame. The registration of the type of frame with windows made of wood and aluminium is essential to the evaluation of the temperature factors at the glass insert and is given only in an informative manner. It is not essential for the calculation of the U-value. The frame depth of wooden windows is used to calculate the U-values of frames according to affix D3 of DIN EN ISO 10211:2010-05.

The registration of the functional joints is used to establish the factor of joint leakage. Those results influence the loss of heat by airing of the built-in windows in connection with the length of joints. The registration whether there exist frame ventilators in faced frames or as combined form is important for making offers and, therefore, will be recorded. Ventilations in flats and apartments (to which belong airing elements that are not for windows and can, for example, be situated under the window sill) will not be shown in the program.

From the large number of different window types, mainly installed in residential buildings,
15 basic types were selected and implemented.

The total surface of the window elements is calculated by the shares of frames, glazing and panels leading to the absolute value. There is also issued the surface of glazing and of the frame as absolute value as well as the respective percentage.

Furthermore, the program delivers as result of the calculation the length of the installed joints of the building, the window seals (single) and the border connections of glass and panels.

2.3 Glazing info

It is possible to select single, double or triple glazing as insulation unit. For double glazed window the constellation 2 x 1 and for special double window and casement window constructions the constellation 2 + 1 is provided.

The calculated Ug-values of the glazing are also considering inclination. Therefore, the tool is also suitable for the glazing of skylights and winter gardens. If a built-in window has any bars a selection menu appears for a more detailed description of the kind of bars according to the classification of DIN 4108-4:2013-02, table 10. If built-in windows are to be evaluated the spacing stay must be distinguished.

2.4 Report function and data transfer

The dates are internally recorded in the XML-format. The Uwin-project-data-file can be opened as XML or as TXT file and be used by subsequent programs.

The results of the measuring by the U-value tool Uglass can be directly entered in the program. Thereby, a calculation with realistic input data is possible.

3. Outlook

Experience gained by testing and first measuring results achieved by practical use give grounds for expectations that there will be a large field of application of the tool for U-value measuring on the spot in the future.

In addition to that the application of the software will, independent of the use of the measuring tool, be an aid in advising customers on the spot by experts of the window business as well as by energy consultants. The high flexibility of the program, the suitability for various tasks (rapid evaluation of single windows, evaluation of whole facades or buildings) were proved by the tests.

The results of the measurements by the Uglass tool, which to a certain extent were made at new buildings, have indicated that applying the developed tools will not only be useful for the evaluation of old buildings but also for the quality control of buildings under construction.
Therefore, an impetus can be expected leading to higher standards of quality control in the production of insulated glass. In this way the superior aim of energy-saving building can be supported. The results achieved up to now have confirmed the importance of tools to be widely applied.

The software Uwin is available in German only on the project website www.fenstercheck.info.

Short Summary

Two different cooling systems with PCM – a sun protection system and a ventilated cooling ceiling – were installed in four office rooms in Karlsruhe, Germany, and monitored during summer 2010. The thermal behaviour of the systems was measured and compared to an identical reference room without cooling system. To avoid any interference from the users and to get defined boundary conditions, the measurements were performed on weekends with electrical heaters to simulate internal gains. With each of the PCM systems, the maximum operative room temperature could be reduced by 1-2°C, while a reduction of 2-4°C could be achieved with both systems together. While the ventilation system helped to regenerate the PCM, the regeneration of the PCM by night-time ventilation only was a problem.

Keywords: Phase Change Material (PCM); latent heat storage; room cooling; energy-efficient buildings; thermal comfort.

1. Introduction

Phase change materials (PCM) offer a promising alternative to conventional cooling systems. The passive nature of the latent heat storage process allows a high potential for energy efficient systems, especially if combined with some kind of free cooling to regenerate the PCM during the night. Two such systems – a sun protection system with PCM [1] and a ventilated cooling ceiling with PCM - were installed in some office rooms in Karlsruhe, Germany and were monitored during summer 2010. One office room was equipped with the PCM sun protection system, one with the ventilated cooling ceiling with PCM, and one with both systems. The thermal behavior of the systems was measured and compared to an identical reference room without cooling system. The measurements were carried out in a funded project [2].

2. System description

2.1 Sun protection system with PCM

Even if exterior sun protection systems are preferable, interior systems are installed in many buildings. The reasons range from the sensitivity of exterior systems to surrounding conditions like strong winds, to architectural considerations, or simply costs. Conventional interior sun protection systems consist of horizontal or vertical slats, usually with high reflective properties on the side

facing the exterior. A major problem of interior systems is the solar absorption on the blind, which leads to uncomfortably high temperatures at the blind surface and a large secondary transmittance, thus resulting in a high solar heat gain coefficient. This problem can be greatly reduced by incorporating PCM into the blind to cut temperature peaks. In the case of incoming solar radiation, the blind can only heat up to the melting temperature of the PCM because the melting starts and the absorbed heat is stored as latent heat. A further increase in temperature cannot occur until the PCM is completely melted. The PCM thus decreases the blind surface temperature as well as the g-value of the system. The mode of operation of a sun protection system with PCM is depicted in Figure 1. By choosing the melting temperature and amount of PCM accurately, the system can be designed to store the solar radiation energy absorbed during a whole day in summer.

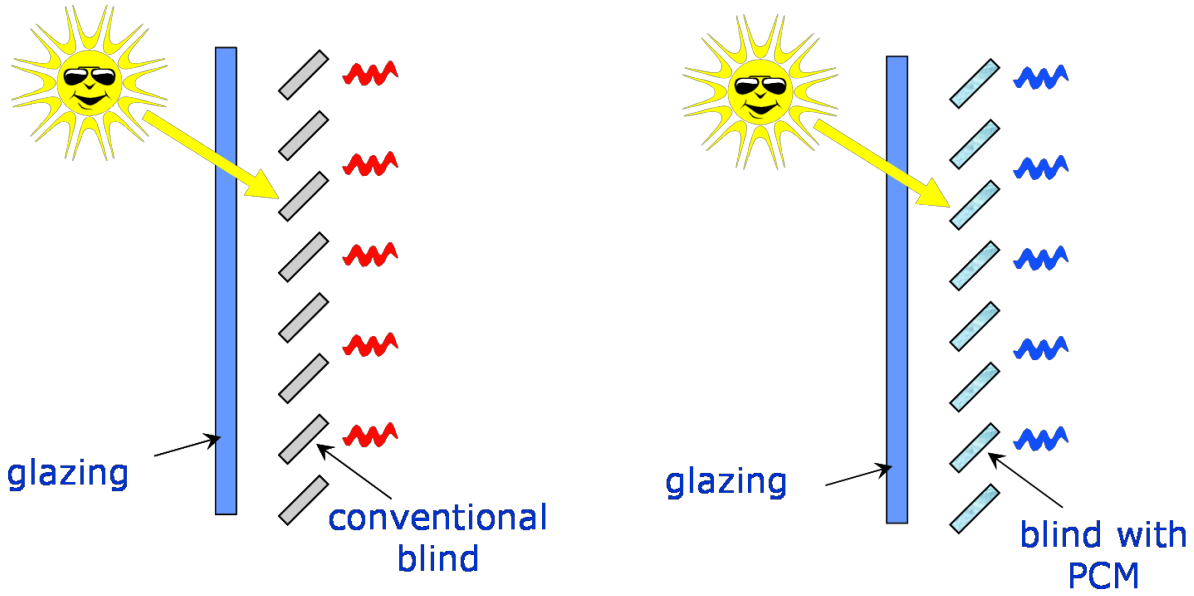

Figure 1: Diagram of a conventional sun protection system (left) and a sun protection system with PCM (right). While the conventional system heats up by absorbing solar radiation, the PCM limits the blind surface temperature to the melting temperature of the PCM.

A first prototype of such a sun protection system with PCM was developed by Warema, the leading manufacturer of sun shading systems in Germany. The PCM used was Delta®-Cool 28, a salt hydrate with a melting range between 26°C and 30°C and a melting enthalpy of 188 J/g produced by the company Dörken. Dörken also provided the encapsulation of the PCM, a hollow polycarbonate blind with a 12 mm gap filled with the PCM and sealed at the ends, so each square meter of blind area contained about 17 kg PCM. To ensure a good sun protection performance, the PCM-filled slats were covered with a white fabric with a normal-hemispherical solar reflectance of 0.78 (Figure 2). Finally, the slats were attached to a rail that was fitted to the ceiling.

Figure 2: Polycarbonate blind with Delta®-Cool 28 (left) and blind covered with highly reflective sun protection fabric (right).

2.2 Ventilated cooling ceiling with PCM

The second system to be monitored was a rear-ventilated cooling ceiling with PCM. The system setup is depicted in Figure 3. During the day (cooling mode), the warm room air is cooled down by the PCM in the ceiling in circulating operation. During the night or when the environmental conditions are favourable (regeneration mode), cool outside air is driven over the PCM to regenerate it.

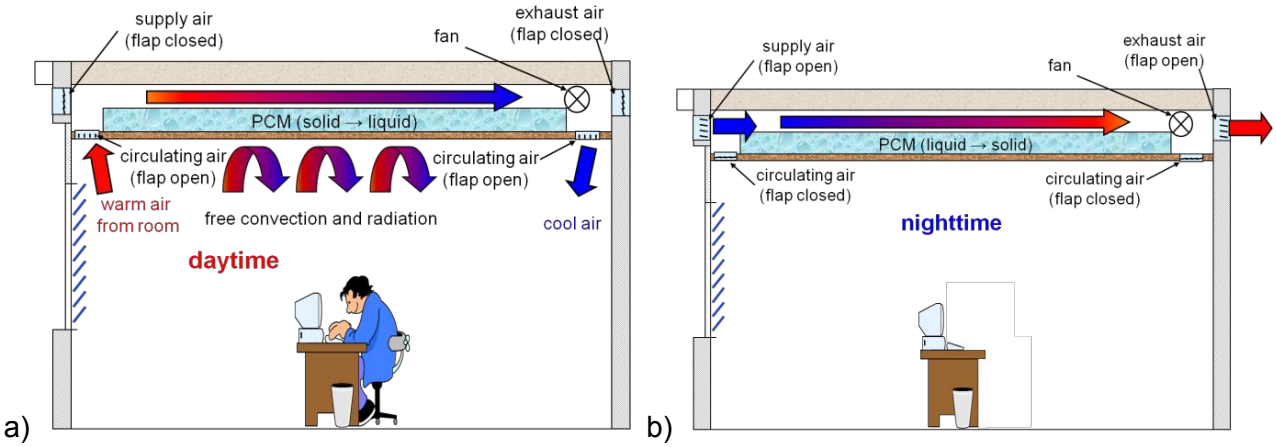

Figure 3: Cooling (a) and regeneration mode (b) of the ventilated cooling ceiling with PCM.

In a first step, laboratory measurements in a defined test room were made to investigate the system behavior and to get experimental data about the system performance [3]. It was found out, that the cooling power of the airflow alone was relatively small, but that a significant cooling power could be achieved directly through the ceiling. Due to these results, the volume flow rate of the air through the ceiling was designed to be as high as possible. Of course, the usual restrictions due to draft and sound protection applied.

3. Monitoring rooms and setup

3.1 Description of monitoring rooms

Four adjacent office rooms in the fifth floor of an office building in Karlsruhe, Germany, were available for the tests. The windows are oriented westward with a window area of about 50% of the outer façade surface. One room was equipped with the sun protection system with PCM, one with the ventilated cooling ceiling with PCM, and one with both PCM systems. The fourth, unmodified room without any cooling system was used as reference room. Each of the rooms was occupied by two people, and contained typical office equipment like computers and monitors. In spite of existing conventional exterior sun shading systems and interior vertical blinds for glare protection, all of the rooms had overheating problems.
In the two rooms with the ventilated cooling ceiling PCM boards were laid on top of the bearing for the suspended ceiling (Figure 4). The boards from the company Dörken were filled with DELTA®-COOL 24, a salt hydrate with a melting range between 24°C and 28°C and a melting enthalpy of 158 kJ/kg. The amount of PCM in each of the rooms was 6.5 kg/m^2. An exhaust ventilation system completed the setup (Figure 5).

Figure 4: Installation of the ventilated cooling ceiling with PCM. On the front left is the globe thermometer for measuring operative room temperature.

Figure 5: Motor-controlled ventilation flap (left) for nightly regeneration and exhaust-air ventilation system (right).

In contrast to the picture in Figure 3 b), it was not possible in the monitoring rooms to connect the air inlet for the regeneration mode directly to the suspended ceiling. Instead, the outside air entered the room via the ventilation flaps in the upper part of the façade and then mixed with the room air before it reached the PCM. This decreased the system efficiency for the regeneration process, but it could not be avoided due to structural requirements.

In the two rooms with the PCM sun protection system, the interior blinds were replaced by the PCM blinds (Figure 6) which had very similar solar optical properties [1]. To regenerate the PCM during the night, the windows could be tilted. In the room with both PCM systems, the regeneration process of the PCM in the blinds could also be supported by the ventilation system of the cooling ceiling.

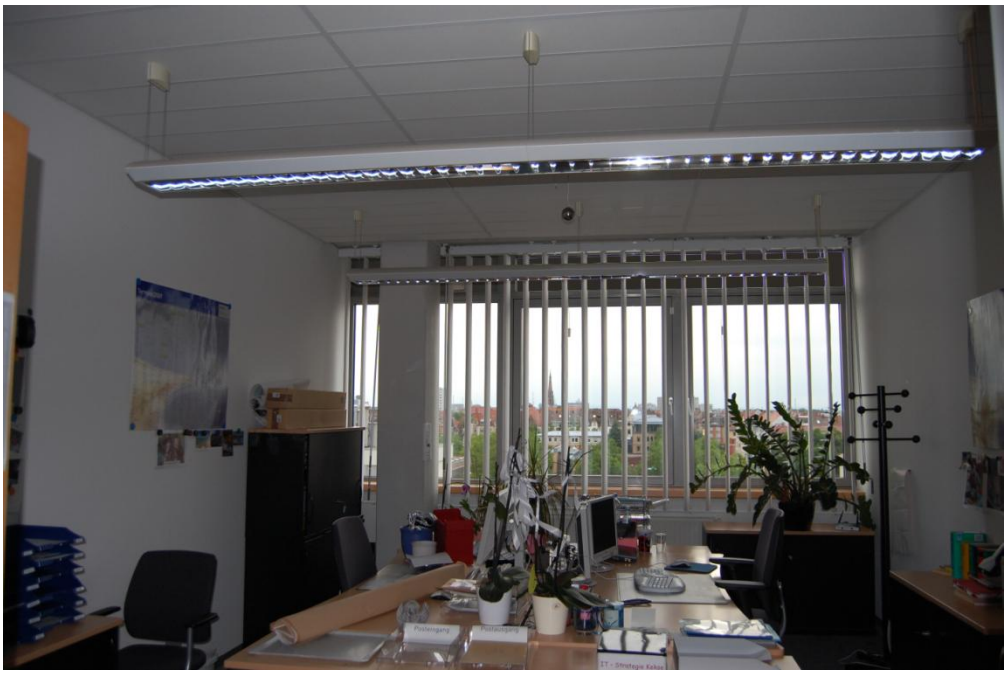

Figure 6: Office with PCM sun protection system installed as vertical blind.

3.2 Monitoring setup

It was found, that the user influence was quite big and made it impossible to extract the effect of the PCM systems from the measured data. To avoid this, measurements were performed during the weekends without any users. The internal gains were realized by electrical heaters with a constant power of 500 W between 9 am and 5 pm. The exterior sun protection system was not used and the windows were closed. The interior blinds were put at 90° (open position) for maximum view-through until the direct solar radiation reached the façade, which happened at about 2 pm. From then on, the blinds were positioned at cut-off angle in hourly intervals to get maximum view-through in combination with good solar shading. At the end of the measurement period, the blinds were turned to 90° again to achieve a good thermal coupling to the outside air for regeneration. The blinds were never retracted to the side.
In the rooms with the ventilated ceiling, the volume flow rate was set to 150 m^3/h (air exchange rate of about 2/h) during cooling mode and to 300 m^3/h (air exchange rate of about 4/h) during regeneration mode. The regeneration was time controlled and took place between 9 pm and 5 am with an additional temperature control, so the ventilation system worked only when the inlet air was cooler than the room air. The ventilation flaps in the façade were closed during cooling mode (purely circulating operation) and opened for the regeneration mode.

The data measured were the temperatures in the systems (at different positions on the PCM blinds and on the PCM boards in the ceiling), the inlet and outlet air temperatures in the ventilated ceiling, and the operative room temperature at a height of about 2.5 m. The cooling power of the air flow was calculated from the temperature difference between inlet and outlet air, the heat capacity of the air 0.34 Wh/(m^{3}K) and the volume flow rate.

4. Results

4.1 Ventilated cooling ceiling with PCM

Figure 7 depicts the measured operative room temperature in the office room with ventilated cooling ceiling with PCM and in the reference room as well as the system temperatures in the ceiling. As soon as the electrical heaters are turned on, the operative room temperature started to rise in both rooms. However, until 2 pm the temperature in the room with the PCM ceiling always stayed about 1°C colder than in the reference room. When the direct solar radiation reached the west facade at about 2 pm, the cooling effect of the PCM ceiling increased further with the maximum operative room temperature at about 32°C compared to 34°C in the reference room. The system temperatures in the ceiling show, that the PCM induced a temperature difference in the air flowing through the ceiling of about 2-4°C, which corresponds to a cooling power of 100-200 W. Since this is not enough to compensate the 500 W of the electrical heaters plus the solar gains, a significant cooling power has to be transmitted from the PCM directly through the ceiling construction. This could be validated by other measurements not presented here.

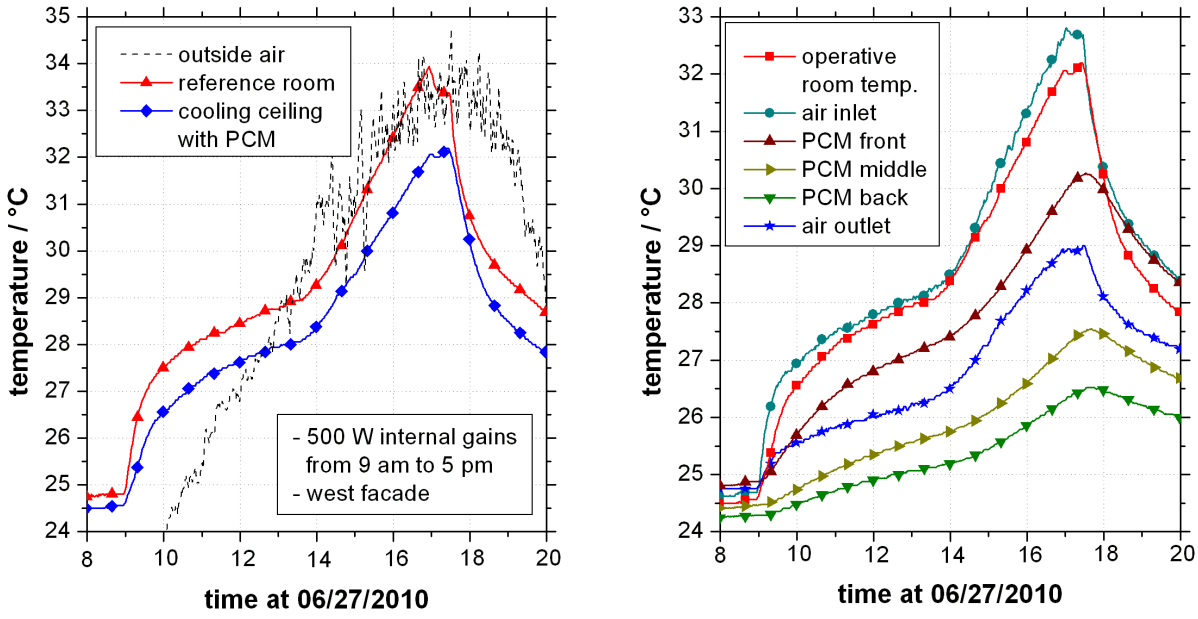

Figure 7: Measured operative room temperature on a warm summer day in the office with ventilated cooling ceiling with PCM and in the reference room (left) and system temperatures in the cooling ceiling (right).

The regeneration of the PCM in the ceiling was investigated for two scenarios:

- ventilation system on and windows closed,
- ventilation system on and windows tilted.

In both cases the PCM could not be regenerated completely during the night. However, this was mainly due to the fact, that the cool outer air could not reach the PCM ceiling directly, but mixed with the room air first.

4.2 Sun protection system with PCM

The measured operative room temperature in the office room with the PCM sun protection system and in the reference room as well as the system temperatures of the PCM blinds are depicted in Figure 8. The course of the operative room temperature in the two rooms was very similar until about 2 pm, when the direct solar radiation reached the west façade. From then on, the operative room temperature in the reference room increased quicker and reached higher maximum values than in the room with the PCM blinds. The PCM blinds reduced the maximum operative room temperature by about 2°C. The room side surface of the PCM blinds stayed quite cool (Figure 8 right) with maximum temperatures of about 28°C (the melting temperature of the DELTA®-COOL 28). Conventional inner blinds typically achieve much higher temperatures as can be seen by the temperatures of the air gap between blinds and glazing that reached maximum values of 38°C. Thus the PCM blinds help to improve thermal comfort for the inhabitants by reducing the radiant heat flow from the glazed part of the façade.

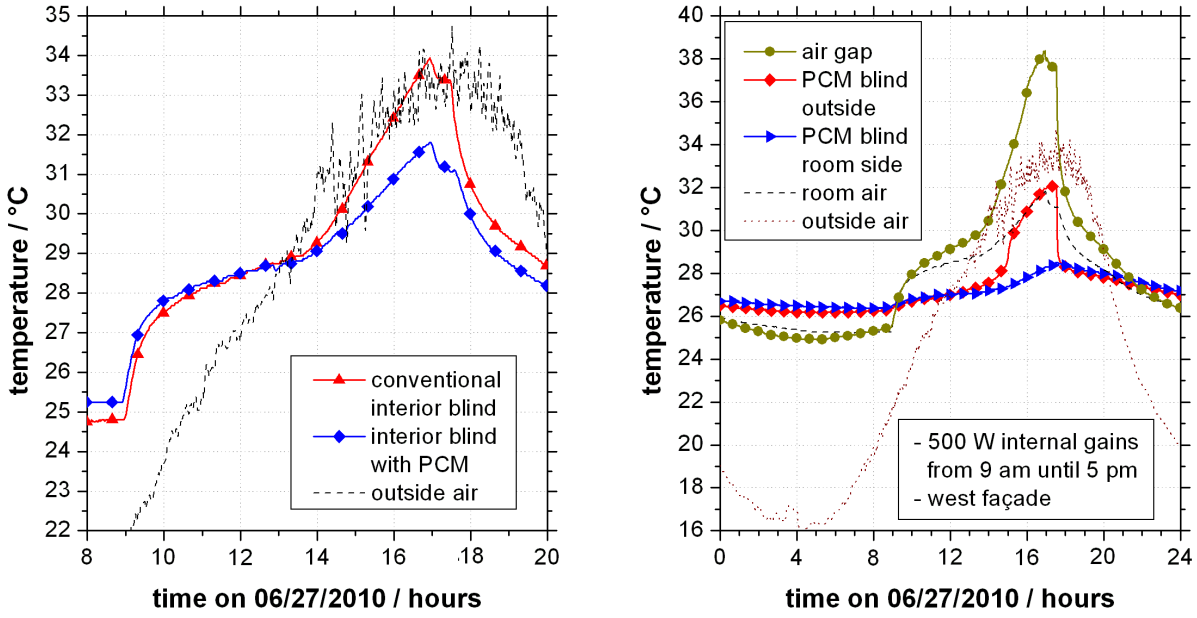

Figure 8: Measured operative room temperature on a warm summer day in the office with PCM sun protection system and in the reference room (left) and system temperatures of the PCM blinds (right).

The regeneration of the PCM in the blinds was investigated for three different scenarios:

- windows tilted without ventilation system,
- windows closed with ventilation system (ventilation flaps open), and
- windows tilted with ventilation system (ventilation flaps open).

Even with nightly outside air temperatures as low as 14°C it was not possible in the first and second scenario to regenerate the PCM completely. Only a combination of tilted windows and ventilation system achieved satisfying results.

4.3 Synergy effects

Possible synergy effects when using more than one PCM system were investigated in the room where both PCM systems were installed. For comparison, Figure 9 shows the measured operative room temperature in all of the four monitoring rooms. Without direct solar radiation (until 2 pm), the operative room temperature in the room with both PCM systems was quite similar to the temperature in the room with the PCM cooling ceiling. From then on, the cooling effect of the PCM sun protection system started to combine with the cooling effect of the PCM cooling ceiling. This re-

sulted in maximum operative room temperatures about 2°C lower than in the rooms with only one PCM system and almost 4°C lower than in the reference room.

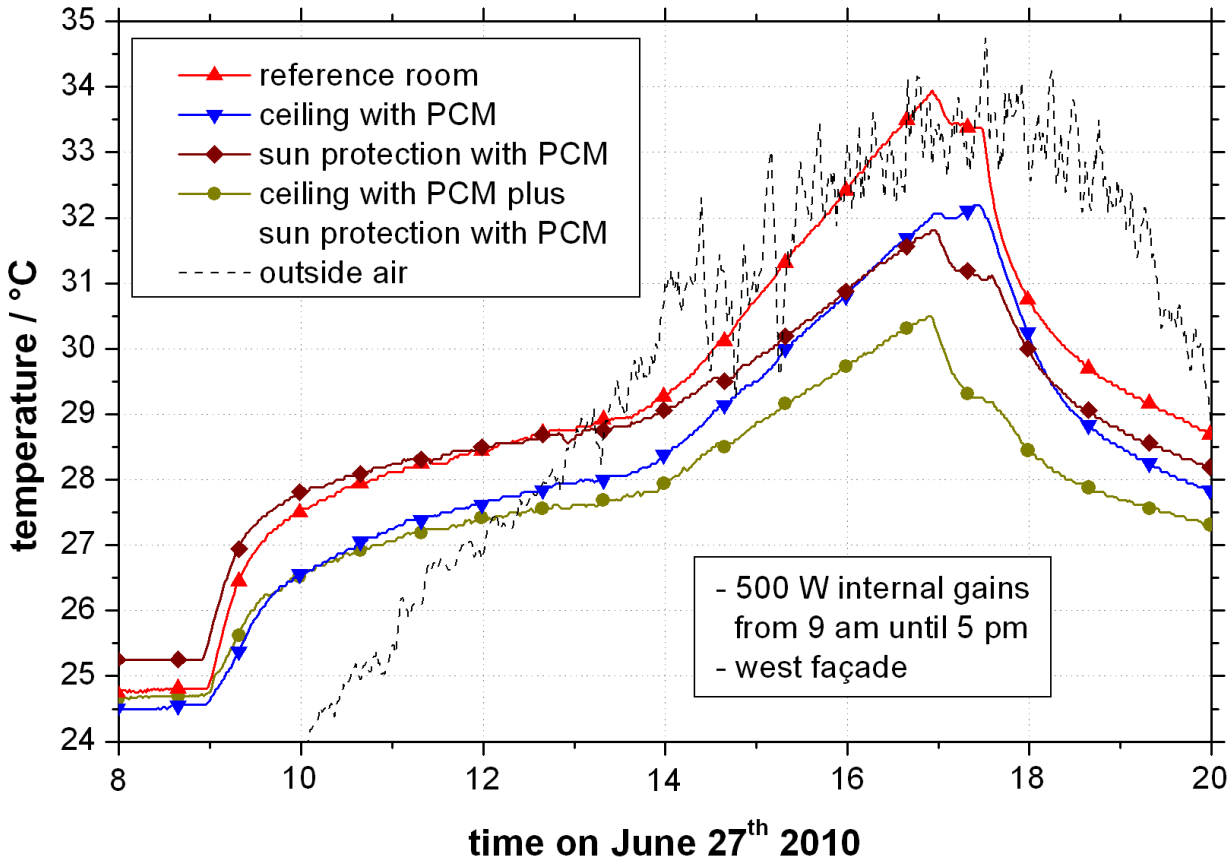

Figure 9: Measured operative room temperatures on a warm summer day in all of the four office rooms.

5. Conclusions and Outlook

The measurements showed that the two PCM systems investigated here - a ventilated cooling ceiling with PCM and a sun protection system with PCM - could reduce the operative room temperature significantly. While each of the systems worked well separately, a combination of the two systems showed considerable synergy effects, reducing the operative room temperature even further. However, the regeneration of the PCM by natural night-time ventilation only was a problem in the test rooms. For the PCM sun protection system the regeneration should be supported by a ventilation system, while for the cooling ceiling with PCM the outside air should be guided directly onto the PCM.
The results showed that PCM systems can be used for room cooling, but the setup and especially the regeneration of the PCM has to be planned carefully.

6. Acknowledgements

Extended Abstract

The built environment is a central aspect of daily human life. Building processes are also among the most cost intensive processes that we come into contact with. As for residential buildings, many people take 20 or 30 years, or even more, to pay back their home loans. Refurbishment of buildings is seen as a possible major contribution to lowering the impact of buildings on the environment [1] while being, ideally, economically promising and keeping the social identity of our built environment. On the other hand, regulations are often centered on the sustainability of new buildings [2], and there is a lack of regulations tailored to refurbishment [3]. At the same time existing buildings are seen as a key factor in local identity, and as a hub of socio-ecological development [4].
The EU funded BEEM-UP project (Building Energy Efficiency for Massive market UPtake) [5] has the goal to demonstrate the economic, social and technical feasibility of retrofitting initiatives for a 75 percent reduction in energy consumption in existing buildings, and lay the ground for massive market uptake. BEEM-UP involves key expertise to implement and demonstrate innovative building and energy management approaches with the overall aim to improve energy efficiency in existing buildings and obtain better indoor comfort conditions in three ambitious retrofitting projects. The main emphasis is placed on the economic and ecological life cycle assessment and comparison of the different projects and applied measurements in Sweden, the Netherlands and France. All projects are large-scale residential buildings with a focus on social housing, apartments and flats. All three sites are representative examples in the respective countries of building cohorts that are due for refurbishment.
One of the main goals of the BEEM-UP project is to compare the refurbishment approaches of the different countries, and to provide an exchange regarding related problems and solutions. For this purpose an ecological as well as life cycle cost assessment has been carried out for all three sites. For each site six refurbishment scenarios have been defined through intensive consultations with the building owners and other stakeholders, for instance tenants or tenant representatives. First preliminary results indicate that it is economically and technologically feasible to achieve 75 percent reductions in energy consumption for the existing building stock.
However, these preliminary findings point to institutional and social impediments that may not lead to massive market uptake in the social housing real estate community. Social housing institutions face distinct regulations and economic constraints, which can inhibit their uptake of energy retrofit policies [6]. On the one hand, national and EU wide policies nudge building owners towards basic energy-efficiency measures. On the other hand, institutional factors historically embedded into the social housing framework like rent controls and governmental rent subsidies inhibit a more equitable distribution of refurbishment costs between tenants and building owners. Moreover, discounted third-party capital is limited and subsidies at the national and local levels cannot

support the level of refurbishments needed across the housing stock.
However, there is economic value in energy-efficiency refurbishments of the building stock. An increasing number of studies document increased transaction values for buildings that are relatively more energy-efficient [7,8]. However, BEEM-Up has shed light on other sources of value at the property level. Namely, firms that have developed the product, process and organizational innovations associated with energy-efficiency retrofits could be financially more nimble and efficient in their housing portfolio relative to their non-innovative peers. In addition, there are more ways than transaction value and rental income to see the financial benefits of energy-efficiency. Alternate sources of income from renewable energy and even less explored financial benefits from taxation and depreciation that are currently linked to energy-efficiency investments are another source of savings for energy-efficiency that is far less explored. Thus, political and economic capital is required to shift institutions and firms towards an innovation mind-set to meet the needs of an ecologically improved building stock.

Full Paper

1. Introduction

Economic as well as energy and climate-political specifications require new criteria for the holistic modernization of houses of the era of promoterism (Gründerzeit). Innovative reconstruction solutions are on display in Vienna and are being evaluated from the point of view of economic efficiency, energy efficiency, legal framework and users' satisfaction using several demonstration objects within the scope of the research project "Günderzeit with future prospects". Present results have uncovered that a wide range of innovative and practically useful components are available for the comprehensive and highly innovative modernization of houses of the era of promoterism, with which historical buildings under favorable framework conditions, can also be converted to the nearly zero-energy or energy-plus standard.

Extremely strong external walls of solid brick masonry, road façades designed in a complex manner, often with stucco ornamentation, immense floor heights and wooden beam ceilings or massive arched ceilings above the basement as well as wooden frame windows with single glazing and room-kitchen layouts: these are the typical attributes of houses of the Promoterism era that were built between 1848 and 1918. Seen from the point of view of the available stock of promoterism houses in urban areas, the spectrum ranges from the multistory workers' residence in the suburban area – many with façades that have in the meantime, been cleaned-up – up until the palace of the era of promoterism at the center of the city.
All over Austria, there are more than 600,000 apartments in buildings of the construction era preceding 1919 thus making the ratio of the stock of promoterism houses in Austria a total of approximately one-fifth. In Vienna alone, there are about 200,000 primary residential apartments in this building segment. Of about 35,000 buildings that were constructed in Vienna before 1919, about 20,000 classical apartment houses make up promoterism in a narrower sense.
The sustenance and further development of this stock of buildings is therefore a central task confronting the residential and real estate sector in the face of the huge number of promoterism residential structures available and the strongly growing need for apartments. The reconstruction of buildings of the era of promoterism is realized virtually at the point of intersection of architectural and building-cultural issues as well as construction-related legal requirements for the attainment of binding energy and climate-political targets in conjunction with the search for adapted technical solutions that can be implemented in a user-adequate and cost-efficient manner.

The project "Gründerzeit with future prospects" that was launched in 2009 within the scope of the research and technology program *Building of tomorrow Plus* of the Federal Ministry of Transport, Innovation and Technology and will run till 2015, is committed to this assignment.
In addition to basic research work on technological, economic, legal and social-scientific issues, individual sub-projects stretch from component development up until the implementation of demonstration projects. Innovative reconstruction solutions will be developed on the basis of five demonstration objects that may be used as a model for houses of the promoterism era and

subjected to comprehensive power consumption and comfort monitoring.
The major objectives in the implementation of innovative measures are the improvement of living comfort, reduction of energy consumption, usage of more efficient and possibly CO_2-neutral heating systems, improvement of architectural quality and thereby, overall guaranty for a contemporary living standard. The prerequisite is, in any case, a sound static condition of the respective building since the measures required for the static retrofitting of the object – particularly in the event of a planned expansion of the attic – may by far, transcend all economic considerations.
Attention should be drawn explicitly to the fact that this is not about simply “wrapping up” houses of the promoterism era and thus “sacrificing” a central urban architectural building segment to a banal efficiency and modernization approach. On the contrary, the major challenge lies in developing innovative solutions for buildings of the promoterism era that are structurally adequate and technically as well as economically implementable.
The spread of the results – multipliable innovative reconstruction concepts that are particularly adapted to the conditions of the stock of promoterism buildings – will be realized amongst others, through the project website www.gruenderzeitplus.at.

2. Energy efficiency and technical solutions [1]

There is a widely held view that the energy-technical quality of buildings of the promoterism era is “not so bad anyway” given the “thickness of the solid brick walls”. This is correct only insofar as a building of the promoterism era has better average values than for instance, a non-reconstructed building of the 1960s. the fact however is that buildings of the promoterism era with a typical thermal heat need within the range of 120-160 kWh/m².a is “worse off” by the factor 5 to 10 than residential buildings that are newly constructed in accordance with today’s customary low-energy or passive house standard. By replacing windows alone, the energy performance of a building of the promoterism era can be improved by just 10 percent.
On the contrary, innovative reconstruction measures can translate into a thermal heat requirement of less than 30 kWh/m².a also for the stock of the promoterism era thus attaining a contemporary energy-technical standard.
It can also be justifiably argued that not all technical standards based on today’s criteria should be applied to historical buildings; this fact is also reflected in the Building Ordinances of the Federal States with numerous exceptional provisions for buildings with segmented façades, buildings in protected zones or monument-protected buildings. Practical examples however show that there are still enormous architectural and technical potentials lying dormant also in buildings of the promoterism era, with which excellent results can still be achieved even in relation to comfort and ease and that have so far, hardly been exhausted.

3. Legal challenges [2], [3]

Major legal questions in the reconstruction of buildings of the promoterism era arise in connection with the utilization of neighboring plots in the insulation of fireproof walls (minimum standard of energy vs. property), for sustaining side gaps and building lines (intrusion in the subjective rights of neighbors) as well as in respect to restrictions in monument-protected buildings and buildings in protected areas (public service restrictions).
While reconstructing the demonstration building in Wißgrill Alley, the huge number of detached fireproof walls particularly proved to be problematic because the installation of insulation on the firewalls requires the consent of the neighboring property owner. There can be no insulation without such consent – a delicate issue that was successfully resolved through high communication competence and creative offers. Even though detached fireproof walls do not constitute any architectural characteristic of buildings of the promoterism era, they may constitute up to one-third of the façade area. The insulation of the fireproof wall is thus compelling from the point of view of energy efficiency and living comfort.

4. Costs and Economic feasibility [1]

The decision on if and how a building of the promoterism era should be reconstructed depends largely on the costs of the measures implemented as well as on economic feasibility. From the point of view of the property owner, the user-investor dilemma – seeking to ascertain if the measures (window replacement, façade insulation, renewal of the heating system) associated with energy savings “pay off” – is of less relevance as a consequence; rather it is more relevant if a (higher) overall dividend can be achieved in the medium to long-term. In the process, not only will investment costs and attainable savings flow into the costs of energy, but also the usage of residential building promotion funds and finally also, tax-related aspects. Moreover, it is also customary practice to expand the attic in the reconstruction of a building of the promoterism era, which in most cases, finally enables the realization of positive overall proceeds. The reason for this is that tenancy-rights-related statutory provisions strictly regulate rents that can be charged. In case of reconstructed old buildings, reference value rent applies to fresh tenancy, and clearly higher rent can be charged for reconstructed attic apartments. Should residential building promotion funds be used however, only a so-called maximum covering sum can be charged for the term of the state loan; the tenant will then be paying back the complete costs of reconstruction; proceeds will be realized only thereafter.

5. Monitoring

To be able to make a clear statement on the actual performance of the building and the individually applied technologies, buildings must be subjected to a technical power consumption and comfort monitoring. In addition to the measurement of power consumption and comfort parameters, user-satisfaction and economic feasibility of the reconstruction measures can also be evaluated within the course of extensive monitoring. From the viewpoint of building developer and property owner, monitoring constitutes a significant instrument of quality assurance with multiple benefits. In addition to the high level of safety during initial operation and acceptance certification of the building, the constant optimization of operational management leads to a reduction of running expenses and thereby, to the improved rentability of the building. In addition to this, learning experiences that have been gained and facts acquired with respect to the behavior of the building will be used directly in future projects.
In the course of the leading project “Gründerzeit with future prospects”, documentation and the related monitoring will be done in line with Best Practice examples through a period of two years. For the first time ever, highly innovative reconstruction measures will be applied on promoterism buildings in the individual demonstration projects and subjected to attendant research works covering the following dimensions:

- Documentation of applied technical reconstruction measures particularly innovative measures on the building shell and the building equipment and appliances
- Documentation of the costs of the innovative reconstruction measures for investment and running operational management
- Monitoring of energy consumptions and central comfort parameter through two years including evaluation and the optimization of operational management
- Social-scientific attendance through survey conducted on residents (satisfaction with reconstruction particularly with the innovative measures implemented)
- Certification in accordance with the Building Evaluation system TQB
- Recapitulative evaluation and presentation of results, conclusions regarding further development of the funding of residential constructions

6. Demonstration buildings

6.1 Demonstration project Wißgrill Alley [4], [5], [6]

The first demonstration project was successfully completed already at the start of 2011. It is a comprehensive reconstruction including the expansion of the attic that was implemented by Ulreich Bauträger as property owner and building developer along with Gassner & Partner as General Contractor for planning and design.

Object Wißgrill Alley before and after comprehensive reconstruction and attic expansion (Photos: Ulreich, Gassner & Partner)

The building in Wißgrill Alley in Vienna Penzing was constructed at the turn of the millennium and thus belongs to the category of houses of the promoterism era. The object is in the direct proximity of a rail route and has a huge number of detached fireproof walls and a segmented street façade.
The holistic modernization of the building was at the forefront of the demonstration project to guaranty a contemporary living standard with high living comfort. The aim was to present a sustained system solution with the energy refurbishment of the old building and the highly efficient expansion of the attic, which shows reproducibility for a good number of houses of the promoterism era. A qualitatively highly valued reconstruction of the building could be realized through the implementation of the following measures:

- Joining of apartments for the realization of the contemporary concept of space
- Expansion of attic floor for the creation of additional utility area
- High insulation standard of all external structural components
- Renewal of all windows and doors
- Airtight design of structural component connections
- Integration of thermal solar panels in façade area
- CO_2-neutral thermal supply through pellets-central heating system
- Renewal of all supply lines through central access
- Application of efficient building equipment and appliances and external illumination with LED
- Draining of basement floor for the sustenance of the structural substance of building
- Roof integration of photovoltaic modules as isolated application for an attic apartment
- Automatically-controlled sunshade system on the attic floor
- Integrated greening on slanted roofs and flat roofs
- Creation of balconies and terraces in yard
- Area greening also spanning neighboring yard and designing of exterior space
- Erection of elevator within the building

Altogether, the thermal heat requirement could be reduced by more than 80%, it is approximately 30 kWh/m²a in the essential part, 17 kWh/m²a on the attic floor. The attainment of the target values could be confirmed through energy consumption monitoring.

The applied controlled inflow and outflow ventilation systems contributed significantly to the

efficient reconstruction through heat recovery. A reason for the decision to install the controlled ventilation devices was the location-related high level of dust and noise exposure due to proximity to the rail route. To generate facts for other construction projects, the building developer decided to also partially apply ventilation solutions without heat recovery in addition to devices with heat recovery to investigate impacts from a measurement-technical point of view. This facilitates the direct comparison of the performance of the individual ventilation variations.
Four different ventilation concepts that were captured from a measurement-technical point of view and are to be evaluated, were applied in Wißgrill Alley:

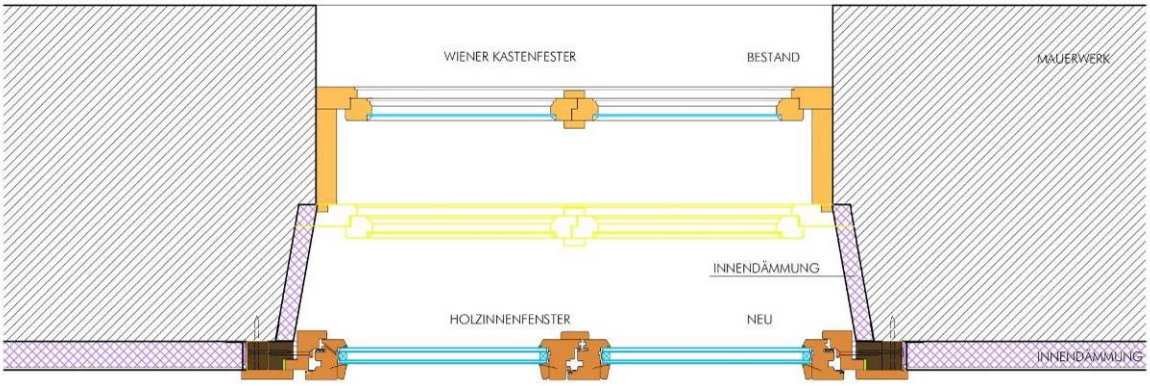
- Central comfort ventilation system for apartments in newly expanded attic floor and partly in the main part of the building
- Single room ventilation devices with heat recovery system
- Apartment-wise waste air facilities with window frame ventilation
- Window ventilation

As is well-known, the behavior of the user has the strongest impact on the comfort parameters CO_2 content and relative humidity, which provides information on the quality of ambient air. Yet the comparison of the CO_2 content of the 4 ventilation concepts applied shows clear differences. The CO_2 content in comfort ventilation ran quite constantly through the period of 3 months. Only a few measurement values exceeded the reference value in accordance with Pettenkofer of 1000 ppm. The measurement values of the remaining ventilation concepts are subject to a much higher band width and are constantly at a higher level. A tendency can be observed, towards a drop in the CO_2 content of the single room ventilation device and window frame ventilation during the months of summer. This is attributable to the additional length of time in which the windows are kept open when external temperature increases.

6.2 Demonstration project Kaiser Street

The reconstructed demonstration object in Kaiser Street of the 7th municipal district of Vienna is the monastery building of the Congregation of the Mission of the Holy Vincent de Paul (short: Lazarists). The planning and local building supervision was done by Architect Kronreif_Trimmel & Partner (Arch. Günther Trimmel). The building was erected in 1904 and is part of a square ensemble comprising a church and a residential building opposite the monastery. The complete ensemble is monument-protected. The reconstruction that was completed in May 2013 shows that a modern living standard is possible even upon compliance with the requirements of monument protection.

In addition to the thermal reconstruction of the roof truss, yard façade and fireproof walls and the application of a central ventilation system with heat recovery and particularly the installation of interior insulation and complementation of the box-type windows to be sustained by applying inward lying wooden window frames that are suitable for passive houses, can be highlighted as innovative reconstruction measures.



Square and Street view of Kaiser Street before and after reconstruction (Photo: AKP)

External insulation did not come into question in the face of the sustenance-worthy, segmented closer façade comprising small ceramic tiles. The thermal improvement of the building shell was possible only through the application of interior insulation.

The possible consequences of different interior insulation systems were highlighted, evaluated and examined for damage hazards. The major parameters for hazard assessment in the process were external impacts such as climate and exposure to driving rain, internal impacts such as interior air humidity and user's behavior and structural component-related impacts such as water absorption and water retention capacity and the diffusion behavior of construction.
Investigations carried out by the Construction Physics company Schöberl und Pöll using the software Ham4D_VIE of the Technical University of Vienna revealed a maximum insulation strength under conservatively assumed marginal conditions with capillary-active material of 2.5 cm for the long-term safety of the structural component.[7]
The structural-physical computations made by the company Xella Porenbeton were done using the non-steady computation program WUFI-Pro 5.0. According to the simulation, there will be no further rise in the water content of the brickwork in the following years at 8 cm interior insulation. The complete wall structure dries up in the dry seasons of the year and there is subsequently, no increased accumulation of humidity in the wall construction.
In the aftermath of the computations and experience reports, a 5 cm strong insulation system without diffusion barrier and with capillary-active mineral insulation board was applied.
To counter the uncertainties emanating from the structural-physical simulations regarding the maximum strength of interior insulation, the construction was subjected to permanent monitoring. Together with the Technical University of Vienna, the structure is monitored at different cross-sections within the scope of "Gründerzeit with future prospects" using measurement sensors integrated in the brickwork and the risks or eventual accumulation of moisture ascertained and evaluated.

Solution was worked out for the reconstruction of the monument-protected box-type windows in cooperation with the Federal Bureau of Monument Protection, in which the external wings the box-type windows are retained, maintained and refurbished. The interior wings are dismantled, the box extended and a wooden window suitable for passive houses and with 3-fold thermal protection glazing installed. The overall U-value of the window construction is specified by the window constructor as Uw= 0.9W/m²K.

Kaiser Street: Box-type window with interior insulation, old interior wing shown in yellow (Source: AKP)

6.3 Demonstration project Eberl Alley

Another demonstration object in Eberl Alley, 2nd District (Property owner: Kronberger, Planning: Schöberl&Pöll) is to go down in the history of refurbishment in Vienna, as the first house of the promoterism era that is reconstructed in compliance with passive house standard. The house that

was erected in 1888 was badly damaged in 1945 after being struck by a bomb and was reconstructed in the year 1952. The windows overlooking the street were replaced by plastic windows in the seventies. The peculiarity is that reconstruction is performed in cooperation with all tenants and can be implemented without renting-out.

Pilot Project Eberl Alley: First reconstruction in Vienna in passive house standard (Photo: Kronberger)

Since no building of the promoterism era has ever been reconstructed as passive house all over Austria, the project commands a high demonstration value. The reconstruction of the façade to passive house quality and the installation of passive house windows and doors as well as the high quality insulation of the ceiling of the lower floor stand out as major actions undertaken. Moreover, an additional living room was created in the course of expanding an attic floor. The reconstruction contains the renewal of the complete building equipment and appliances and electro-technical equipment including conversion to energy-efficient lighting system. A groundwater thermal pump and a photovoltaic facility were installed for the supply of heating.

Eberl Alley: Groundwater thermal pump and extraction well

A reduction of thermal heat needs by more than 90% was attained through the measures adopted. The energy balance sheets of the building show that the designated reconstruction measures

achieve passive house standard on one hand while immense energy savings are generated on the other hand. With innovative refurbishment measures implemented and adequate power supply put in place, the overall assessment of energy indicates that savings in excess of 80% can be realized specifically in relation to thermal heat needs, energy needs, primary energy needs and CO_2e emissions!
In addition to the positive ecological impacts, modern living standard can be created by increasing thermal comfort and reducing energy consumption following the implementation of the innovative package of measures.

6.4 Demonstration project David‘s Corner [8]

The ensemble of three buildings of the promoterism era in Vienna Favoriten forms the corner of a typical perimeter block development. But for a few exceptions, the 34 residential units were still in their original room-kitchen configuration. Altogether, the three buildings including the 5 business premises on the ground floor have a utility area of 2,350 m². Two objects have a cleared façade, one object, a fully preserved segmented façade. The objects were in a state that strongly requires reconstruction (moisture, leaking roof, leaking windows etc.). With warehouse halls covering most of its area, the yard was in a desolate situation. The thermal heat requirement of the 3 objects before reconstruction was about 121 kWh/m²a, heat supply was realized through gas converters, while hot water preparation was realized through electrical storage heater in individual apartments.
The buildings are owned by Condominium Immobilien. After a long planning phase, the project is being implemented by Bluewaters, the real estate trustee chancery Dirnbacher, Treberspurg & Partner Architekten and Imoplan ZT for building equipment and appliances. Completion is scheduled for 2014.

Ensemble David‘s Corner, Yard view in accordance with planned reconstruction (Photo, Graphics: Bluewaters)

At the center of the project is the joint development of all three objects. In addition to the restructuring of the yard that will also span neighboring plots and the joining as well as redesigning of the residential layout plans, thermal optimizations make up all external structural components, the efficient expansion of the attic floor and the joint house service facilities-related development of the ensemble make up the peculiarities of this demonstration project. A controlled living room ventilation system is applied with heat recovery in combination with central heating supply with low temperature heating system supported by a solar-thermal facility. The thermal heat requirement can be reduced by factor 5 through the refurbishment measures adopted.
The implementation of the overall concept shows that a highly grade energy-related refurbishment is not only technically feasible with the availability of the respective large utility area but also economically feasible in non-profit yielding locations.

Short Summary

Paper deals with energy demand calculations based on stochastic principles. This allows for the use in very early stage of the design, because there is not necessary to wait for complete set of input data. At the same time, such calculations can be used for quick analysis of larger group of building having their main parameters within given range. Overall tendencies, possibilities of refurbishment etc. can be evaluated from the calculated results.

Keywords: Integrated building design, energy demand calculations, stochastic approach

1. Introduction

In principle, at least two different approaches in calculation and interpretation of theoretical energy demand of buildings can be identified. For the first approach, very detailed multi-zone and dynamic models are used, with the best possible description of all parameters, detailed information on building use, local climatic data etc. for one studied building. This is very useful especially for research on new technical systems, for analysis of measured data and for detailed performance estimation. Large amount of input data is needed.

At the same time, it seems to be necessary to have an instrument allowing the observation of the problem “from above” by slightly simplified calculation, but for larger group of buildings. This approach is suitable for overall assessments, for studies on tendencies in particular typological group of buildings, for setting of targets and policy making. Such approach can be used as a real design supporting tool as well – advantageously in one package from the very early stage of the design to final delivery of the project.

2. Procedure and input data

The core model remains in all studied cases identical, based on usual procedure according to international standard [1] The calculations using steady state monthly method are repeated automatically for large amount of combination of input data (typically several hundred up to thousands). Stochastic principles for selection of input data and for expression of the results are used [2].

In general, all input data can be set in different modes:
- exact value, if available,
- reference to standard or legislative requirements (upper limit or lower limit, as interval),
- most realistic default values created automatically within the software tool.

The results are expressed in the form of statistic evaluation of all calculations done for generated data sets (overall distribution, minimum and maximum for 90% of results, mean value, probability of reaching usual targets). A sensitivity analysis can be used for "fine-tuning" in the next step of the building design.

3. Examples

3.1 Thermal transmittance requirements

Example 1 represents the simplest use of this type of calculations. Discussion about future target level for mean value of thermal transmittance of building envelope was based on such results. Method of reference building [2] was used considering following value of thermal transmittance: wall 0,30 W/(m^{2}K), roof 0,24 W/(m^{2}K), windows 1,50 W/(m^{2}K), slab on the ground 0,45 W/(m^{2}K). Fig.1 illustrates clearly that setting of one constant limit only is not an optimal option. The effort for reaching of such targets differs by different group of buildings.

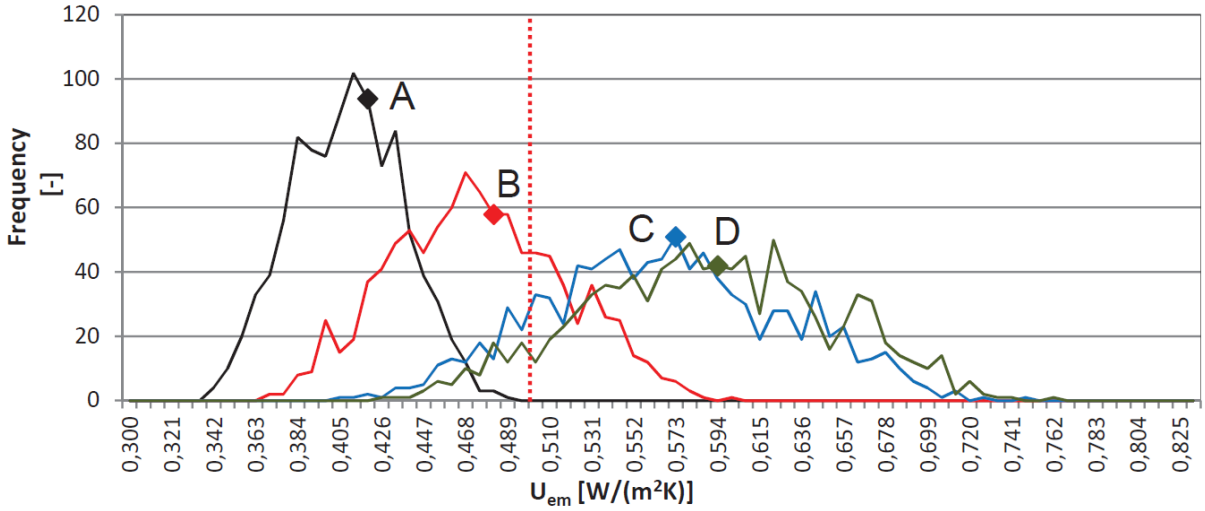

Fig.1 Distribution of mean value of thermal transmittance of building envelope (U_{mean}) for 4 types of buildings: small (A) and large (B) family houses, small (C) and large apartment buildings (D). U_{mean} = 0,5 W/(m^{2}K) represents the discussed requirement. Each curve represents results for 1000 combination of input data according tab.1.

Tab.1 Main input parameters for calculation in example 1

	Type	Built volume [m^3]	Number of floors	Fenestration ratio (differs per facade orientation) [%]
A	Small family house	240 – 560	1	5–35
B	Large family house	400 – 1 000	2–3	5–35
C	Small apartment building	1 500 – 6 000	4–7	10–50
D	Large apartment building	3 000 – 15 000	7–10	10–50

3.2 Space heating demand

Fig.2 brings overall information on apartment buildings with the built volume 5 000 m^3 – 8 000 m^3) having required value of thermal transmittance [2] by all building components. No data about building geometry was known. Different information was available on heat recovery from ventilation air and about number of inhabitants.

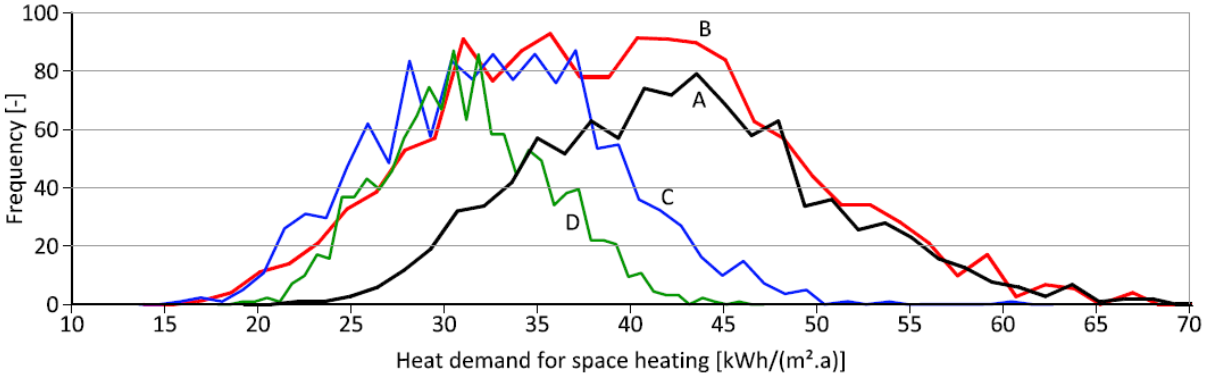

Fig.2 Comparison of heat demand for space heating of middle size apartment buildings with required values of thermal transmittance [2]. In cases A, B, C no information about building geometry, orientation, compactness, fenestration ratio, shading and number of inhabitants was available. Following values were considered more exactly in case D: Built volume 6500 m^3, number of inhabitant 45. Overall efficiency of heat recovery from ventilation air was considered as follows: A no recovery, B no information about heat recovery available which means the efficiency varies from 0 % to 70 %, C and D: efficiency 70 % exactly.

3.3 Refurbishment targets

The stochastic method was used to analyze the energy saving potential of refurbishment of middle-size apartment buildings. This set of virtual buildings is characterized by simple cubic form, built volume in the range 5.000 m^3–8.000 m^3 and 4 to 8 floors. The compactness level varies in the range 1,0–1,2. Compactness level is defined here as the ratio of the area of vertical part of building envelope to its possible minimum for given geometry. The dimensions are created automatically within the given parameters for each round of calculation. Fenestration ratio is considered for each façade orientation as follows: S 35 %, W 25 %, E 25 %, N 20 %. The number of inhabitants is determined indirect as 35 m^2/person.

The stochastic energy demand calculation was performed for the existing stage and for different levels of refurbishment (Tab.2) in 1.000 plausible combinations in each case. The results are presented in Tab.3 and Tab.4. For the first two refurbishment levels (envelope upgraded to today's requirements or recommendations, respectively [3]) natural ventilation is expected. Mechanical ventilation with heat recovery is planned for higher levels of refurbishment. Level 04 contains components suitable for passive house level. Only level 05 expects the change of layers in floor slab (mostly very costly and complicated operation). The generated geometry of the overall sample of buildings is characterized by a mean value of A/V (surface area/volume) 0,37 m-1 and a mean value of floor area 1.980 m^2.

Tab.2 Basic data on energy quality of virtual apartment building in Example 3

Altern.	Thermal transmittance U [W/(m^2K)]				Heat recovery efficiency [%]

Tab.4 Space heat demand and potential for its reduction evaluated from mean values for buildings in Example 3

	Exist.	01	02	03	04	05
Space heat demand per capita [MWh/(pers.a)]	5,5	2,0	1,6	1,1	0,8	0,6
Reduction of space heating demand [MWh/a]	----	177	194	222	237	244

4. Conclusion

The described method has a large potential for further development by increasing of building typologies, by setting default values for different climatic conditions. A simplified but correct estimation of cooling energy demand would be welcomed as well. For educational purposes and for wider use a computer tool with simple dialog via internet was already prepared [4]. It enables quick evaluation of space heat demand, in each case based on 1000 combination of input data for studied apartment building (or group of buildings). Similar approach could be effectively used during evaluation of applications for public support of energy advanced solutions. This approach was used [5] for overall estimation of total costs (investment + operation costs in 30 years) for apartment buildings in the discussion about cost-optimum level requirements [6].

CESBA – a collective initiative for the new building culture in Europe

Markus Berchtold,
Managing Director of
NENA Network

markus.berchtold@nena-network.eu

Andrea Moro
iiSBE Italia President

andrea.moro@iisbeitalia.org

Short Summary

CESBA „Common European Sustainable Building Assessment“. is a collective initiative for the new building culture in Europe. To reach the EU 2020- goals a common, regional adaptable, mass-oriented approach is needed. CESBA as a bottom up policy harmonization process by project partners from several transnational EU-projects and delivers a framework for this highly political course. Join CESBA on http://wiki.cesba.eu/.

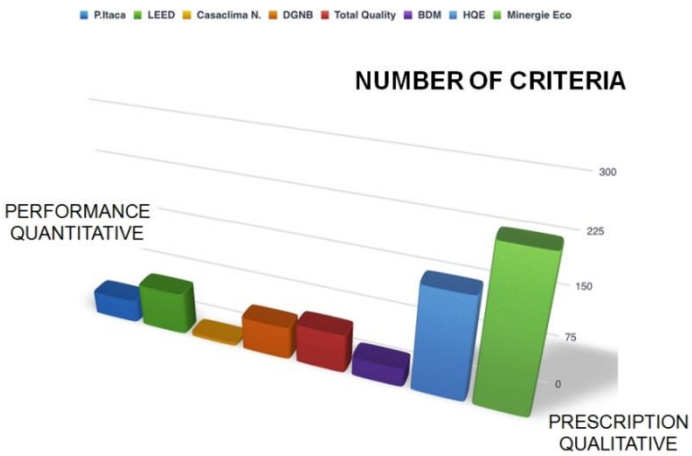
Keywords: CESBA, building culture, building assessment, Europe, bottom up process, open source, NENA-Network

1. CESBA – a collective initiative for the new building culture in Europe

The building sector is a cornerstone of the EU climate protection program and has an important role to play in the achievement of the Europe2020 strategy, in particular in relation with the flagship Initiative “Resource efficient Europe”. The significance of the sector is illustrated by the fact that the construction market accounts for 10% of GDP in the EU and that construction and use of buildings influence 42% of energy consumption and about 35% of greenhouse gas emissions.

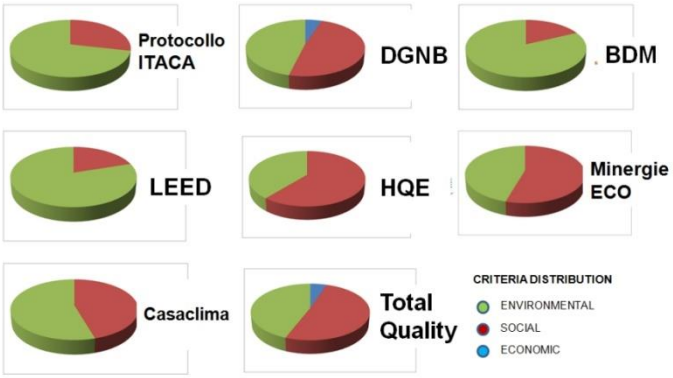
Further buildings play a central role in our societies, providing places to live, work or enjoy leisure activities. They are the basis of our urban environment, impacting the social, economic and ecologic aspects of our lives. Indeed, our health, comfort and safety as well as our economy and our natural environment are strongly connected with the construction sector activities.

Building culture is not only defined by the sum of certain quality indicators. The processes including certification, training and assisting services along the whole building life-cycle are significant parts too. However, the plethora and mismatch of building regulations at EU and national levels leads to considerable administrative burdens, confusions among the actors and to a very fragmented sustainable construction market.



2. Toward the harmonization of sustainable building assessment

Since the launch of the first environmental building assessment system in 1990 (BREEAM), the number of labels and certifications in Europe has proliferated, in particular in the last period.
A transnational survey and comparison of the existing sustainable building rating systems available in Europe has been carried out in the context of the Interreg projects Enerbuild (Alpine Space) and IRH-MED (Med). The surveys showed that more than 60 different assessment systems are



available at local, national and international level but also that they differ in many important aspects. The main consequence of the absence of a common approach is the impossibility to compare the assessment results produced by the different tools. Consequently the scenario seems very confused.

The main critical issues that emerged from the study are:

- very different frameworks of the assessment tools;
- different assessment methods: coexistence of performance based and strategy based tools;
- different number and type of issues included in the tools;
- different ways to score the performance.

Different number of criteria in some of the main certification systems

Different distribution of criteria among the key issues: environmental, social and economic

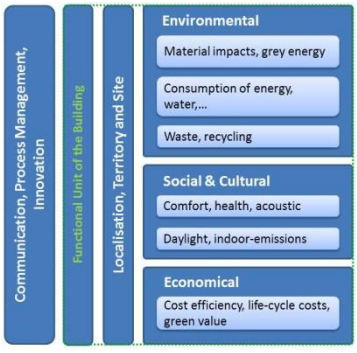
These substantial differences between the assessment systems are not facilitating their wide diffusion at the European level. Common public policies and common market actions would need a common approach. The first steps toward the needed harmonization of the sustainability certification systems should be:

- to define common principles regarding building sustainability certification;
- to define a core of common criteria and indicators that would allow a comparison between the performances of buildings certified with different labels.

The first point concerns the need to agree for instance about the sustainability issues that should be taken in account, the assessment methodology, the contextualization procedures and the structure of tools. The second point means that it would be necessary to identify at European level a common set of key criteria (and relative indicators) that should be adopted by the national/regionals labels in the way to allow the comparison of buildings performance.

To reach this objective the CESBA framework has been launched starting from the clustering of several EU projects that have addressed the issue of sustainable building assessment harmonization: Enerbuild, AlpBC, CABEE, Marie, IRH-MED, CEC5, OpenHouse, SuperBuildings. The idea is to implement a common platform between the European regions with the objective to follow in the definition of a common approach to environmental building certification and to promote the harmonization of certification systems.

The core of CESBA initiative will be the common European set of assessment criteria for sustainable building. The aim is to establish a shared least common denominator for the rating systems used in Europe, in the way to make possible a comparison between the labels and to have a common understanding of environmental, social and economic priorities. More specific set of criteria, context based, will also be defined at macro-regional level (Alpine regions, Mediterranean regions, North regions, etc) and at regional level.



3. CESBA – Common European Sustainable Building Assessment

The development and implementation of new standards require synergic actions and initiatives. Current building assessment tools not only have variable elements including structure analysis, assessment methodology, and the identification of variable impact issues but also use different scoring methodologies. This lack of conformity makes comparison of results difficult. A harmonization is needed.

The participation of the civil society is essential in the bottom-up approach of generating common mass-oriented, open-source building sustainability assessment guidelines as well as in the establishment of building standards for the constructing of building stock itself. The system of analysis that describes the sustainability quality of buildings must be transparent to the layman.
As Europe is a mélange of regional building cultures European buildings standards must be open to regional needs and circumstances.

CESBA discuss and unites following aspects of future building culture:

1. Quality indicators to measure the quality of the building processes and the achieved quality standards. These indicators consolidated in the following framework, which goes along with the suggestion done by CEN/TC 350 and 6 European projects:

2. Integration of all aspects of the building life cycle: Services, Trainings and Certification processes for all aspects along the building life cycle. Purpose and target setting, design tendering, Planning, Procurement, Implementation, Commissioning, Monitoring / Usage.

Performance indicators can play an important role in all the life cycle stages of a building and for different key users. Investors and developers can use them to define the performance targets. Public organizations in defining the tenders for Green Public Procurement. Professionals as guideline in the design phase and comissioning. In the use phase the indicators allow to understand if the building is correctly managed.

The adoption of shared common reference indicators by building certification systems, training organizations, consultancy activities, etc.. will facilitate a common approach at European level toward sustainable building. This would help the fulfillment of the EU objectives in this field.

4. The “Mass certification” approach

One of the main intents of CESBA is to promote the mass certification of public buildings firstly, and private buildings as next step. To reach the objective of 100% of buildings certified, it is necessary to adopt assessment systems that follow some key principle:

- regional contextualization. The assessment systems must reflect the local environmental, social, economic priorities. This has to be reached adopting an opportune weighting system of criteria;
- open source. The framework will be developed with the contribution of all the stakeholder in building sector. A shared framework has a better opportunity to be accepted and to reach a wide diffusion;
- use of local technical standards. Professionals are usually trained about energy calculation methods adopted locally and that are used in the mandatory energy certification. The request to perform calculation using technical standards used or developed in other countries or regions could be a barrier to the diffusion of building assessment;
- time effective. The assessment process has not to request too many time resources. For this reason the mass oriented assessment systems shouldn’t include a large number of criteria, focusing on the assessment on the key ones;
- low cost. The overall cost of the building assessment and certification process should be not expensive. High cost are a major barrier in the diffusion of environmental labels.

These characteristics are more used for the assessment systems promoted by public organizations and usually applied in tendering, incentive based policies and building regulations.

5. Next steps for CESBA:

1. Defining and collecting front runner projects and activities in all parts of CESBA, establishing an open source knowledge-hub - http://wiki.cesba.eu/. The wiki approach will facilitate the increase of the CESBA framework trough the contribution of experts all around Europe;

2. Holding follow up meetings and open exchange among all stakeholders – common CESBA Sprint Workshop http://www.cabee.eu/events/. Exchange and interaction between the stakeholders is considered a priority in the CESBA process. CESBA is a multi-user framework that intends to be used by all the stakeholders in the building sector;

3. Structuring the collective process (CESBA task force, regional CESBA contact points). CESBA is characterized by an open source approach. This means that it is requested the collaboration and contribution of the collectivity that will be reached by means of the establishment of local contact points.

4. Further political engagement of all kind of stakeholders including civil society. To reach the objective of adopting a common approach to sustainable building assessment is fundamental to obtain the political sustain of the stakeholders. For obtaining it, specific actions will be implemented to disseminate the CESBA open source approach.

5. Promotion and collaboration activities JOIN CESBA - http://wiki.cesba.eu.

Human Scientific Factors to Enhance Life Cycle Sustainability of Housings

Dr. DI Harald Deinsberger-Deinsweger
CEO Wohnspektrum - Housing Research & Analysis
Austria
Lecturer at TU Graz, Carinthia University of Applied Sciences, Austrian Academy of Psychology, Danube University Krems
deinsberger@wohnspektrum.at

Short Summary

The presented work is dealing with psychological and physiological contributions to enhance the performance of blue, green or smart housings and dwellings.

Based on scientific research results the main goal of the work is to define ways of enhancing the life cycle sustainability of housings by considering the human quality factors.
Another task is to explain the thesis that sustainability without humanity is an insufficient goal and with regard to housing structures hardly realizable.

Within the paper a scientific methodology (Research Report Part I) will be presented which is able to analyse precisely the human quality of housing projects. It comprises all essential factors which are relevant for the performance and acceptance of buildings from a human perspective. The topic will be explained in the form of real projects and respective research results (Research Report Part II).

Keywords: life cycle sustainability; housing; human quality; housing psychology; housing physiology; housing theory; housing quality analysis

(A) Introduction and Correlations

The **main thesis** of this work implies that humane building leads sustainable building. Concerning housings we can state, that without humanity there is of course no social, but also no economic, nor ecological sustainability possible at all.

This thesis can preliminary be explained (illustrated) by mentioning at least three correlations.

(1) Prolonging the duration of use and the life cycle endurance

There is one main causal connection to be considered: The higher the human quality of residential buildings the longer and more intensively they will be occupied on average.
Usually the by far biggest amount of resources and energy has to be spent during constructing buildings: It starts with the production of raw materials, the manufacturing of building materials, the fabrication of structural elements and components used for constructing houses. Next all these materials and products have to be transported to the building plot and at last the construction of the building itself. Understandably the whole procedures need lots of energy and resources. If we

take into account the whole life cycle effort of resources and energy, it becomes immediately clear that this initial stage of a buildings life cycle requires the by far biggest share.
Further high peaks of energy and resources effort are usually phases of reconstruction or remodelling. The final peak of a buildings life cycle is reached when demolishing and disposing the materials. Perhaps in a further step a new building will be erected and the life cycle starts again.
The longer the period between erection and demolishing the less resources are spent on average per year. The more years of occupation the lower the average amount of spent resources and energy.
Of course the ongoing consumption of energy (heating, cooling, electricity etc.) is of importance as well as the sort of used materials. But independently from this the duration of buildings "life" remains as one main (and often not fully recognized) factor of life cycle sustainability which used to be frequently underestimated or not even realized in its whole momentous context.

The duration of buildings existence usually depends on two major qualities: the technical/material/physical quality and the human quality.
As we all know the physical quality depends on the used materials and the structural engineering.
But what does the human quality rely on? That is depending on physiological, psychological and social factors (see below). What we can state in advance is that, the higher the human quality or living quality of a building the longer it will tendentially be used, the less often it will be reconstructed or remodelled in order to meet the human needs or even demolished and built new - which of course is related to the highest waste of resources and energy.
The longer the period of occupation, or more specifically the longer the period between constructing and reconstructing or demolishing the higher is generally the impact on life cycle sustainability.

(2) Reduction of urban sprawl and splinter development / dispersed settlements

The second aspect concerning sustainability and human housing quality is dealing with the topics urban sprawl and uncontrolled settlements in the open country - the so called dispersed settlements.
It is well known that dispersed settlements from an ecological point of view used to be highly problematic. First of all they produce much more traffic compared to compact settlements; second, the whole infrastructure that has to be build and maintained in order to reach every single house is enormous; third, they also usually need much more resources and energy during building and occupation; and so on. So this form of settlement used to be on principle not very sustainable at all.
But what has this got to do with housing quality?
The less quality high density housings are able to provide, the more often people tend to built their own "sweet" home out in the country. In order to prevent dispersed settlements we have to construct buildings of high living quality in higher density areas. Consequently we may reach the point that wishes to change the habitat do not come up in peoples minds that easily.

(3) "Leisure escape" from cities

The lower the habitation quality of housings plus surroundings used to be in cities and in high density areas, the stronger the intentions of people to leave the place any time they are able to. Human beings are usually looking for places which fit to their natural needs and which are offering some recreational values.
So some people seek to build or buy a second home close to nature if they can afford it. Some people are renting their little green spaces or allotment gardens where they can stay near the city. In Austria and parts of Germany such spaces are called "Schreber-Gärten". In Russia and eastern Europe the so called datchas are very common for the same reason. Usually a datcha is a small weekend house with a little garden around. Similar trends can be obeyed in many regions all over the world.
All these trends lead to the same consequences: They produce more traffic and also a higher consumption of energy and resources. And all these trends have the same purpose: to

compensate the deficiencies and errors of urban housings and housing developments.
If a residential area is able to provide a high habitation quality and additionally some recreational effects, the inhabitants would have less reasons to escape from their home at any spare time. And they would of course have less reasons to build or buy a second home in the nature, too.

Intermediate Conclusion

The term habitation quality or human quality reveals as one of the major factors for the sustainability of buildings and settlements. If we disregard the human quality factor in its whole momentous impact, the topic sustainability of housings can hardly be reached.

Concerning traffic and housing there are two studies recently published [1], [2] dealing with the connections between individual mobility and housing.
These studies are posing very clearly, that certain forms of housing produce either more or less individual motorised traffic. In very dispersed regions the level of motorisation is the highest. (Which means the number of motorised vehicles per 1000 inhabitants is the biggest.) This context is not a big surprise but there is another result which is very remarkable concerning the entire energy consumption of a family household including everything: heating/cooling, electricity etc. plus traffic. If one compares the overall energy consumption of a so called low-energy-house with car to an average standard house without car, the latter features a much more better performance.
Types of settlements where people need at least two or more cars are much less sustainable even if the buildings themselves were constructed in a sustainable way. As a first main conclusion we have to develop types of housings and settlements where people don't need cars or even do not have the desire to use them very often.
Other results of the studies show very clearly, that dispersed settlements require an outstanding higher amount of infrastructure concerning not only streets but anything else like electricity, water supply, wastewater disposal and so on. The effort is not only higher when constructing all the infrastructure but also during the whole life cycle for maintaining the infrastructure and keeping it in appropriate condition.
So what shall we do now? Shall we force people to live in high density areas? Despite the fact that this would not be very humane it would not be very effective too - because of (3).
It would be much more effective to develop housings and settlements of high density plus high habitation quality where people like to live and where they do not have the desire to escape anytime they can, where they are encouraged not to use cars but other forms and means of locomotion.
As a summary we can state that high density without high human quality is senseless and sometimes counterproductive.

If we consider the results of (1), (2), and (3) we can conclude that it all mainly depends on one central term - the human quality of housings. Therefore the first step ought to be explaining the "human housing quality", which has been done during the theoretical and empirical research presented in this paper.

(B) Research Report Part I: Housing Theory and Science

(B1) Background and Problem Definition

The theoretical research dealt with the exploration of the scientific basics for designing and analysing human living spaces (=human habitats). During the research an overall theoretical conception - a **theory of human habitat systems** (shortly 'habitat theory') [3] has been developed which is able to comprise the complex systemic interconnections between human being, dwelling and housing environment. The term 'habitat' includes in this context the whole living space related to housing: dwelling plus interior as well as exterior areas (green spaces, balconies, terraces etc.) and the immediate surrounding field.
The main aim behind was to generate a comprehensive theoretical conception which indicates profound conclusions for conceiving housings close to human nature and needs, based on

stringent scientific fundaments.
From the theoretical perspective there is a deep gap between architecture and human sciences.

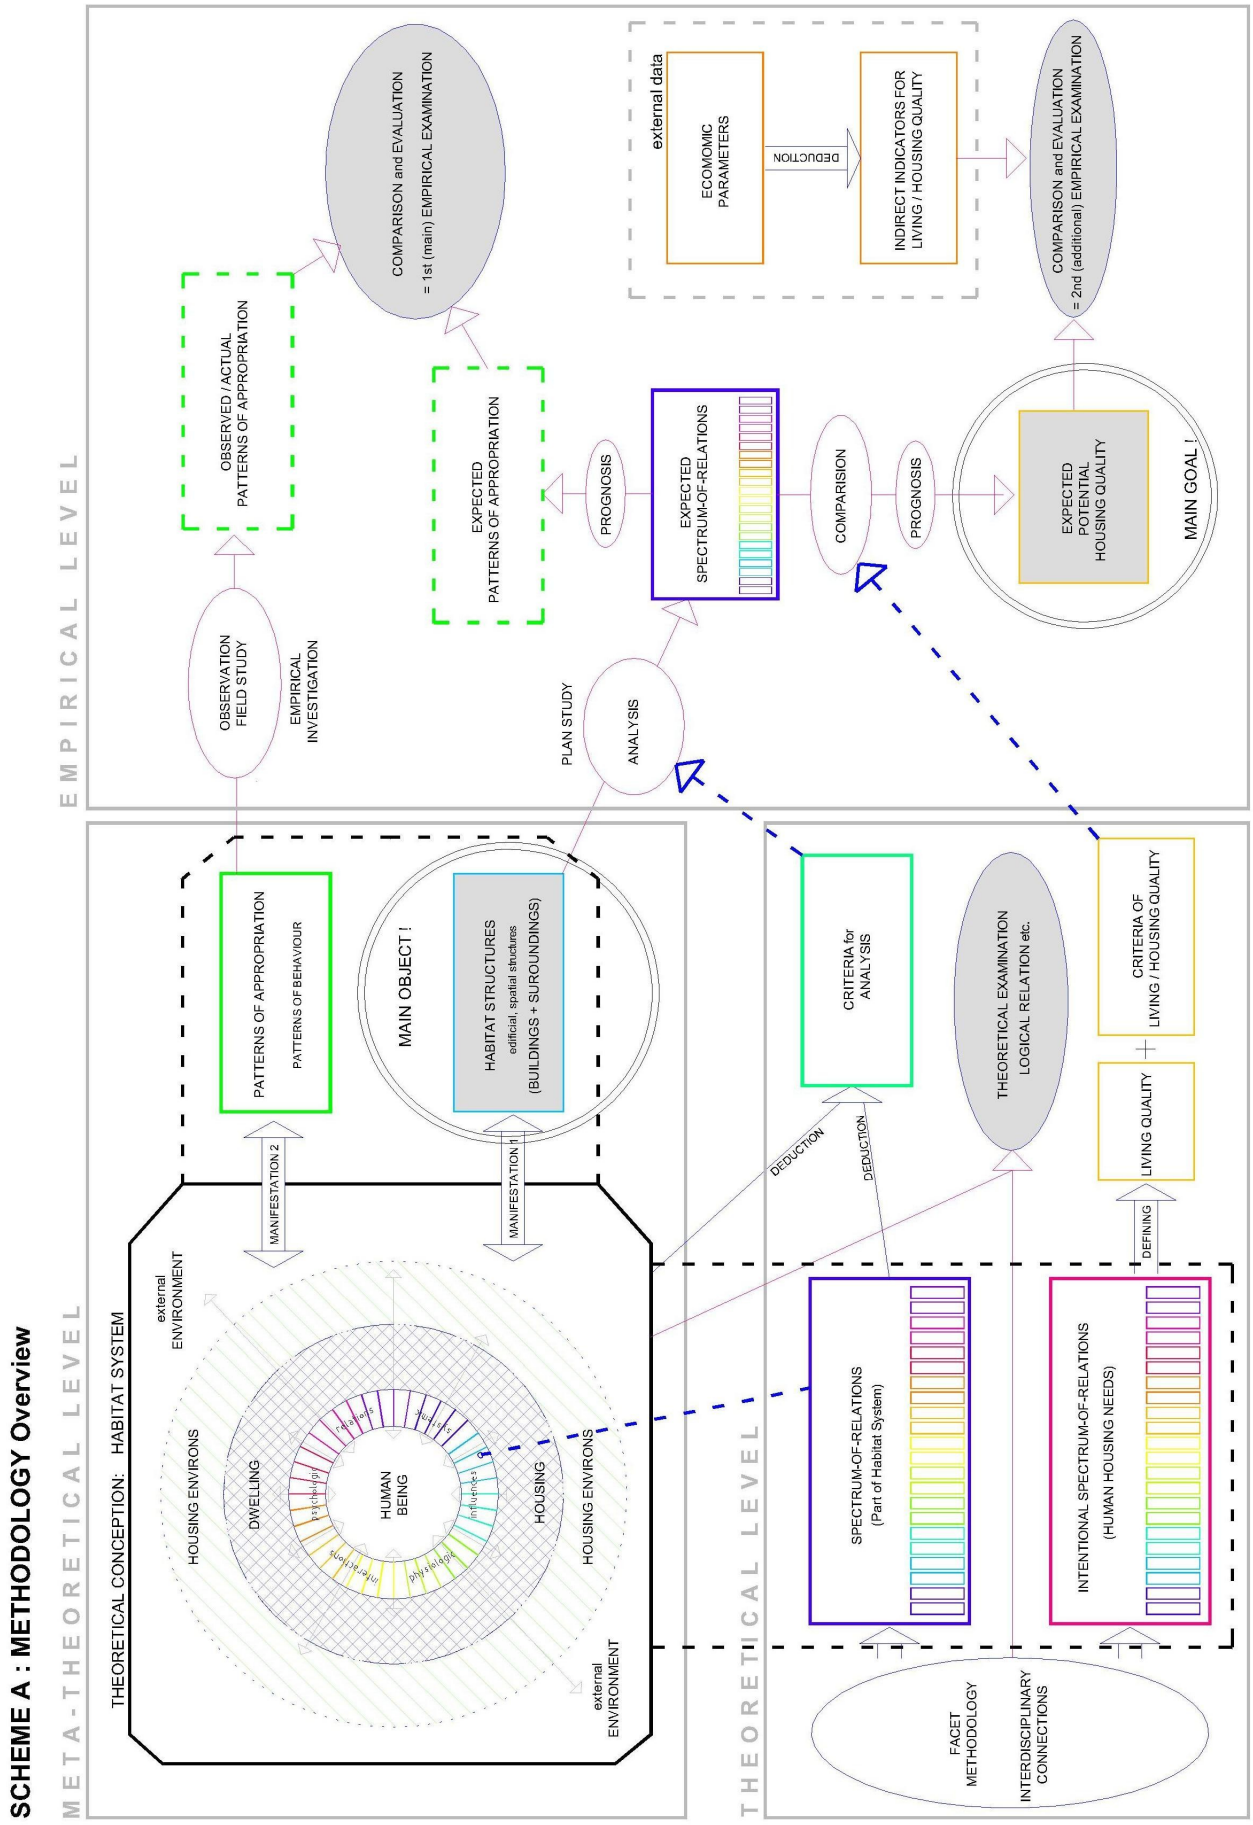
- Architects are planning and developing habitat-structures (buildings and spatial structures). They are therefore concerning themselves with housings a priori – i.e. before they are inhabited. So the architectural education is mainly based on technical and artistic fundaments that are adjusted to the construction and forming of buildings.
- Human scientists (like psychologists) can rely on a wide scientific fundament that is primarily related to the human being. They are ordinarily investigating housings after they have been erected and inhabited for a while (i.e. a posteriori). The real objects of investigation are thereby human beings in the respective spatial or social context. They do not offer an appropriate methodology for analysing housing concepts. They may give advices by mentioning some relevant aspects from their special perspectives, but it is commonly not their aim to create theories for planning housing structures.

Behind that planning theoretical deficiency another main deficit is hidden. There has been no definition of the **human habitat** itself so far - a definition which is valid from a general scientific perspective and which describes the essential characteristics of a human habitat in a compact and practicable way - so that it can be used as a basis for the creation of a housing theory.

As one result of that splitting a scientific conception was missing which could define human habitats in such a comprehensive way that conclusions for forming and conceiving housing structures can be drawn. This "lack of theory"[4] has been mentioned several times in the respective scientific literature [5], [6] and has been extremely evident within the housing-related sciences, especially in architecture [7].

The specific aims of this work can be explained by mentioning the leading questions: Which characteristics do edificial or spatial structures have to feature in order to be able to become a humane living space (a habitat) in its best sense - and therefore also become sustainable in an human way? And: How can the human quality of a habitat be defined scientifically?
Leading hypothesis: The human quality of a habitat is determined by the quality and quantity of the actual and possible relations between the human being and his habitat plus environment. Therefore the whole "system" human-dwelling-environs (= habitat system) had to be ascertained and defined.
Working hypothesis: The human quality of a habitat can be defined by identifying the respective habitat system.
In this context the theory of human habitat systems is providing a tool to define the human quality of apartments, buildings, residential areas etc. - be they either planned or built.

(B2) Short Portrait of the Research Work



The research has been carried out on 3 main levels. (see also scheme A)

(1) Meta-theoretical Level (Scientific Theoretical Work)

On the first level the theoretical fundamentals - a **theory of human habitat systems** - had been conceived by a detailed definition of:

- the habitat system and its primary components/elements
- the relations and exchange processes, which are determining the characteristics of the system
- the interconnections between habitat system and the edificial, spatial structures (**habitat structures**) which are representing the physical manifestation of a habitat system
- the interconnections between habitat system and patterns of use and behaviour of their inhabitants (**patterns-of-appropriation**) which are representing the behavioural manifestation of a habitat system.

According to the main aim the theoretical conception has been composed systematically and pursuant to clear scientific theoretical principles (e.g. Logic of Research, C. Popper [8]). The **primary target** was to structure the theoretical conception logically and traceably with clear sentences which can be examined theoretically and/or empirically.

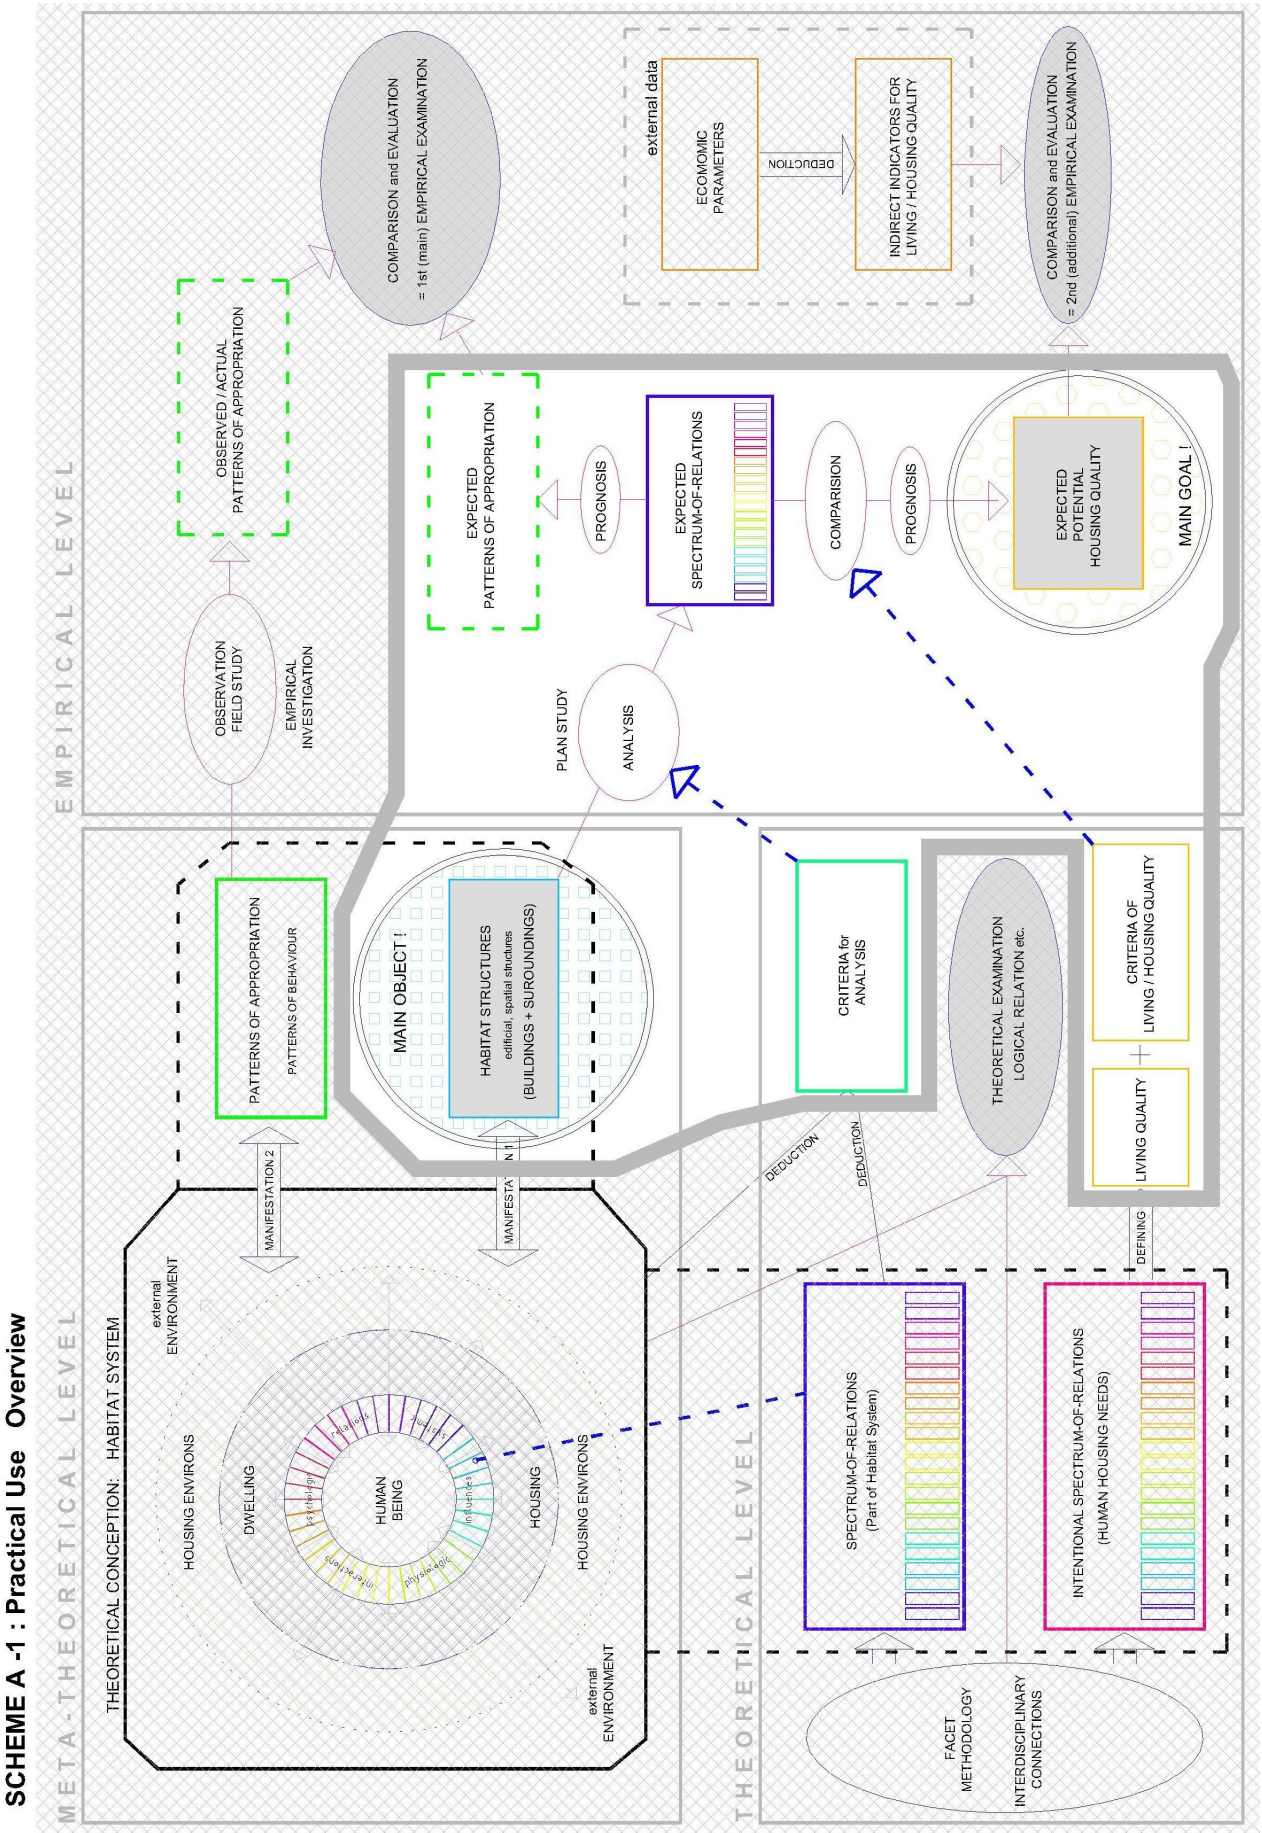
(2) Theoretical Level

(2a) **Spectrum-of-Relations** and **Human-Housing-Needs** [10]

On this level the relations between the human being and his housing environment have been compiled. Which interconnections, exchange processes and relations are there on principle between a human being and his housing environment?
The first main target was to explain and define the relations within a habitat system, between a human being and his habitat, his living environment (the spectrum-of-relations).
The second main target was to explain and define the most important needs that are related to the habitat and generally to "homo sapiens". This is of special importance because the term "living/housing quality" can only be defined by the help of the so called human-housing-needs (the intentional spectrum-of-relations).
In order to meet these objectives, interdisciplinary connections have been assembled systematically. Especially human sciences like housing psychology first of all, as well as environmental psychology, social and developmental psychology, housing physiology, building biology etc. provided substantial contributions to the whole spectrum.

(2b) Theoretical Examination
The newly developed theoretical conception had to comply with the following criteria [9]: It has to be synthetic without internal contradictions. This also implies a theoretical examination in the form of logical analysis. It must not be metaphysical or esoteric etc. Which means that it must not defy examination, be it empirical and/or theoretical.



(3) Empirical Level

The empirical examination consisted of analysing existing housing objects.

(3a) **Analysing habitat structures** [11]
Step 1, Compilation of Criteria for Analysis: First the criteria and parameters for analysis have been derived from the theoretical basis (the human habitat system including the spectrum-of-relations). In this initial stage the **methodology of analysis** had been conceived in general.
Step 2, Selection of built examples: Because the habitat theory is meant to be of general validity, it was essential to choose an appropriate variety of different housing objects.
Step 3, Analysing work: The selected housing objects had been investigated by studying and analysing plans and other documents. The analyses are primarily able to generate two results: the expected patterns-of-appropriation and the expected housing/living quality of the respective object.

(3b) **Documenting the patterns-of-appropriation**
A habitat system is manifesting itself in a behavioural sense in the form of patterns-of-appropriation - i.e. patterns of use and behaviour of their inhabitants. Appropriation is in this context standing for establishing a relationship to one's own living environs and it also means that a physical, spatial environment becomes a personal living space (a habitat!). Appropriations can be empirically explored and described by observing actual processes (behavioural patterns) or traces and signs of use, adaptation, shaping, forming etc. I.e. patterns-of-appropriation are empirically recognizable.

(3c) E**valuation and Empirical Examination**
First Empirical Examination plus Evaluation: The next step has been represented by the evaluation of the findings and conclusions of analysis (3a) and field research (3b).
By **comparison** between the expected patterns-of-appropriation (3a, step 3) and the observed actual patterns-of-appropriation (3b) the habitat theory or respective sentences of the theory could have been verified or falsified.
Second Empirical Examination: Additionally the results of analysis has been compared with several so-called "economic" parameters (as far as available) like vacancies, duration of occupancy etc. All those parameters are representing in this context indirect indicators for housing quality.

(B3) Conclusions and Resume

Potential Impact on Sustainable Housing Practice (Analysing, Planning and Designing)

The potential impact can be explained by comparing the two schemes A and A-1: After the research works the potential practical use became clearly visible. By means of the criteria for analyses we are able to check out the potential housing/living quality of buildings and residential areas in detail and in advance; and we are able to define the expected patterns-of-appropriation in advance.
This leads us to one major goal: it becomes possible to carry out analyses on a scientific and systematic basis **before** the building is erected and occupied, still **during the stage of planning**.

Afterwards we are able to return to the main task and to answer the initial question:
How can we enhance the human quality of housings and settlements and therefore also their sustainability?
- By using this sophisticated methodology of analysis during planning and hand in hand with planning.
- By using this methodology of analysis before reconstructing a housing complex, remodelling a building, or redeveloping a whole housing settlement.

Finally optimization of habitation quality as well as reduction of deficits become possible. By a clear and detailed definition of the specific qualities of an object, such analyses could support avoidance of deficiencies and provide the basis for various improvements concerning the human-related aspects.

Sustainability plus Benefit to the Inhabitants

The research results could provide contributions to enhance sustainability on three levels:
- ecological sustainability: prolonging the life-cycle endurance of buildings; reduction of dispersed settlements, splinter developments, urban sprawl; reduction of leisure "escape" and traffic etc.
- social sustainability, of course: increase of human housing quality, living quality, better interpersonal relations between the inhabitants, etc.
- and also economic sustainability: higher occupation rate, higher quality for equal price, etc.

The benefits are on principle valid for all forms of housing, i.e. the high-budget as well as the low-budget segment. With the latter there are even much more improvements necessary and possible.

(C) Research Report Part II: Examples and Analyses

The ongoing practical research is illustrated with the aid of 3 examples:
See appendix: Examples 1 to 3

Example 1: "Pruitt Igoe" - the most unsustainable housing complex in history [12], [13]

Example 2: "Terrace-house-settlement"; Sustainability despite energetic / thermic deficits?

Example 3: Cohousing project; Social plus ecological sustainability? [14]

These three examples are just meant to offer a short insight for a better understanding of the topic. The complete analyses are of course much more comprehensive and detailed.

Example 1: Pruitt-Igoe

"The most unsustainable housing complex in history caused by psychological deficits"

Housing object:

"Pruitt-Igoe"
St.Louis, USA
ca. 2800 housing units
completion 1956
occupation peak 1957: 91%
1965 occupation rate ca. 33%
1971 only 600 Inhabitants left
demolished 1972 - 1976

Main reasons for the failure were psychological planning mistakes. First of all: wrong zoning within the building.

(A) Semi-public areas within the building without possibilities for visual control lead to:

- "silent" vandalism (deteriorations)
- aggressive vandalism (damages)
- places of fear ("Angsträume")
- stronger tendencies for crimes
- ... and even crimes occurred within the buildings communal areas

(B) Semi-public areas directly abut on private ones, this leads to:

- "crowding" situations
- antagonistic behaviour
- diminished feeling of being secure
- reduced willingness to get into contact with others
- reduced responsibility for the living surrounding
- lack of social control

  ... which amplifies the consequences of (A)

This vicious circle started turning from the beginning - very slowly but consequently and unstoppably. All this ended up in the complete demolition of the whole housing complex, which therefore became the most unsustainable housing project so far
- despite the fact that from a constructional point of view the buildings were better than most of the others in the surrounding at that time.
- despite the fact that the comfort of the apartments were clearly above the average standard of this period.

Example 2: "Terrace-house-settlement"

"Human sustainability lacking energy-efficiency"

Housing object:

"Terrace-house-settlement"
Graz, Austria
552 housing units
planning 1965
built 1972

Housing Concept:

- separate individual apartment units
- each unit has got a private terrace or balcony or a small garden
- In the outside: attractive semi-public areas with various possibilities for appropriation
- no motorised traffic within the settlement
- including places for social interactions, places for playing, places to stay for people of any age.
- high personalization potential (most apartments)
- private spaces without heteronomous control
- high sensory variety (visual first of all)
- etc.

The housing complex had been built 40 years ago and is still fully occupied - despite several constructional deficiencies concerning thermal insulation, moisture penetration etc.
- and despite several psychological deficits: some small parts of corridors and staircases are lacking social control; the higher floors are more isolated from the area-of-appropriation etc.
But this deficits are obviously outweighed by the positive aspects.

Conclusion: If a building complex has got a high human quality it remains occupied even if the physical factors are not very sustainable.

Example 3: "Cohousing - Lebensraum"

"Human and ecological sustainability"

Housing object:

Cohousing project
"Lebensraum" ("Habitat")
Gänserndorf, Austria
32 housing units
built 2005

Ecological Building Concept:

- natural and recyclable building materials
- very low energy building
- high thermic insulation
- use of solar energy (passive and active)
- ecological water management
- ecological waste management
- etc.

Housing Concept:

- separate individual apartment units
- each unit has got a terrace or balcony and a small garden, where the inhabitants can stay private
- high personalization potential
- attractive and spacious communal rooms and areas, located at the right positions
- offering opportunities for various forms of social interaction
- offering appropriate facilities for people of any age
- integration of natural elements
- special offer for children: "adventure" area - not predetermined by adults
- semi-private corridors (partly problematic)
- no public areas, little contact to people outside the settlement
- high systemic isolation (infrastructure etc.)

The housing concept tries to comprise ecological, biological and social issues in order to reach a sort of overall sustainability.
It aims for combining humanity with ecological building standards.

Short Summary

Sustainable construction is a relatively new concept that aims at integrating the objectives of sustainable development into the construction activities. Multiple methodologies and approaches for assessing building sustainability at international, European and national level are being used. However most of them form part of national initiatives and consequently are only used at national level. Also, many of these assessment methodologies are conceptually developed without user-friendly applications, thus not meeting the industry needs of responding to manageable steps in practice.

ACCIONA Infrastructures as coordinator and Fraunhofer as chair of the Scientific and Technical Committee lead the European project OPEN HOUSE (OH) financed by the European Commission within the seventh Framework Programme (FP7). The project aims to develop and to implement a common European transparent building assessment methodology, complementing the existing ones, for planning and constructing sustainable buildings by means of an open approach and technical platform. The methodology was developed on the basis of existing systems, international initiatives and European standards with a view to harmonizing building assessment. It includes a set of qualitative and quantitative indicators grouped in 6 categories: environmental, social, economic, technical, process and location.

OPEN HOUSE methodology was implemented in 68 buildings used as case studies distributed in 35 European countries in order to assess the applicability of the methodology and to gather constructive feedback to improve it. This paper focuses on the first analysis of the feedback from case studies. It reveals that the OH online assessment tool is user-friendly and facilitates the building assessment. The OH methodology is seen as holistic and covering all aspects of sustainability. In addition, the analysis shows that there is still work needed to adapt the set of indicators to national context but most of them were applicable in all European countries.

On the basis of the feedback analysis, this first version of the OH methodology will be refined in order to establish a European reference point for building sustainability labelling.

Keywords:OPEN HOUSE; Building Sustainability Assessment; Assessment tool; Case studies.

1. Introduction

According to the DG Environment, construction constitutes one of the largest waste streams within the EU (it accounts for 450 million tons of waste every year and represents about one fourth of all the waste generated in Europe). About 40% of the overall energy consumption in Europe is related to the building domain and represents about 1/3 of Europe's CO2 emissions [1]. More than 50% of all materials extracted from earth are transformed into construction materials and products, the domain also uses 25% of all virgin wood [2]. Construction works also account for 16% of the water annually used worldwide [3]. However, the importance of the construction sector is not manifested only in its impact on the environment. Also on the level of society considerations, construction practices affect core issues, such as accessibility, comfort, health, safety and security.

Sustainable construction is a relatively new concept that aims at integrating the objectives of sustainable development into the construction activities. Building projects can be regarded as sustainable only when all the different dimensions of sustainability – environmental, economic, social and cultural – are taken into account. Developing and using building sustainability assessment methods is one solution to explore in order to promote a more sustainable built environment [4].

At International, European and National level a number of methodologies for assessing the sustainability have been developed like LEED (Leadership in Energy and Environmental Design), BREEAM (Building Research Establishment Environmental Assessment Method), SBTOOL, DGNB Certificate(certificate from the German Sustainable Building Council) or LEnSE (Label for Environmental, Social and Economic buildings). Also, during the last years international, European and national standardisation bodies have developed sustainable construction standards. International Organization for Standardisation (ISO) and the European Committee for Standardisation (CEN) have worked actively in the last few years to define standard requirements for the sustainability assessment of buildings.

The main challenge of the European project OPEN HOUSE is to develop and to implement a common European transparent building assessment methodology, complementing the existing ones, for planning and constructing sustainable buildings. The OPEN HOUSE methodology aims at being user friendly but also scientifically rigorous. It is developed with a transparent approach enabling stakeholders and the general public a free access to an open source of information through an accessible platform.

The following paper presents the OPEN HOUSE methodology as well as the experiences after the completion of 68 case studies carried out in different European countries in which the methodology has been applied and tested.

2. Materials and Methods

2.1 OPEN HOUSE Methodology

The European project OPEN HOUSE (FP7 ENV-2009.3.1.5.2) has been established under the framework of a FP7 R&D programme by a European consortium of 20 partners from research institutions, the building industry and the political sector. Running from February 2010 to July 2013, its objective is to merge existing methodologies for sustainability assessment of buildings towards a common view. With the aim of being widely adopted in Europe, the OPEN HOUSE methodology is developed in a fully transparent, collective and open process, with extensive communication and interaction between all stakeholders.

The OPEN HOUSE methodology has been developed on the basis of existing methodologies like BREEAM, LEED or DGNB, international initiatives like iiSBE or SB Alliance as well as standards from ISO/TC 59/SC 17 and CEN/TC 350.
It also includes outcomes from former or current EU projects, like LEnSE or SuPerBuildings, with the adoption of a common structure for sustainability assessment of buildings.

The first version of the OPEN HOUSE methodology is composed of 56 indicators classified in six categories: Environmental Quality, Economic Quality, Social/Functional Quality, Technical characteristics, Process Quality and The Location (Figure 1) [5].

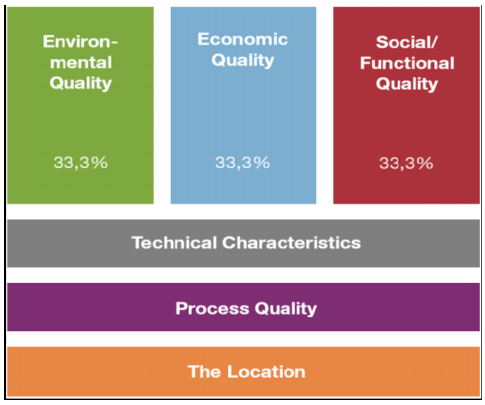

Figure 1: OPEN HOUSE categories for the sustainability assessment of buildings

The analysis of more than 60 assessment methodologies led to the identification of more than 500 indicators. Methodologies analysed vary from regional ones like the one developed by the Basque Government to worldly renowned systems like LEED or BREEAM [6,7].

Finally, 56 sustainability indicators were selected after being grouped into the six categories and questioned by the partners for their acceptability and feasibility in different European countries. This set of indicators is optimised for office buildings and versions for other building types will be developed in the following phases of the project.

Furthermore, 30 indicators were identified by the project partners as essential for the sustainability assessment and highlighted as ‘core indicators’. The complete list of indicators can be found in Figure 2.

The comprehensive description of the 56 indicators can be found in a reference document called Assessment Guideline. This guideline includes information regarding: objective of each indicator, assessment methodology, calculation - rating and documentation guideline.

In the first version, for each sub-indicator a maximum of 100 points can be achieved: the baseline of 10 points is obtained by fulfilling the standard of the specific EU country – the maximum by achieving best practices towards sustainability goals (e.g. targets of the EU in 2020) [5].

As mentioned in ISO 21929-1 [8], there are no commonly agreed methods for weighting. Hence, the OPEN HOUSE partners are elaborating a weighting strategy based on the analysis of the ones from existing methodologies and including the opinion of different stakeholders from the building sector.

2.2 Case studies

In order to assess the applicability of the OPEN HOUSE methodology and to gather constructive feedback to improve it the methodology was implemented in 68 buildings used as case studies distributed in 35 European countries (Figure 3). The test of all indicators in case studies will allow a general improvement of the assessment guideline as well as the integration of national peculiarities in terms of calculation methods, rating and documentation requirements.

Environmental Quality	**1.1**	**Global Warming Potential (GWP)**
	1.2	**Ozone Depletion Potential (ODP)**
	1.3	**Acidification Potential (AP)**
	1.4	**EutrophicationPotential (EP)**

Figure 2: OPEN HOUSE indicators (core indicators are in bold)

Two kinds of assessments were conducted during the case studies:

- Basic & Quick Sustainability Assessment: to get a first idea of the sustainability level and propose actions to improve it. The evaluation of the building performance is based on assumptions.

- Complete Sustainability Assessment: to give a whole overview of the sustainability performance of a building. The Evaluation of the building performance is based on detailed documentation.

The assessment of the case studies was done thanks to a user-friendly online tool developed during the project (http://oh.building-21.net/). With the help of this online tool the calculation and rating system was transformed into an easy questionnaire whose answers led to the automatic calculation of the score achieved.

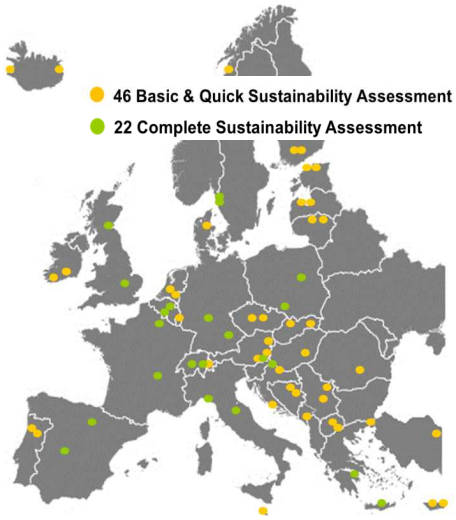

Figure 3: OPEN HOUSE case studies

Apart from the assessment of each case study the assessors were required to provide information about applicable norms and national practices for each of the OPEN HOUSE indicators. The goal was to collect essential information about country regulations and best practices. Moreover, the assessors needed to complete a feedback for each of the indicators. The feedback form was provided as an excel spreadsheet with drop down menus options and open narrative feedback to be entered. The goal of these forms was to collect feedback in a standard way in order to automatically process and analyse the information. In addition, all assessors were specifically asked to provide the time they spent on assessing their building with OPEN HOUSE (excluding training, administration, filling in the feedback forms, national standards/regulations).
Thanks to feedbacks from case studies, questionnaires and workshops it will be possible to develop specific weights and benchmarks for each European country in order to take in account regional particularities.

3. Results and Discussion

3.1 Estimated assessment time

Regarding the estimated assessment time, for Basic & Quick Sustainability Assessments the time spent varied from 38 hours to 113 hours. The average time necessary to carry out the Basic & Quick Sustainability assessment was 96 hours (12 days).Complete Sustainability assessment was more time consuming and the time spent varied from 50 to 320 hours and the average time was 202 hours (25 days).

3.2 Category applicability

The applicability for the six categories is represented in Figure 4, based on the feedback from 52 case studies. The environmental quality was considered as completely applicable for 20 case studies (38%) and partly applicable for 29 (56%). The reason for not being always applicable mostly came from the difficulty to carry out the LCA, either because of lack of information concerning the building components or because of the complexity of the assessment method. However, LCA indicators were positively evaluated as important indicators for a sustainability assessment.

The social quality was considered as completely applicable for 20 case studies (38%) and partly applicable for 31 (60%) The reason for not being always applicable mostly came from the fact that some indicators (like Public Accessibility or Service Quality) were not considered as relevant for a sustainability assessment of small office buildings and that additional measurements (e.g. for indoor air quality) or specific simulations were not available.

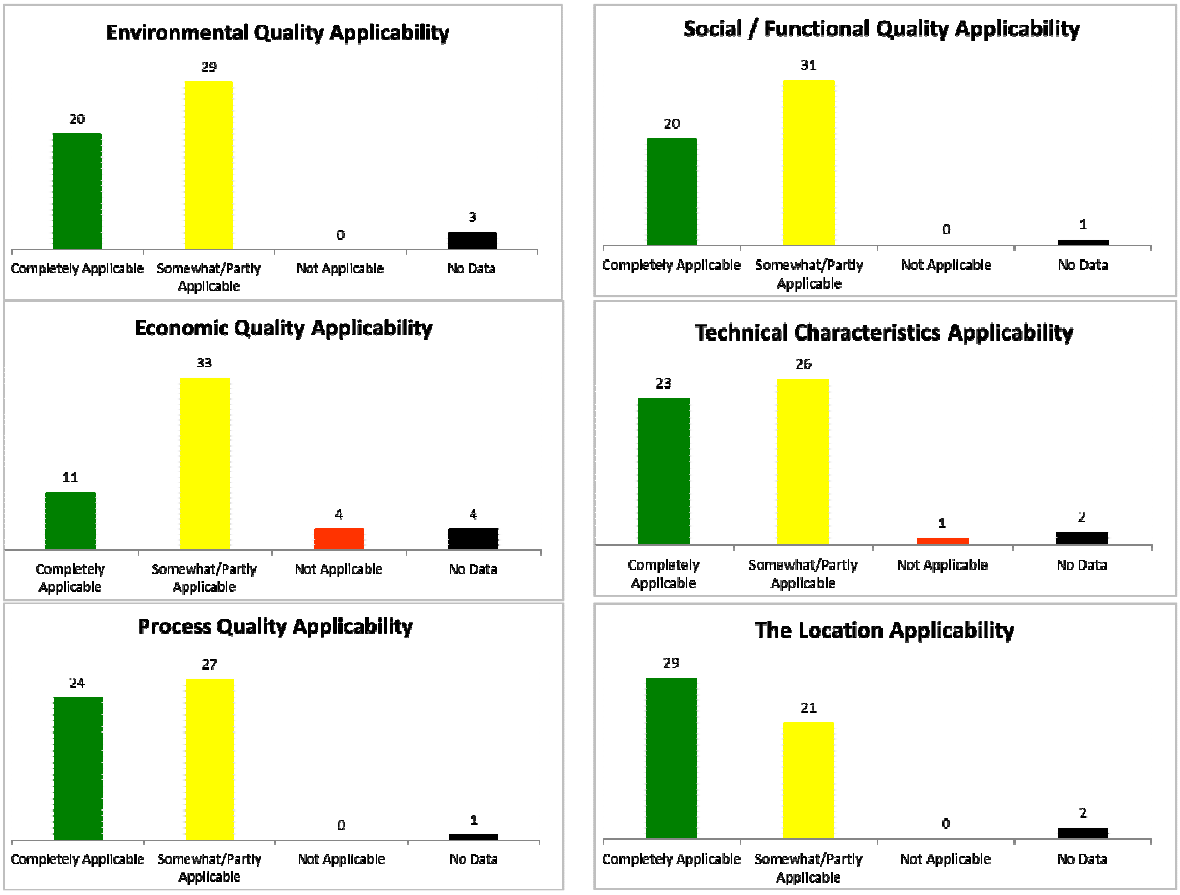

Figure 4: Category applicability

The economic quality was considered as completely applicable for 11 case studies (21%), partly applicable for 33 (63%) and not applicable for 4 (8%). The reason for not being applicable mostly came from the difficulty to carry out the LCC, because of lack of information concerning the costs of building components and the seldom use of LCC in Europe.

The technical characteristics category was considered as completely applicable for 23 case studies (44%), partly applicable for 26 (50%) and not applicable for 1 (2%). The reason for being partly applicable mostly came from the difficulty to gather documentation.

The process quality was considered as completely applicable for 24 case studies (46%) and partly applicable for 27 (52%). The main reason for not being applicable was the difficulty to access documentation that was not produced during the planning phase, but required by the assessment.

The Location category was considered as completely applicable for 29 case studies (56%) and partly applicable for 21 (40%). The reason for being partly applicable mostly came from the difficulty to gather documentation.

3.3 Compatibility for different building types

Most of the selected case studies were office buildings and the applicability of the methodology for office buildings was considered as very high as there were only few comments stating problems related to this typology.

On the other hand, out of all case studies, 7 buildings mostly had educational or cultural use. The feedback comments showed that no changes were needed to adapt the current version to educational or cultural buildings, and the methodology was flexible enough to be applied to

different kinds of buildings with quite similar uses.

3.4 Compatibility for different construction phases

The distribution of case studies on the next diagram shows that most of case studies were new buildings (built in the last 10 years), but existing buildings recently refurbished as well as under construction or in design phase were also represented (Figure 5).

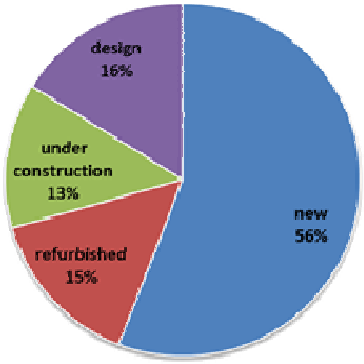

Figure 5: Construction phases represented by the case studies

The OPEN HOUSE assessment methodology was developed with the idea that the sustainability assessment starts early in the design phase and continues until the building is built and occupied. However, if the assessment is done during the planning phase, there are uncertainties about the final concept of the building and it is also neither possible to evaluate the construction phase nor measure the indoor air quality for example. If the assessment is done only after construction, it may be difficult to get information about the planning process or the building materials.

3.5 Compatibility between different countries

The scores obtained for all categories by each case study are presented and grouped by country for a first overview of national performances (Figure 6). Moreover, this first assessment is not representative of the final building performance according to the concept of the OPEN HOUSE methodology because weightings for sub-indicators and indicators have the default value 1 and benchmarks are the same for all countries.

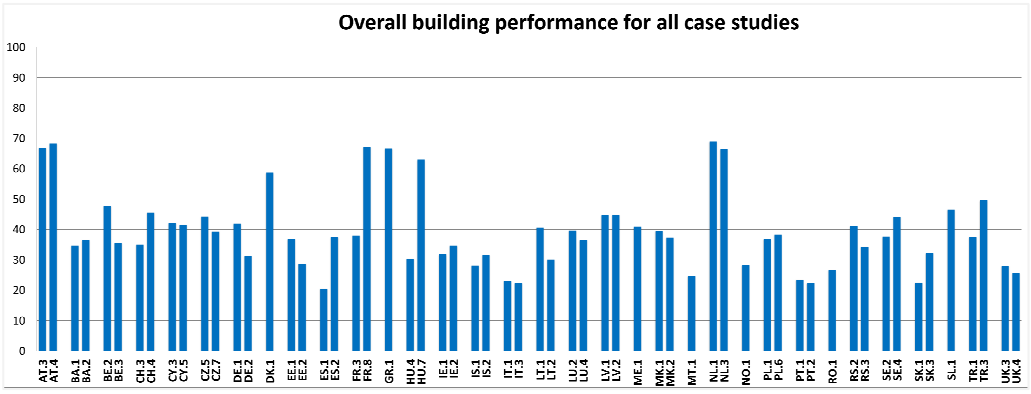

Figure 6: Overall building performance for all case studies in different countries

In general the overall building performance (average of environmental, social/functional and economic categories) performance was quite similar for different case studies in the same country, except in Hungary and France where big differences could be seen, due to the difference in the Economic Quality. In the end, the overall building performance may be a good indicator of the

national building practices performance in the variety of European countries (Figure 6). Of course, in order to validate this statement, data from more than 2 case studies per country are necessary.

The overall performance of each case study was quite low (on average 40%, the best one achieving 69%). The average score for each category was: 33% (environmental quality), 56% (social functional quality), 34% (economic quality), 45% (technical characteristic), 55% (Process Quality) and 63% (location). The low performance can be explained by the high influence of the economic quality (33% of the overall performance) for which low score was achieved due to the poor availability of data concerning the Life Cycle Costs.

4. Conclusions

The OPEN HOUSE methodology was successfully implemented and tested in 68 buildings used as case studies distributed in 35 European countries in order to assess the applicability of the methodology and to gather constructive feedback to improve the assessment. The first analysis of the feedback from assessors revealed that the online assessment tool is user friendly and facilitates the building assessment.

The OPEN HOUSE methodology was seen as holistic and covering all aspects of sustainability. Some aspects to be improved from the methodology were the time needed to assess the building and the data requirements in some indicators.

The methodology was considered as highly applicable to office buildings and flexible enough to be applied to other building types (educational or cultural buildings). When the assessment was done during the planning phase, there were certain uncertainties about the final concept of the building and this difficult the assessment of some indicators. In some case studies in which the assessment was done in existing buildings it was difficult to get information about the planning process or the building materials. For each category, it seems that case studies located in the same country achieved a similar score. If we consider that these buildings are representative of the best local practices, their performance can be used to scale the local reference values. However, more than 2 case studies per country are needed for precise benchmarking.

Keywords: Carbon management; Existing Buildings; Performance Based Evaluation;

1. Short Summary

The need to de-carbonize existing buildings with the use of various renovation approaches is on the rise. This paper reviews the key drivers in the literature and describes a performance based evaluation method to assist in the decision making to renovate existing buildings. A base case of an existing apartment building was used to demonstrate the effectiveness of a proposed evaluation method. The result of the study recommends the inclusion of the key drivers and proposes a method to quantify the performance of the proposed renovation scenarios and provides the owner with a decision making method to minimize carbon impacts associated with the renovation and operation of the existing buildings in the future.

2. Introduction

With energy efficiency and carbon emissions growing in importance in recent years, more detailed exploration into the sources of carbon emissions can be seen in recent research work. Looking at the close relationship between energy consumption and carbon emissions, energy consumption can be used as a rough indicator as to the carbon emissions - where renewable resources are not the main source of energy. Statistics show that an estimate of 40 percent of total energy consumption worldwide goes into the building and construction industry [1]; therefore, the building sector is a significant contributor of carbon as well as other emissions [2]. On a building level, the most commonly used mode of energy accounting in buildings is calculated either though energy analysis or using guidelines set by the ISO (International Standardization Organization) for Life-Cycle Assessment (LCA)[3]. Using LCA to determine the impact of a building on the environment involves accounting for and calculating all the energy processes revolving in and around the production, maintenance, demolition and running costs of the analysed building. These processes are generally divided into two distinct categories: embodied energy processes and operational energy processes; the energy products of which sum up to the total life-cycle energy of a building.

Although the overall impact of a building cannot be assessed solely on either embodied energy or operational energy on its own; the study and optimization of each of the two sub-components has the potential to explore the factors affecting each and eventually reaching a compromise. Therefore as can be clearly deduced, the study of embodied energy has notable reason for slowly gaining importance and becoming a topic of further research. However, while studies have been conducted in many countries worldwide; the localized analysis of embodied energy in the building industry in Egypt remains a topic of discussion. An important point to note as discussed by Haynes[4] is the separation between embodied energy and embodied carbon. The distinction is important since a comparison of embodied energies of two buildings might show that one has higher energy content than the other. However energy content alone should not be considered as an indicator to its impact on the environment, as the very same building with higher embodied

energy may be of a clean renewable source whereas that of the building with lower energy may be based off of fossil fuels-having overall a greater environmental impact.

Locally in Egypt, where the current supply for energy is in need of expansion in order to cover the growing energy demands, a reduction of embodied carbon content through the replacement of current energy sources with clean renewable energy would be of significant impact in the construction sector. Based on energy reports from 2009 published by the Energy Information Administration under the Department of Energy [5]; Egypt's main sources of energy were oil and natural gas accounting for 47 and 48 percent of the country's total energy consumption respectively. Such a high reliance on fossil fuels indicates a high level of embodied carbon since not only will transportation be based on fossil fuels, but also nearly all other processes including material extraction and/ or manufacturing, processing and then later assembly, maintenance and disassembly would all rely on carbon-embedded energy sources as well.

3. Literature Review

3.1 A General Overview

A general overview of the existing literature on embodied energy has shown and confirmed the growing importance and consideration of embodied energy in the growing trend of more energy conscious building. Embodied energy which is the amount of energy that goes into creating a final product; assesses and calculates the amount of energy invested into producing the materials used in creating it, the energy invested in extracting these materials as well as the energies consumed in any associated transportation processes, assembly, fixing, and the eventual maintenance and demolition of the product. Where the calculation of embodied energies of simple products constructed of a single material and of a single source may be simple and straightforward, the calculation of the embodied energy of a building with its vast number of components and subcomponents is far more complex. In order to accurately calculate a building's embodied energy each and every underlying component must be traced back to its original source and have all energy investments into its production calculated. These calculations need a vast amount of records, data and precision in order to present accurate results. These factors in addition to a diverse "un-standardized" calculation procedures have resulted in an abundance of embodied energy calculations varying in both accuracy and precision; thus, also making them difficult to compare and optimize. Hence, it comes as no surprise that a review of existing literature shows an agreement regarding the inaccuracy of embodied energy calculations and the large variability of results. The literature repeats that existing frameworks of calculation which in themselves broad and not stringent enough causing differences in methodology and discrepancies in calculations. Furthermore, even works such as the ICE database a project published by the University of Bath – considered to be the most widely used existing database for carbon emissions- is in itself acknowledged by its authors to have a degree of inaccuracies in its inventory despite attempts to adhere to a standardized procedure in publishing the embodied energy coefficients but remains a central source for most of the quantitative coefficients on a variety of material types.

3.2 Classification of the literature

A review of existing literature shows that the current research work in the field of embodied energy can be divided into three main categories: 1) *Standardization* of embodied energy calculation methods, their frameworks as well as their boundaries; 2) *Application* of methods and Analysis of Case-studies by building type; 3) *Optimization* of Low/Zero Carbon (LZC) material use and de-carbonization using smart retrofit proposals to lower the overall direct and indirect energy use; and 4) Scalability of approaches and means of evaluation. These initiatives although explored partially through recent work are generally in early stages of exploration, and thus identify gaps in the existing literature and field, and thus mark areas in need of further research.

3.2.1 Standardization of methods

An important point of recent research has been revolving around the method of embodied energy calculation. A review of existing literature repeatedly calls for the need of establishing standardised

calculation methods for estimating accurately embodied energy in buildings. A search for a standardised methodology or set of guidelines to abide by when calculating embodied energy is not existent at the moment thereby resulting in discrepancies and variations in energies reported. The work of Manish Dixit, Jose Fernandez-Solis, Sarel Lavy and Charles Culp at Texas A&M University is invaluable in this field. Work published includes an extensive overview of existing literature and in three different papers published in 2010, 2012 and 2013 attempt to identify the parameters and existing guidelines that could help establish clearer calculation methodologies, frameworks and system boundaries for embodied energy calculations. In their first paper Dixit et al. [6] establish the existing gap in comparable embodied energy databases. Based on this conclusion their second work then focuses on the existing parameters that could aid in creating a unified protocol or set of guidelines, for a more standardized calculation method in determining embodied energy. Simultaneously, the work also identifies the challenges in existing resources and the causes of discrepancies and inaccuracies that would need to be minimized in order to reach a more accurate and comparable set of results. Their most recent work published earlier this year (2013) builds on earlier work and proposes a boundary definition to unify the energy processes accounted for in embodied energy calculations. A model such as this one if abided by internationally would allow for standardized comparison between calculations globally.

3.2.2 Application of methods

While some sources worked on optimizing the actual calculation procedure, other sources conducted calculations based on one of the existing methods to draw general conclusions from case-studies on different building types. Among the case-studies conducted is Bruno Lee, Marija Trecke and Jan Hensen's study of industrial halls[7]. The case-study conducts a comparison between the embodied energy of a simple rectangular industrial hall using three different materials: once fully in steel, once in concrete and once as a hybrid system; concluding that the all-concrete alternative had largely greater energy content in comparison. By contrast, a report published by [8] employed an alternative approach to case studies; breaking down the components of the building under examination and determining the components' corresponding embodied energies. Instead of treating buildings as a whole; this breakdown allowed for the clear identification of building constituents most responsible for embodied energy content.

3.2.3 Optimization of materials

Another series of works acting in parallel to those of the previous two is the attempt to optimize material selection itself when minimizing embodied carbon. Work in this field ranges from the selection of a single material and its optimization, to analysis of certain systems or entire buildings. These works try to identify the components that would result in reduced energy embodiment and suggest possible alternatives to functional equivalents with higher energy or carbon contents. Work such as that of Venkatarama and Jagadish [9] has tested the variations and differences in embodied energy contents of a range of different brick-types, mortars as well as floors or roofing systems. Conclusions show and list the different material types tested in order of highest to lowest embodied energy content; the results of which would allow energy conscious selection of material by designers. Other studies such as that of Shukla et al. [10] conducted studies on the scale of a home; comparing the embodied energy of an abode home to that of a traditionally constructed home built out of concrete, cement and burnt brick. The outcome of the test showed that the use of adobe reduced the embodied energy per 100 m² of built-up-area by 245 GJ; showing the significance of material selection on the overall energy content. Other sources such as the work of Ramesh and Crishna [11, 12] tackle more specific topics local to a particular area such as the use of vernacular materials for construction and the optimization of reinforced concrete through consideration of embodied energy within [13] or the assessment of the amount of embodied energy found in various types of stone used in construction in the UK [11]. Looking at the life-cycle of buildings, other sources look to reduce operational costs and energies, by optimizing the choice of materials for different building components. Utama and Gheewala for instance examine the use of local building materials and their relationship to reducing energy consumption in one-landed homes in Indonesia. The use of bamboo double-walls or sugar mill ash for bricks for instance are alternatives specific to the local region suggested to replace materials of higher energy content for

walls [14]. A paper of similar direction by Radhi [15] focused on wall-cladding systems, testing the carbon emission reductions in terms of reduced embodied and operational energies. Here the tests are based off a case-study building in the United Arab Emirates (UAE) testing a variety of cladding materials. Stucco, aluminium siding and vinyl siding are among some of the materials tested and results show a maximum CO_2 reduction when Exterior insulation and finishing systems (EIFS) are used and least reductions occur when a masonry veneer is used.

3.2.4 Scalability of methods

Other published work such as that by Emmanuel and Baker look at the larger picture in some of their work and lists a set of “drivers” suggested by Davies and Osmani that could push construction towards lower carbon construction [16]. These suggestions as discussed by Emmanuel and Baker[17] can be divided into three main categories; financial, technical and legislative. These “drivers” suggested by Davies and Osmani are a parallel route to carbon reduction in construction. Where research in the reduction of embodied energy and carbon emissions focuses on the micro-scale of an individual building, larger-scale incentives such as these could have a profound effect on neighbourhood, district and city-scales. With the implementation of such incentives research being done in narrower fields could be taken from theory or single case-studies to potential large-scale implementation.

4. Research approach

In order to begin work in this field, it was first necessary to conduct a general literature review both internationally as well as locally in order to determine the local lags in research. Based on this research it was decided that a localized framework for the calculation of embodied energy in existing buildings in Egypt was the area of work most needed to suit both markets of design and construction. This was concluded as further research and the optimization of construction materials, alternative construction systems or even transportation processes to reduce embodied energy totals would be reliant on the former establishment of a fixed framework or calculation methodology; and thus must be established beforehand. In absence of comparative studies locally, a residential apartment building case study was selected to calculate the total embodied energy of the building and compare it to similar building worldwide. This case-study was intended to act as a prototype for the calculation of embodied energy of a building; acting as an initial benchmark to introduce embodied energy calculation in the local research market. Two retrofit scenarios were then studied to understand the impact on carbon emissions using a performance based calculation method. A set of conclusions and future areas of research to advance this work was documented.

4.1 Proposed framework

The structure of the proposed framework is similar to previous frameworks in the literature, however, adding the building life cycle stages; and make the main drivers of embodied energy visible across the building life from construction to obsolesce. This resulted in three main drivers visible in the framework; the energy embodied in construction (CE), energy embodied in Transportation (TE), and the energy embodied in the material (ME). The calculation method followed an (I/O) input output process using a carbon calculator to calculate the embodied energy and a simulation tool to calculate the predicted operational energy of the building (Fig.1). The framework is comprised of the Input Building Design Parameters, the Embodied energy component (EE), the Operational Energy (OE) component and the Output energy component which is the total of both (Fig.2).

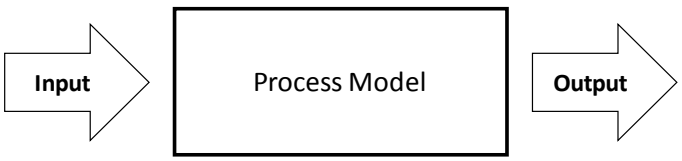

Fig.1: Input Output (I/O) Model

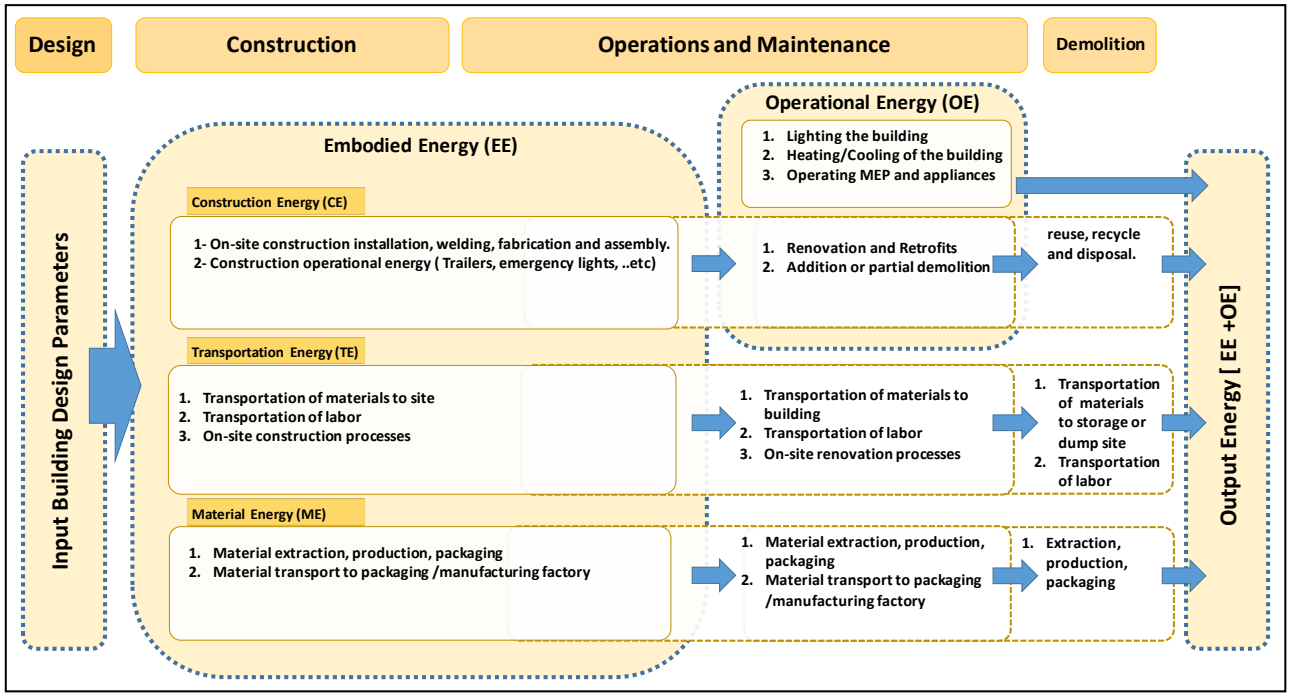

Fig.2: Proposed framework

5. Case-Study

5.1 Building Information

The case study is comprised of a three-storey residential building located in New Cairo, Egypt. The building consists of forty apartments ranging from 100 – 204m^2 in area each; amounting to a total area of 6,339m^2 of net usable residential space. Other spaces encompassed within the building include an underground garage and storage; a main lobby area, outdoor gardens, as well as a laundry to serve the residents; totalling to a final area of 12,610m^2. The structural design of the building is a reinforced concrete skeleton structure of the beam and slab type with brick internal partitions, typical building process in Egypt. The envelope of the building consists of red-brick walls (25cm in thickness) for external walls, held together using ordinary mortar 'Portland cement'. In terms of finishing, the external walls are coated with plaster and three coats of paint. Doors within the building are divided into three material types: metal doors, aluminium doors and wooden doors. Windows are all made of aluminium, and aluminium screens are used throughout the building complex to regulate the amount of direct sunlight allowed into the building.

5.2 Methodology and Reasoning for tool selection

After reviewing a series of calculators available online to calculate embodied energy and carbon, the calculator created by the Environmental Agency was selected for conducting the base-line carbon study. Since the assessment of initial carbon content in the existing residential building is only a portion of determining the impact of the building's entire life-cycle, a suitable calculator had to be selected that would fit within the larger framework opted for and explained previously. The calculator provided by the Environmental Agency allowed for the calculation of pure initial embodied energy (irrespective of the operational and demolition energies) and calculated the embodied energy from 'Cradle to gate' including the carbon emitted during transportation processes. Since there are no calculators modified specifically to Middle-East or the region in general, the calculator was used with caution and awareness that the carbon emission factors embedded will provide results that are not specific to the region. With this in mind the intention was to begin with a basic case-study using the existing calculator; accumulate the sources of possible differences that would make the calculations more accurate and specific to the region, identify the factors and processes that may affect the results and modify accordingly in future calculations.

5.3 Performance based Evaluation

To encourage the usage of performance-based evaluation (PBE) of the existing buildings, it is essential to shift the current regulatory systems from prescriptive to performance- based approach. A prescriptive approach “describes the way with a building asset has to be constructed instead of the ends of the building process, and it is related with type and quality of materials, method of construction, workmanship. Such approach is strictly mandated by law, codes, standards, regulations and it is based on past experience and consolidated know-how. Using a PBE approach does not preclude the use of prescriptive specifications. Although the benefits of the adopting of a PBE approach are significant, it is recognized that employing a performance-based approach at any stage in the building process is more complex and expensive than using the simpler prescriptive route. So, the application of this approach should not be regarded as an end in itself. When simple building are concerned or well proven technologies are used, the use of prescriptive codes results more effective, efficient, faster, or less costly, so prescriptive specifications will continue to be useful in many situations. Therefore, to better utilize the above framework, a newer generation of tools is required to have the ability to simulate not just the operational energy alone but the overall Life Cycle Energy inclusive of the Embodied Energy (EE) and Operational Energy (OE) through the integration of both carbon calculators and performance based simulation tools (Fig. 3).

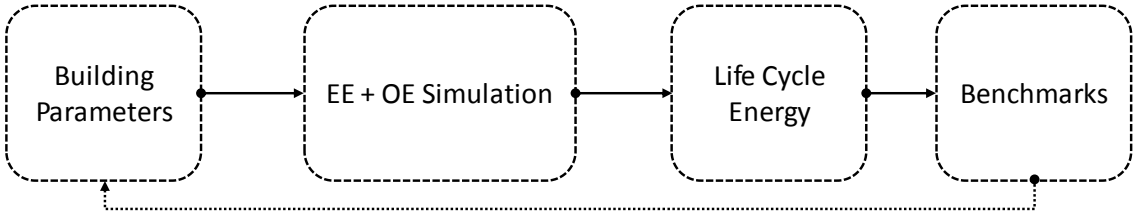

Fig.3: PBE Approach

5.4 Results

5.4.1 Quantities, Comparison and Discussion

After converting the material amounts obtained from the bill of quantities into the required input format in tonnage, the carbon emissions were estimated to be 3,663.8 tonnes of fossil CO2e broken down as shown in (Fig.4). According to the calculation method, the emissions are estimated to be within -/+ 25% of the actual expected value. Comparing the results to similar calculations conducted by other research entities the results seem to fall within acceptable ranges (Fig.5). It is however difficult to rate the accuracy of the results as the results are often reported in different units and no standardized published ranges exist as references.

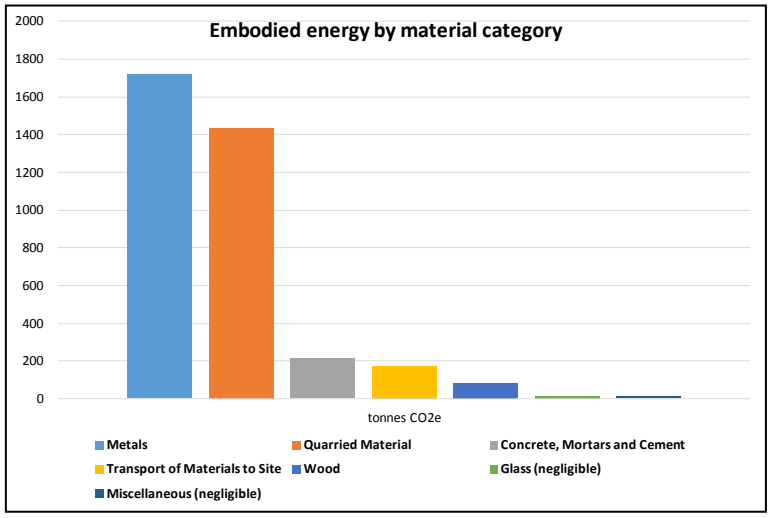

Fig.4: Embodied Energy by Material Category

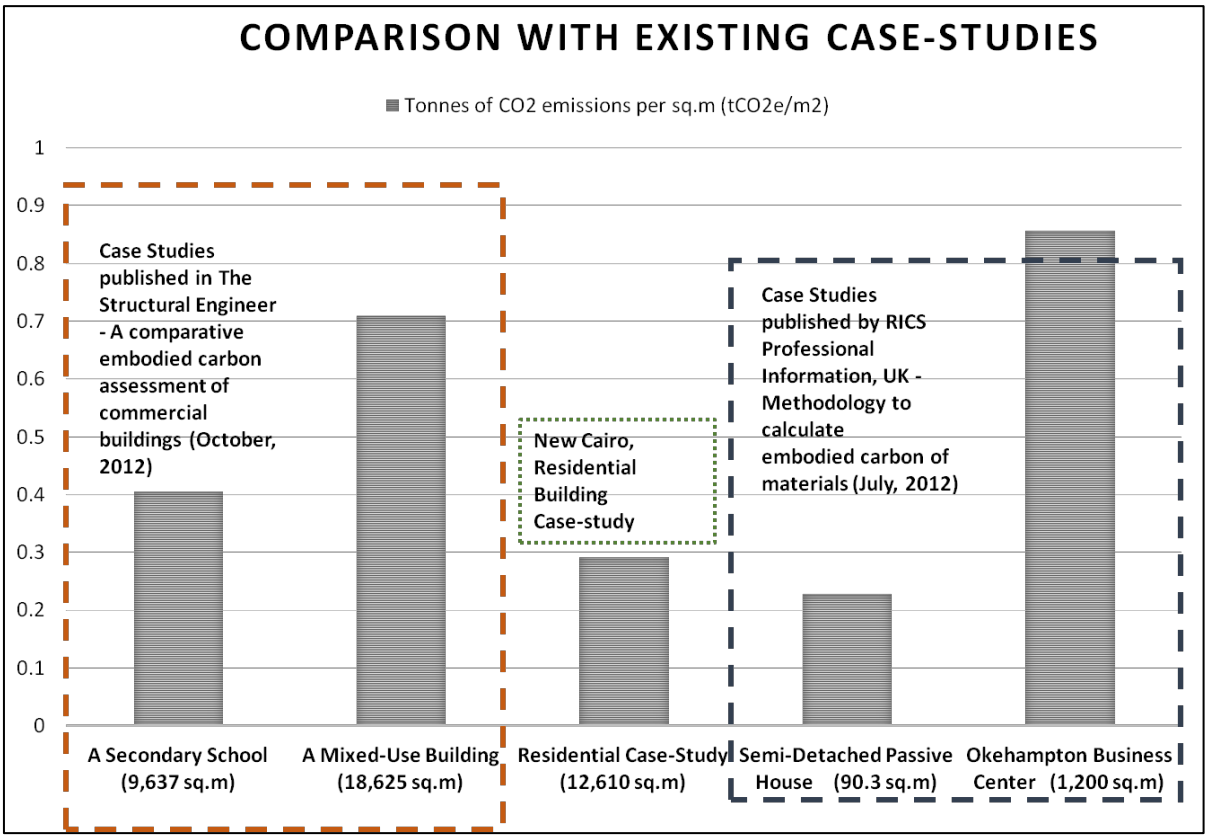

Fig.5: Comparison with Existing case studies

5.4.2 Limitations faced and assumptions made

Limitations faced while conducting the case study included the absence of a tool specific to Egypt or the Middle-Eastern region in general. Differences in geographic location signify differences in local materials, local production processes and carbon emissions in transportation and energy production. These differences thereby signify different carbon emission factors for the embedded materials in a region such as the Middle-East as compared to the emissions factors tabulated by the ICE – Inventory of Carbon Emissions - which is specific to the processes and emissions in the UK. This therefore indicates an expected inaccuracy in results when using the calculator in for a building in the Middle-East. Furthermore, among the inconveniences that was encountered while conducting calculations was that reported quantities were rarely reported as a weight. Instead reported quantities varied in units (sq.m., meter run, as well as in number of individual units) all of which had to be converted to obtain the tonnage of the materials used. Where sufficient dimensions where not provided, realistic assumptions were made associated to cross-sections of hand-railing systems, dimensions of doors, window frame etc. As paints were reported in term of surface area coverage, a standard assumption was made that every litre of paint covers an area of 12 m^2. Regarding the sources of the materials, where clear reference to the origin of the material was not made and re-tracing the specific origin of the batch of material on-site was not possible, an acceptable assumption was made from among a list of known places of import. Accordingly steel was assumed to be imported from China arriving by boat through the Ain Sokhna Port. Aluminium was assumed to be coming in from a production facility 100 km North of Luxor, totalling transportation distance of about 578 km to site. Similarly glass was assumed to be brought in from a production facility in Ain el Sokhna, totally 140km from point of origin to site

6. Discussion of research gaps, results and analysis

Throughout the research process several gaps in the field of embodied energy were identified.

Among topics of further potential research and study are the following:

1. The establishment of a parallel Carbon Emission's Coefficient Inventory such as that of University of Bath (ICE – Inventory of Carbon & Energy) that is specific to the local region[18].
2. A need for alternatives to high embodied energy construction materials currently used extensively in the Egyptian construction market such as: the reinforced concrete solid-slab, cement mortar and burnt clay bricks.
3. A search for alternative, renewable resources to substitute current high carbon-content energy sources. High embodied energy does not necessarily mean high embodied carbon.
4. Creating a set of guidelines for designing low-embodied energy buildings
5. Advancing the capabilities of simulation tools to cover a wider scope of the building life cycle.

7. Conclusion and future work

7.1 Data and research need locally

Localizing the literature review to the Middle-East and more specifically Egypt, the search identifies a large gap in published work. Differences between local building techniques, building materials; their extraction processes as well as their maintenance and transportation are all parameters that would significantly alter the expected embodied energies calculated when compared to results conducted in other countries. Differences in construction approaches and techniques reflecting local needs, trends, climatic zones, economic constraints and material availability are all parameters affecting the embodied energy of a building. When checked against existing studies done in other countries such those done in the Australia, India, the UK or the US, local results would certainly output completely different results than its counterparts. This prediction thus brings to attention the large gap in existing work, and the need of organized research work in this area.

Based on the local and international literature review a need for a localised standard for the calculation of embodied energy is needed. Although the significance of embodied energy has not yet been acknowledged nationally within Egypt, its importance is growing internationally and will need to be introduced gradually. Further research on embodied energy is especially important in a hot country such as Egypt because the embodied energy as a component of the total life-cycle energy is larger than that of an equivalent building in a colder country due to higher operational energies and as a result of more extensive heating loads. As stated by Nebel et al. [19] *"In heating dominated regions, embodied energy represents a relatively low percentage of total life-cycle energy, which may not be true for a moderate or cooling dominated region due to the latter's relatively low operational energy."* Therefore with embodied energy holding a greater share of the life-cycle energy (LCE) in hot countries, investing in research in this field would lead to a significant reduction in overall LCE.

7.1 Decarbonizing Existing Buildings

When decarbonizing a building, it is important to note that a building passes throughout many processes before reaching the end of its life-time and its point of demolition or reuse. At each of these stages different mechanical and non-mechanical processes take place, each of which consume energy and add to the total embodied energy content. With all these processes taking place, there is ample opportunity at each of these instances to reduce the amounts of energy being expended and carbon embedded.

7.1.1 Decarbonisation of Operational Energy Processes

When looking at existing buildings, because the possibilities in terms of material replacement are limited; most research has focused on the reduction of carbon content through the reduction of operational energy. Amidst the limited amount of work on decarbonizing existing buildings limited

research[17] explains different methods of reducing energy consumption in buildings. Depending on local climatic conditions, heating and cooling load reductions are approached differently. Other aspects however, remain the same for all regions. Among the recommendations made are the installation of control systems that allow users to monitor and adjust temperatures according to their needs, the replacement of high energy-consuming lights by installing low-carbon emitting light sources such as LED lamps, and the use of more efficient appliances, electronic devices as well as machinery. In temperate, cooler climates, the addition of insulation to all large surfaces to reduce heat loss is also a major factor. According to the Energy Saving Trust[20], the insulation of walls, lofts and flooring in their respective order contribute to most savings in terms of carbon emissions when compared to the insulation of other elements. It can be placed internally or externally depending on the building type and height, and windows can be secured through the installation of secondary glazing systems, the use of double-glazing or triple-glazing, and draught-proofing against unintended leakages. Where in cooler, more temperate climates the focus is on reducing heat from escaping, in hot climates the goal is to increase air movement and the prevent more heat from entering. The use of vegetation and shading structures to increase airflow through reduced temperatures around the building is essential. Furthermore, vegetation-based solutions are among the recommendations made for reducing heat admitted into buildings and can be employed in the form of surrounding vegetation, planting roof gardens and the use of landscape. Water features on the roof are also highly recommended to prevent exposed roof-surfaces. Vegetation on the roof is in fact recommended in both hot and cold climates.

7.1.2 Decarbonisation of Material Energy and Construction Processes

In an existing building the flexibility and impact of this section is relatively limited because the building has already undergone most construction processes; and materials have already been consumed. However, potential exist during maintenance and refurbishment. Below are some recommendations that can be conducted during refurbishment.

1- Materials in need of replacement can be exchanged with similar materials of lower embodied energy and carbon-emission. These materials could be of a local source to reduce transport energy, could have low extraction energies and may have low processing energies. Also they would preferably have an expected life-time equally as long as the expected life-time of the building or longer, and/or be capable of re-use or recycling at the end of the building's lifetime.
2- Construction processes during all maintenance works should be kept as minimal as possible without endangering the safety of the building (which would need more intervention)
3- All minor and major works should employ minimal energy expenditure.

7.1.3 Decarbonisation of Demolition Processes

The end of the building life-cycle is reached when the building under consideration undergoes demolition, reuse or the recycling of its original components. For an existing structure whose structural system and materials are already in existence, decarbonisation can be employed by demolition and disassembly processes that are as energy and time efficient as possible. A low energy-consuming technique of disassembly over a long period of time could very well amount to the same amount of energy expended by a high-energy content demolition method; hence, the factor of time is an important consideration.

Short Summary

Employees and staff influence building operation in various ways. The subjective opinions and resulting behaviour of users are not only determined by ‘objective’ comfort parameters (temperature, draught), but depend decisively on social aspects [1,2]. What makes the user of a building satisfied with his physical working environment?

Parameters, which determine comfort related behaviour and user satisfaction, can be found on personal and organisational level. Two main factors influencing user satisfaction and behaviour are: (1) Individual possibilities to control work environment and comfort, e.g. can users influence operating parameters of the technical systems? (2) Information on the building and its operation, e.g. do users have the feeling that their concerns and complains are taken seriously, do they feel involved in the energy performance of the building?

To get an overview of the social and psychological factors that play a role in the context of the built environment in office buildings, a questionnaire was created by author Magdalena Wicher. The findings should provide an indication for the social interrelation of the agents and thus be integrated in an agent based model (ABM).

The questionnaire about the social and psychological factors affecting satisfaction in office buildings has been distributed through an online tool (unipark) in Austrian buildings that are designed as lowest energy buildings and with plus-energy building techniques. It has also been used to analyze a low-energy high-rise office building in Graz, Austria, which will be the reference for the ABM. The questionnaire is online-based and was created in the form of a post-occupancy evaluation. POE surveys are a common instrument for assessing user satisfaction in buildings and to evaluate the indoor thermal comfort [3,4].

The questionnaire contains several items on staff’s behavior in non-comfortable indoor conditions which allows to analyze the effects of user behavior on energy consumption of the building. Among these it also provides input data concerning the comfort of occupants for an agent based modelling (ABM) of the user behaviour.

Agent-based modelling (ABM) is a simulation methodology that can account for the interaction between agents, e.g. the exchange of informational messages between individuals in an network can be modelled and how this exchange affects changes in behaviour [5]. ABM has attracted wide interests in the social sciences because it is particularly able to reflect the relationship between human behaviour and factors present in the environment that can influence human behaviour.

Agent-based modelling also plays an upcoming role in environmental psychology. The simulation of the complex interaction of humans and their social and physical environment is characterised by the complexity of the involved factors and processes [6].

The activities of the staff of a high rise office building in Graz to realize their personal thermal comfort conditions are the starting point for the ABM. Persons are assumed to be comfortable if indoor conditions are within the “comfortable” region of the comfort diagram according to the PMV/PPD-model of ISO 7730. A list of possible activities to alter the thermal comfort variables is available, among others: turning on the central heating system, opening the door of the own room to the corridor, opening the window next to the own working place, turning on a fan on the own desk, change one’s clothing.

Persons like to talk about thermal comfort and thermal variables in the office, in specific if conditions prevailing are on the brink of the comfort region. People also talk about their activities to reach the comfort region. So chats among colleagues are the relevant occupants’ interactions that are taken into account. Agents will act, if the limit of their accepted operative temperature/ humidity/ draught region is reached. Colleagues acting the same way will improve the conditions. Colleagues counteracting will worsen the situation.

It is the goal of the ABM to model the collective effect of user activities. Questions of interest are: To what extent can an “average user” be defined? Is the “average user” always (in all temperature domains) the same? Are there any indications for clustering of user behaviour? When do agents act? When do agents communicate? A first simple model will provide stochastic communication within the same room, an advanced model will let agents communicate with all other agents according to a „friend“-relationship (same project, same room, same preferred comfort range).

The agent based simulation could further be used to draw conclusions of the building’s operational energy use. The suitability of the model of agent based social simulation of user behaviour for the context of (nearly) zero energy office and service buildings is tested.

Abstract

In recent years, the so-called long-term environmental sustainable CLT (cross-laminated timber) building system has been a topic of great interest for multi-storey apartment buildings. This system can be an alternative to current reinforced concrete building systems and it offers great advantages in cost, speed and carbon reduction, while opening many questions in the design field.
In this paper, we present innovative student design projects for mid-rise buildings made of CLT. The presented projects are a part of the master studio “Timber in the City – Red Hook”, held at TU Graz, Faculty of Architecture in the summer semester 2013. The first objective of the project was to investigate the possibilities for design using scale models, in combination with parametric design and engineering. The second objective was to define an innovative and interactive facade system as a sustainable design element.

Keywords: timber, mid-rise building, sustainable building system

1. Introduction

Single-family buildings constructed with the Cross Laminated Timber (CLT) system are already fully established in Europe, given that the level of energy efficiency of these buildings may be compared with passive houses. Another very important application is the reconstruction of facades, where panels are used with solar panels to achieve high-performance insulated facade elements [1].

In the last few years, there has been a rapid and noticeable development of CLT building systems for multi-storey apartment buildings. The height of constructed multi-storey apartment buildings is closely linked to the building codes and building insurance in individual countries, and it varies between three floors in Austria to thirty floors in Sweden.

Presently, the tallest timber buildings in Europe are the eight-storey residential building “Bridport House”, designed by Karakusevic Carson Architects, and the “Stadthaus”, designed by Waugh Thistleton Architects in Hackney, London. In Australia the highest building is the recently completed ten-storey apartment building “Forte”, designed and constructed by Lend Lease in Victoria Harbour, Melbourne. In 2012, the Canadian architect Michael Green developed the so-called FFTT system, proposing 30-storey buildings with predominantly wood solutions (with steel beams) for high-risk seismic areas like Vancouver [2].

2. CLT in Multi-Storey Buildings

The reason for the rapid development of the CLT structural system and the establishment of related building codes is associated with climate change and multiple benefits of CLT, such as structural and environmental behaviour. From a structural point of view, its benefits concern mechanical properties across to advantages during assembly, which also influences, the financial benefit of this product.

Cross Laminated Timber panels can be produced in a factory environment with different surface qualities, which means the material is faster to use and build on site and therefore highly cost-effective. In the production, the timber panels undergo a process whereby they are stacked crosswise on top of each other and glued to each other with high pressing power to form large-format solid timber elements. The crossways arrangement of the longitudinal and crosswise laminates reduces the swelling and shrinkage in the board plane to an insignificant minimum, while its static strength and shape retention increase considerably.This process delivers an alternative to concrete and steel that can withstand the same pressure as prefabricated concrete [7]. A part of the fabrication process is CNC milling, with the opening and guides for installation milled for each individual panel. In Austria the maximum panel size is about 3m x 16m x 0.5m and is limited by means of transport.

From an enviromental point of view, wood is naturally CO_2 neutral and energy efficient in every respect. For example, by using CLT one ten-storey building reduces CO_2 equivalent emissions by more than 1,200 tonnes when compared to concrete and steel [2].

The largest influence on the final price of CLT buildings is determined by the price of the raw material and labor costs, which vary extremely across countries. On the one hand, the price of the raw material wood for such buildings is 10% higher than the price of the material for massive constructions like concrete or brick. On the other hand, however, prefabricated CLT panels increase productivity by lowering labor requirements and facilitating assembly. This decreases the total building costs about 40% compared to the same buildings built with reinforced concrete [2].

All these benefits have convinced many countries all over the world to use CLT technology, along with their willingness to change the national standards according to the constantly improving CLT building technology. In many innovative projects [2], [3], [4], [5], [6] they try to push the boundaries of the building possibilities and to show the great potential of this building system. If we consider the use of CLT in hybrid structures, it facilitates the use of such constructions in multi-storey buildings in countries with highly restrictive building codes.

From an architectural point of view, wood greatly improves the quality of a building's interior or exterior space. In contemporary architecture, there are a number of architects who use a wood structure as primer or secondary structure. In the projects "Centre Pompidou" in Metz and "Haesley Nine Bridges" the architect Shigeru Ban used glulam structures for the primer non-standard roof construction. For the Tamedia New Office Building in Zürich Ban designed a five-floor building with the main modular structure entirely in timber. Although the design possibilities of CLT for multi-storey buildings have not been sufficiently explored, there are currently many initiatives worldwide that promote wood as a sustainable building material.

One of these initiatives was a competition for Canadians and Americans in 2012/13 on the topic "Timber in the City". The program intended to engage students and young architects in repurposing old cities with buildings that are made from renewable resources. The competition challenge was to design mid-rise, mixed-use housing units sited in Red Hook, Brooklyn. The main focus was on the structural use of timber, with an emphasis on innovations in wood design. This interesting competition inspired us to choose a similar competition program for our master studio, for which we restricted the topic timber to CLT panels and the Kielsteg system. We placed this limitation bearing in mind the timber industry in our country. Austria is a European country with a century-long timber building tradition that has led to innovations like the CLT [7] and Kielsteg [9] technology. Austria introduced the CLT structural system in one and two-storey house building.

Kielsteg elements are lightweight and strong wooden construction elements that can be used to build roofs and structural floors with large clear spans. They have a linear cellular structure, with strips of timber forming top and bottom flanges, and are connected by zigzag webs of plywood or oriented strand boards (OSB) [9] .

The Austrian forest industry is a sustainable system and companies producing CLT panels and Kielsteg elements obtain raw material from sustainable cultivated forests. Additionally, the building codes and insurance requirements in Austria are very strict and the maximum height of buildings is limited to three floors.

3. Challenges of Timber

The master studio “Timber in the City – Red Hook” held in the summer semester 2013 had the aim to investigate the possibilities to use timber technology as the primary structure or part in a hybrid building structure for mid-rise buildings (Fig. 1).
The first objective of the studio was to define parametric design tools to include static calculations in the early stage of the design process. This approach proved highly flexible in terms of the design decision and real-time feedback for the designer concerning the spans and size of the building elements according to the allowable stresses in the construction. At the same time, our approach allowed us to explore how parametric modelling can contribute to conceptual exploration and how the size of CLT panels and Kielsteg elements can influence the existing design. In addition to parametric design, the students checked their project development by making digital fabricated scale models. The students could rely on their scale models to directly verify the design and remove any flaws affecting the structural stability or aesthetics of the building.
The second objective was the definition of an innovative and interactive facade system as a sustainable design element.

Fig. 1 Scale models of the studio project “Timber in the City”

A special focus of the project was the efficient use of standard materials in hybrid structures, such as wood-concrete or wood-steel. In fact, it is well known that the inefficient pre-fabrication of panel elements often produces off-cuts and waste, which greatly increases the costs of a building. This is why the process of design in this project started with geometry and static conditions. The students were introduced to the fabrication process, technical possibilities and limitations of CLT and Kiel-steg elements, as well as to the mechanical constraints and geometric conditions that satisfy the requirement of material cost-effectiveness.

3.1 Design

An interesting fact is that schools of architecture worldwide do not study the CLT structural system, so there is a lack of understanding of the system or of a more extensive use of this material in design. The CLT system (if present) is usually part of the curriculum of civil engineering schools. This situation opens up many questions, from the structural to the formative aspects.

Timber design can be defined as the most modern method of construction in the market in terms of contemporary “information society”. No other system could explain better the relationship between technology, fabrication methods and architecture [8]. In this way, the proposed parametric approach is an ideal connection for the process of design.

The master studio projects were not strictly limited to the current technical achievements; accordingly, the students were strongly supported to develop new ideas to combine new materials and techniques.

The next part of the paper gives a brief description and shows images of some of the students’ projects.

3.2 Students’ projects

3.2.1 Alfred Angerer, “Hanging Gardens of Brooklyn”

The main idea of the project was to develop a hanging hybrid timber mid-rise building (Fig. 2a). The main structure consists of a CLT core and two steel grates (Fig. 2b). The first steel grate is in the middle of the building and serves as a technical floor. The second one is at the top of the building. Sixteen timber boxes are supported by these elements (Fig. 2c). The advantages of the system are that it is a load-bearing structure without load-bearing walls, it has free floor plan organization (Fig. 2d) and a non-structural façade. The roofs of some boxes were designed as green gardens with multi-functional potential.

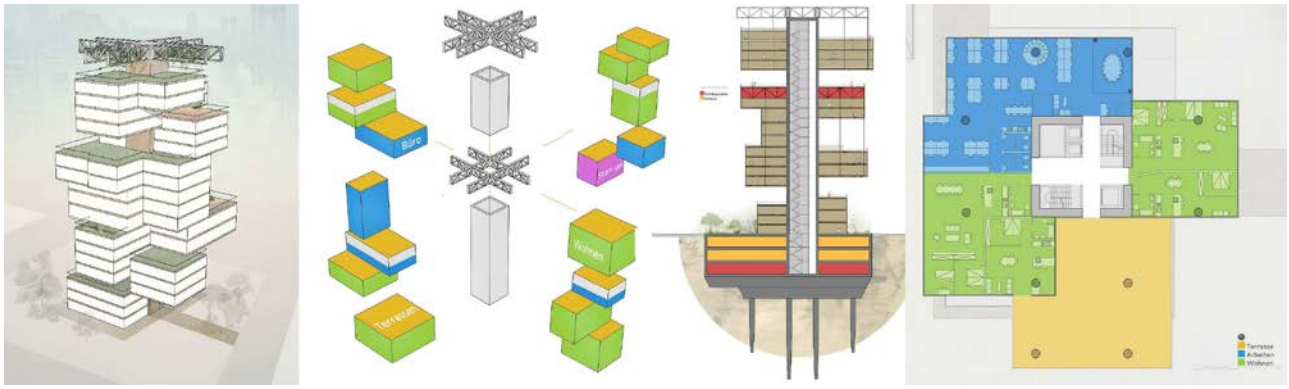

Fig. 2a) Hanging Gardens of Brooklyn, b) the load-bearing structure, c) a section, and d) the free floor plan

3.2.2 Hugo Bernard-Lecharpentier, “Roof Structure”

The whole site is covered with a quad glulam structure. All the four buildings (two apartment and two administation buildings) have CLT cores and slabs and vertical supporting glulam elements (Fig. 3a). The interactivity of the system is integrated in the roof. The glulam roof system is covered with a tensile sensor structure that can be closed and opened depending on different environmental factors like temperature, average radiation, cloud factor or diffuse horizontal radiation (Fig. 3b).

Fig.3 All-timber structure (a) with an interactive roof structure; (b) a render and scale model

3.2.3 Ivana Djuric, “Pipe Structure”

The core (made of curved CLT panels), two glulam bamboo pipes and planar CLT slabs are the main structural properties of this timber structure (Fig. 4a). The free form shape of the bamboo pipes offers an interesting organic appearance and dynamic of the floor plans (Fig. 4b). At the facade level, the grid structure of the pipes is “repeated”, with the irregular bamboo structure adding a special dynamic quality to the planar facade envelope (Fig. 4c).

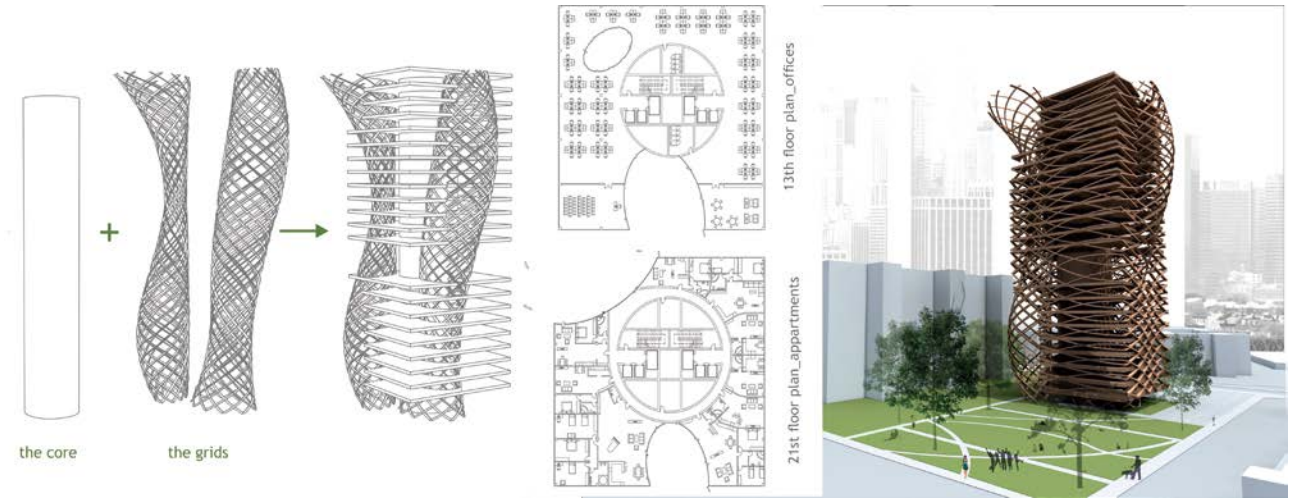

Fig. 4a) Structural system, b) the ground floors, and c) a 3D model

3.2.4 Patrik Müller, “Twimber Towers”

Two twisted towers with a quadratic plan floor are connected via a wood production area at the height of the first two floors (Fig. 5a). Above the two common floors, each tower has 15 floors. The

structural system is completely made of CLT panels. The purpose of the shear CLT walls (Fig. 5b) is to stabilize the twisting geometry of the building. The CLT columns on the facade follow the twisting form; the facade itself is made of insulated glass. The twisting form provides a better flat orientation in the south direction. The twisting design process projects onto the glass facade with different color settings.

Fig. 5a) Twimber Towers project, b) the shear walls in the floor plans, and c) a scale model with an interactive facade

3.2.5 Katharina Puck, “Organic Tower”

The inspiration for this project came from the Aqua Tower in Chicago by Studio Gang Architects. Unlike the prominent horizontal divisions of the Aqua Tower, the Organic Tower has prominent both horizontal and vertical divisions (Fig. 6). The number and size of vertical supports came from a parametric structural analysis. In order to respond to the overheating cubic form design, an organic quality was added to serve as active shadowing elements. The CLT walls and slabs are connected with a locking system. Thanks to the parametric and static model, it was possible to calculate the total number of supports, whose thickness is in correlation with the length of each individual support.

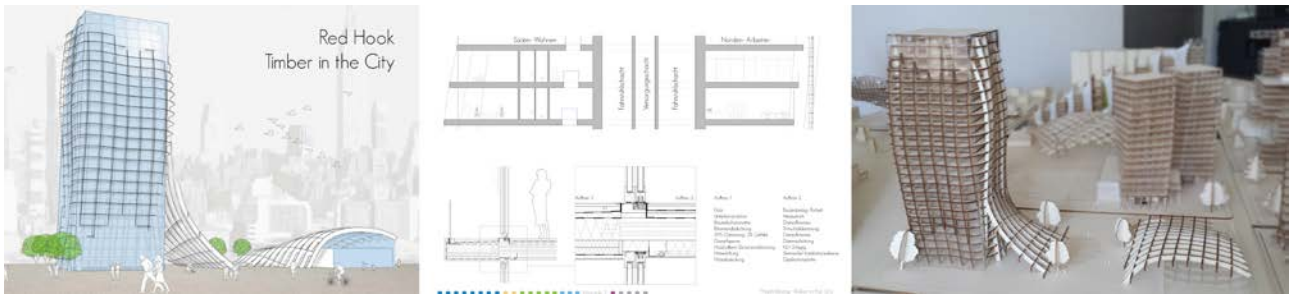

Fig. 6a) Render, b) construction details, and c) a scale model of the “Organic Tower”

4. Conclusions

Many prejudices about wood as a building material in contemporary architectural practice have led to concrete and steel being the most frequently used materials in the construction of multi-storey buildings. These materials and buildings significantly contribute to large volumes of CO_2 output and

climate change. A current challenge concerns the promotion of alternative materials for this type of buildings. Many initiatives worldwide promote multi-storey buildings constructed of wood, which is indicative of a desire to change the situation.

The possibilities of designing multi-storey buildings made of timber are poorly studied, and through our studio “Timber in the City” we tried to evaluate the formal potential of this material. In the first stage of the design process, we implemented parametric design and static calculations, and in the second phase we studied the possibilities of using interactive facade systems. As an analysis of the students’ work, it can be concluded that architectural design with timber offers a great potential and the use of different systems such as CLT, laminated wood or Kielstieg combined with concrete or steel offers up to a 90% better CO_2 balance than standard buildings. The question how the building industry and markets perceive timber buildings is still strongly related to financial interest and safety standards.

5. Further work

In order to further examine the potential of these systems, we plan an intensive cooperation between architects, construction engineers and technologists in the next studio. It will include:

- Analysis of the structural system of the traditional Japanese pagoda buildings
- Possibility of fabrication of curved CLT panels to be used in non-standard structures
- Formal value of single-curved Kielstieg elements and the possibility of their fabrication
- Examination of the possibility of using different types of wood for CLT panels. This primarily refers to using tropical timber (more weather resistant) for the outer panel layer.

6. Acknowledgements

The authors would like to thank our colleagues Elmer Hess, Thomas Bogensperger and the following students involved in the Studio project “Timber in the City” on the faculty of Architecture, TU Graz: Alfred Angerer, Markus Bartaky, Hugo Bernard-Lecharpentier, Ivana Djuric, Kathrin Hirsch, Wolfgang Moritzer, Patrick Müller, Georgi Nikolov, Mateusz Pankiewicz, Katharina Puck, Christopher Satler and Michaela Worschitz.

Short Summary

Part of the research project “life cycle improvement of the building quality” (“LQG”), financed by the Austrian Research Promotion Agency (FFG) and six industry partners is the comparison of sustainable building certification systems.

This study describes the differences concerning infrastructure and mobility in several building certfication systems for residential buildings: the Austrian klima:aktiv declaration system and Total Quality Building (TQB) certification system are compared with the German Sustainable Building Council (“Deutsches Gütesiegel für Nachhaltiges Bauen”, DGNB), the Swiss MINERGIE-ECO® and with two international systems, Leadership in Energy and Environmental Design (LEED) and Building Research Establishment Environmental Assessment Method (BREEAM). It demonstrates how these systems deal with the aspects of infrastructure and mobility, where the deficiencies are and how the criteria could be improved. Moreover, the Swiss leaflet SIA 2039 Mobility – Energy Needs Dependent on Building’s Location (“Mobilität – Energiebedarf in Abhängigkeit vom Gebäudestandort”) is described and applied in its corresponding calculation tool.

Infrastructure and mobility is treated differently in all the systems. Some system boundaries simply ignore aspects of mobility for building declarations in order to do it correct in a “scientific way”. Thinking in a holistic way, from the point of sustainability it is clear that a “passive house” or “plus energy house” does not really work if you need lots of energy for mobility by using this building. A building depends completely from the site, it never changes the site. Therefore the system boundaries have to be extended from the building itself to the urban settlement. Examples are discussed.

Keywords: Certification systems, mobility, system boundaries

1. Introduction

Within the current 5 years cooperative research project about “life cycle improvement of the building quality” (LQG - “Lebenszyklusorientierte Qualitätsoptimierung von Gebäuden”, 2008-2013), financed by the Austrian Research Promotion Agency (FFG – “Österreichische Forschungsförderungsgesellschaft”) and six industry partners, 5 Austrian Universities of Applied Sciences develop inter alia a qualitative database [1] [2]. National and international building rating systems and certification systems, which are analysed by the 5 Universities of Applied Sciences in various ways, do have crucial parts in quality assurance and optimization of buildings. Thereby the criteria of urban building and qualities of buildings are inspected as well by the University of Applied Sciences Upper Austria.

The problem of the system boundaries in rating systems can be figured out well. Are we permitted to refer to a “passive house” or “plus energy buildings” as such, if mobility becomes a grave factor for the energy consumption of a building due to the building’s site? Should the energy demand respectively the energy consumption be assessed without mobility factors anyway? Nowadays, the

term “total energy balance” has to be taken literally and should not ignore basic holistic coherences under the guise of “clean scientific separation”. Fig. 1 shows the system boundaries in “plus energy” houses. The primary energy demand can only be reduced by a conscious use of materials, mobility and energy. “Passive houses” are defined as a necessary loss minimizing, but only with the additional profit-maximizing strategy, which means the use of renewable energies as photovoltaic systems, solar thermal systems, etc., it is possible to achieve the “plus energy“ area. If credits for mobility and grey energy should be produced additionally, the application is unavoidable.

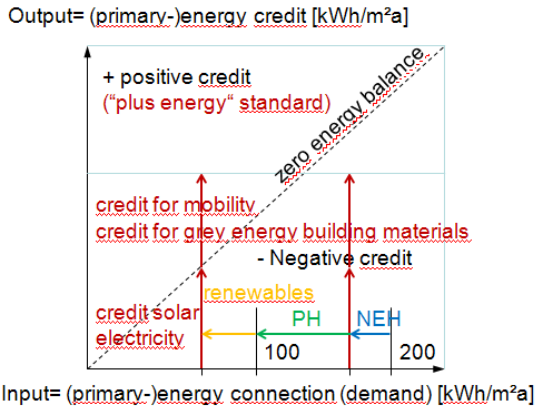

Fig. 1: System boundaries “plus energy” house

2. Urban building aspects of building rating systems

In order to achieve the highest aim of quality optimization of buildings, the user satisfaction, as many criteria of the comprehensive building ratings as possible should be performed eminently. Commencing with a comfortable indoor air quality, which is obviously measureable with appropriate methods with different efforts, a high user satisfaction can also be improved by building structures and location factors. Criteria for mobility respectively infrastructure figure a high importance in these aspects, whereas mobility factors are not only defined by the motorised private transport, because this assumption resulted in the known uncomfortable indications as urban sprawl, environmental pollution and the daily traffic jams in agglomeration areas. These problems will intensify: the trend is towards from 577 cars per 1,000 inhabitants in Austria at present to 680 cars per 1,000 inhabitants in 2021 [3].

Hence, urban and traffic planner demand the first priority for the public transport facilities as tram, underground and bus over the motorised private transport. In addition, safe and secure foot and cycle paths, car-free areas and connections with attractive private and public green spaces have to be encouraged. A previous research project exposed an approximate compliance of the requirements of energy-efficient and ecological urban construction and the parameter for child- and family-friendly urban construction. Moreover, the “house in Green” (rural area) is not identical with the child-friendly construction, quite the contrary: moderate concentrated building structures are mostly more child-friendly than detached houses [4].

3. Survey of building certification systems

The interest in building certification systems increased sharply in recent years. Therefore, more investors discern that sustainability is dependent from both energy-efficiency and consideration of comprehensive ecological, social and economical factor. As a result the approach of lifecycle orientation enforced – at least theoretical. The practical realization will take still a few years due to the enormous complexity of this theme. Basically each relevant certification program affords significant approaches towards broad optimizations of buildings, even if they have various focuses.

Several Austrian rating systems, including klima:aktiv, IBO Ökopass and TQB-Total Quality Building, are long-term securely established. Furthermore, following international certification systems

are appreciable in the German-speaking regions: “Passivhauszertifizierung” (passive house certification) (PHI, Germany), DGNB-“Deutsches Gütesiegel für Nachhaltiges Bauen” (Green Building Certification for Sustainability), Minergie (Switzerland), LEED-Leadership in Energy and Environmental Design (USA), BREEAM-Building Research Establishment Environmental Assessment (GB) and EU Green Building. Since the standard literature about building certification is rather spare, the book “Zertifizierungssysteme für Gebäude” (certification systems for buildings), which was published in 2010, constitutes an important basis for interested parties, who want to enter into the topic [5]. Nevertheless, the book do not contain Austrian building rating systems, but it issues a compact survey concerning main points, costs, etc. of national and international rating systems [6]. The free declaration system “klima:aktiv” can be referred as the simplest system, whereby approaches of ecological, social and economical sustainability are assessed in addition to climate protection and energy-efficiency. TQB is a long-term developed and detailed system, which is 100 % compatible with klima:aktiv. In consequence of the partial specific national requirements the national systems should be preferred from the viewpoint of the authors. Nevertheless, a known international system as LEED or BREEAM can provide advantages for international investors, especially in non-residential construction. Information about the relevant systems and further links can be found in the qualitative database of the research project mentioned in chapter 1 [7].

4. Criteria in building certification systems

It is striking that criteria for location and mobility are considered and assessed particularly different, in marked contrast to criteria for energy-efficiency, which are defined by the EU Directive about the energy performance of buildings (apart from LEED: ASHRAE Standards) [8] [9]. For the comparison only the available catalogues of criteria for residential buildings are used intentionally, but not the particular existing catalogues for urban quarters, although these building certification systems should integrate the most significant aspects of urban building to be holistic orientated systems [10]. The strict separation in building level and urban planning level can result in doubtful partial assessments and is contrary to the holistic approach from the viewpoint of the authors. Fig. 2 depicts a survey of the comparison of the different certification systems for residential buildings. The green bars show the total amount of the criteria, the blue ones the amount of infrastructure criteria and the red bars the amount of density respectively space efficiency. The several systems are described in the chapters 4.1 to 4.6 in detail.

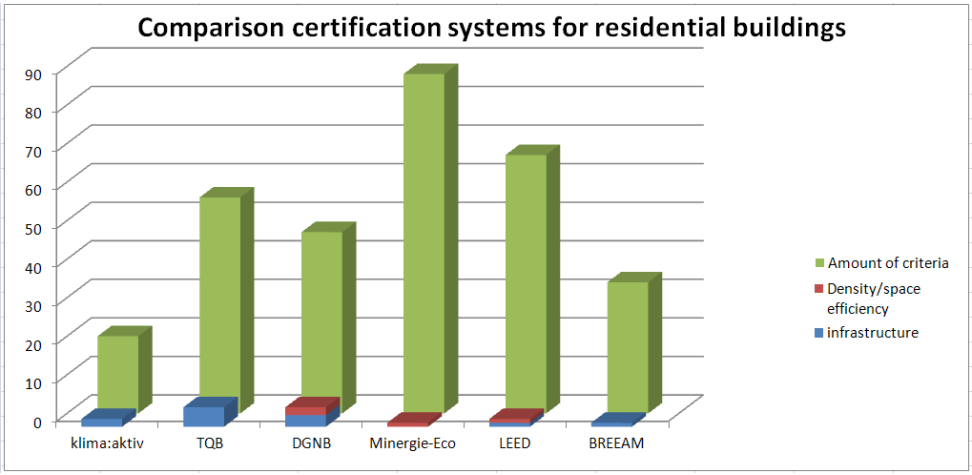

Fig. 2: comparison between the certification systems for residential buildings

4.1 KLIMA:AKTIV

Although klima:aktiv constitutes rather the lowest standard of comprehensive rating systems and does not refer as “certificate” but as self-declaration system, the most important mobility factors can already be assessed: The quality of infrastructure is defined by food supply, leisure facilities, childcare, education, public transport stops as well as foot and cycle paths and cycle storage pos-

sibilities. The demand of the everyday life should be located within a radius of 500 m linear distance and has to be verified in a site plan. The mobility factors are listed in the category “Planung und Ausführung” (Planning and Execution), whereby criteria for site and mobility can achieve maximal 60 out of 1120 possible points (the overall result is limited with 1000 points). Fig. 3 gives a survey of all categories of the assessment klima:aktiv. The percentage of the category planning amounts to 8.93 %, taking into account that only 38.7 % of it deal with site and mobility factors (demand of everyday life, parking spaces for bicycles, etc.) [10].

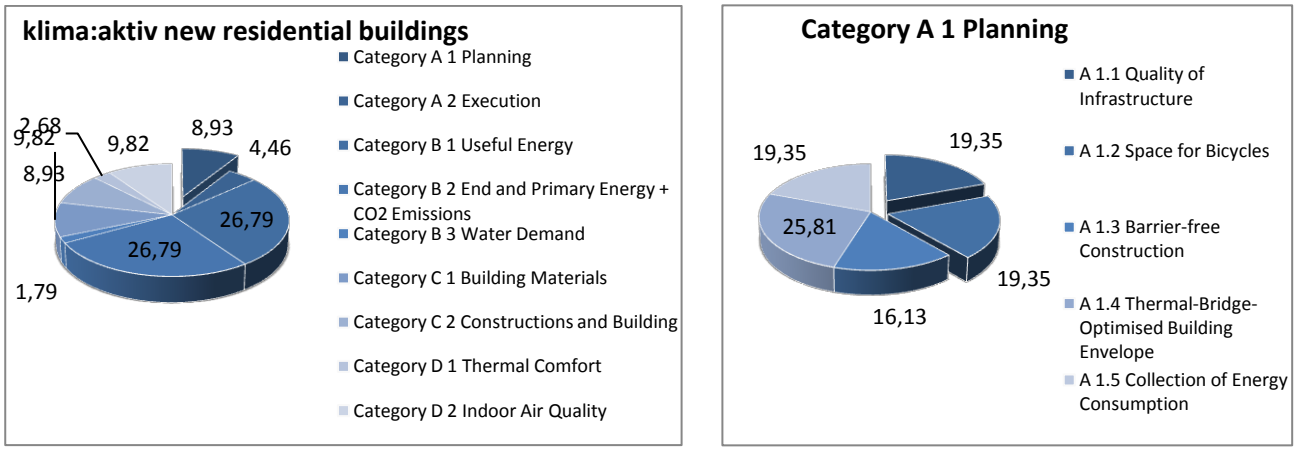

Fig. 3: System "klima:aktiv": survey of all categories of the assessment an categorie A1 in detail. The highlighted parts contain criteria for mobility, 38.7 % of 8.93 % and thus 3.5 % of the total rating deal with mobility [10].

4.2 TQB

This system is a combination of several proved Austrian systems (klima:aktiv, IBO Ökopass, TQ 2002). It can be referred as the most comprehensive and scientifically sound national system and the compatibility with klima:aktiv has to be particularly emphasised. They are nearly identical, TQB divided the requirements into several criteria, but more detailed, whereas klima:aktiv summarizes them in only one criterion. Consequently, a certification process can take place in various phases. The proportion of the energy-efficiency assessment was systematically reduced, to get an equivalent distribution of the requirements for the 5 categories with 200 out of 1000 points each: site/facilities, economical and technical quality, energy and supply, health and comfort as well as resource-efficiency. For that reason the klima:aktiv mobility factors can be found in TQB in principle, but in a more differentiated way. Depending on the distance to the factors e.g. connection to the public transport (300-500 m) or quality of the local supply, of leisure facilities and social infrastructure (500-1000 m) points are assigned. Moreover, the safety of access routes and biking facilities are rated.

4.3 DGNB

The DGNB-quality label is a certificate of the second generation and had the potential to be an international groundbreaking system. Indeed the system takes an exceptional position in comparison with the other systems, because site and mobility factors are assessed in a separate category, but this category does not influence the total evaluation of the buildings, it is mentioned additionally at the certificate. Consequently, it does not play a decisive role in awarding the label (Gold/Silver/Bronze), how the criteria for site and mobility are rated. Hence, situations are possible that buildings are assigned with “Gold”, although the site and mobility factors are miserable. Since the first system release in 2008/2009 it has been criticised on the part of the author that buildings are inextricably linked with their locations and the assessment of the site must not take place separately. Meanwhile following “scientific need for editing” is mentioned in the standard literature for building certification: It says that the current solution was a pragmatic approach to establish a German system, but has to be revised now. Especially the assessment of the site quality should have an influence on the total assessment similar to BREEAM and LEED. The structure emerged

due to the time pressure during the system development, but for several years the balance limits have been enhanced for energetic assessments [5]. As a consequence of the lack of influence, the mobility factors in the DGNB system are not amplified in this paper. In main system only the convenience for bicycles and space efficiency is assigned.

4.4 MINERGIE ECO®

The Swiss system MINERGIE® is available in several versions, where only MINERGIE ECO® is comparable with the assessment of the other systems. At the moment about 200 residential buildings are certified with MINERGIE ECO® in total [11]. Site factors are listed in the category "Gebäudekonzeption" (GN 16) (building concept) and do not have any influence on the result of the assignment. Expandabilities (densification) are rated with only 1.16 %, mobility factors are missing, although the Swiss leaflet 2039 would provide a scientific basis for these factors [10]. In chapter 5 the leaflet and the Swiss situation are described more detailed.

4.5 LEED

Due to 25,000 registrations and about 6,000 certifications of residential buildings in 2009 [5] LEED can be referred as one of the most important international certification system and is surely the most well-known. In "LEED for Homes" the certification levels "Certified", "Silver", "Gold" and "Platinum" can be achieved. Criteria concerning site and mobility are evaluated in the categories Location & Linkages (LL) and Sustainable Sites (SS). LL5 (Community Resources) has a percentage of 2.2 % of the total weighting and assesses the distances to public facilities. Depending on distance points are assigned, if the distance is a ¼ mile (400 m) the maximum points are given, otherwise the facilities have to be maximal a ½ mile (800 m) away from the building. SS6 (Compact Development), which rates the amount of dwelling units per acre (4,046 m^2) of buildable land, attends with 2.9 % to the total evaluation.

4.6 BREEAM

BREEAM is the oldest certification system, hence it was developed 1990, and is considered as basis for the international systems of the first generation (as LEED). It can already refer to 800,000 registrations of residential buildings and 115,000 certifications in GB (2009), of which residential buildings constitute a large part [5]. In total 9 categories are assessed, which are similar in the various versions. In this paper the "Code for Sustainable Homes (CSH)" (2007) is treated. The certified buildings are sectioned in 6 levels; the best buildings can achieve level 6 "Outstanding", followed by "Excellent", "Very Good", etc. In category 1 "Energy and CO_2-Emissions" the criterion ENE8 (Cycle Storage) influences the total result with 4.1 %. Apart from the Cycle Storages there are not any site or mobility criteria.

5. Extended criteria for mobility: leaflet SIA 2039

5.1 General information

Based on the Swiss vision of the 2,000 Watt Society and different deduced leaflets, e.g. SIA 2040 "Effizienzpfad Energie" (Efficiency Path Energy) and SIA 2032 "Graue Energie von Gebäuden" (Grey Energy of Buildings), the leaflet SIA 2039 "Mobilität – Energiebedarf in Abhängigkeit vom Gebäudestandort" (Mobility – Energy Needs Dependent on Building's Location) and the for that reason developed ExcelTM-Tool [12] were published by the Swiss Society of Engineers and Architects (SIA – Schweizerischer Ingenieur- und Architektenverein) in 2011. The purpose is to point out, how criteria for mobility will be considered via the urban planning and the building certificates in future and the provision of a scientific evidenced calculation option for the building-related mobility.

As a strategy of the Swiss Federal Council the 2,000 Watt Society is a criterion for the climate and environmental policy with a continuous output of primary energy of 2,000 Watt and 1 ton CO_2-equivalent per person and year. Initially the building-related mobility is included in the energetic overall view (non-renewable primary energy, greenhouse gas emissions) and mean values are used through correction factors for unknown user mobility. Moreover, the grey energy for the pro-

duction and maintenance of vehicles and infrastructure is considered. The used data for the mundane and non-everyday mobility are predicated on the micro-census Switzerland of 2005. The appertaining socio-economical influencing factors as income, occupation and origin of the users do not affect the results; therefore the data of the average Swiss user is applied. If the mobility behaviour is known, the dedicated calculation method has to be chosen. The calculation is effected by the means of individual-related information and additional of the energy reference area of the building. Due to the available exemplary calculations following perceptions derive therefrom: Optimum locations and mobility facilities enable about 40 % lower energy consumption and greenhouse gas emissions in comparison with the Swiss average values. Detached houses have to feature better values in production and operation to achieve the overall goal. Since the mobility rates in rural areas are more adverse than in urban areas, the requirements are tighten. Fig. 4 represents the interaction for buildings with unknown user mobility, the calculation of the primary energy from everyday mobility. The interaction can be applied for the greenhouse gas emissions.

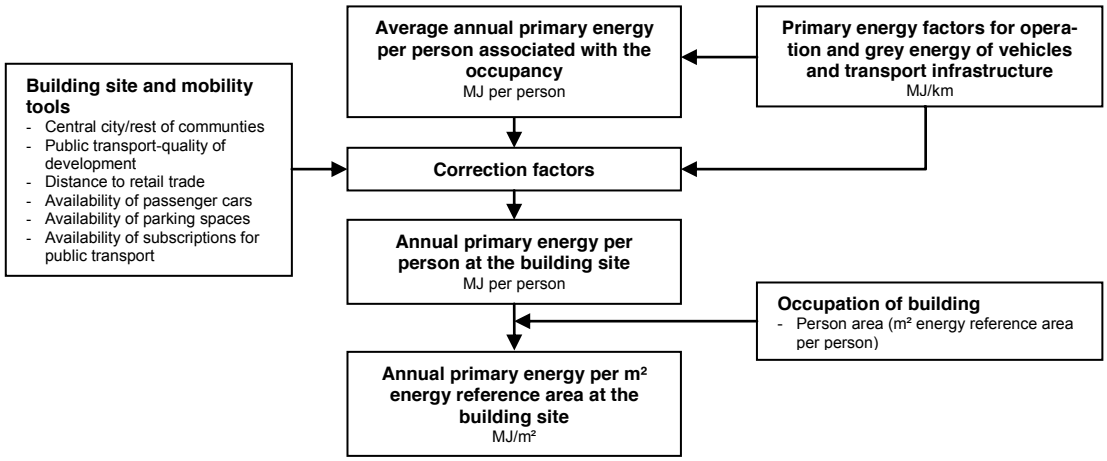

Fig. 4: Interaction for buildings with unknown user mobility [12]

5.2 Results

The optimal sites and mobility facilities enable already an approximately 40 % lower energy consumption and green house gas emissions as opposed to the Swiss average values. As a consequence, detached houses do have to show appropriate values in production and operation to achieve the total goal. In rural areas the requirements intensify due to the unfavourable mobility situation. Fig. 5 reveals the results of SIA 2039 comparing urban and rural area and the car fleets of 2010 and 2050.

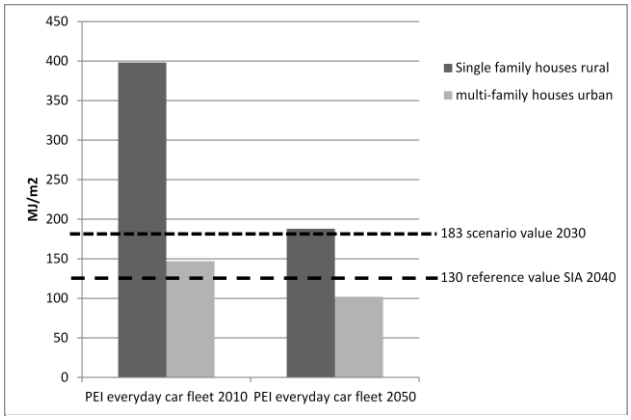

Fig. 5: Results of SIA 2039 comparing urban and rural area and car fleets of 2010 and 2050. The PEI requirements of SIA 2040 can only be achieved in the urban area with the car fleet of 2050 [12]

6. Examples

The following chapters 6.1 to 6.3 describe several examples, whose executions are comprehensive and which focus on the holistic approach.

6.1 Active house as power plant

The two-storey detached house is located in Leonberg, Germany and is executed as a net “plus energy” building”. Following data point out the energy efficient building technology and are displayed in Fig. 6 [13]:

- Southbound pent roof with 15 kWp solar power system and 7 m² solar thermal system
- Solar yield of up to 14,500 kWh/a = 60 kWh/m²a
- 30 kWh/m²$_{\text{Living space}}$a heat demand
- Building management system and monitoring for load-management
- Wall: 0.22 m thermal insulation 032, u-value=0.15 W/m²K
- Roof: u-value=0.12 W/m²K
- Windows: u-value=0.9 W/m²K, 3-glasses-insulation glazing, U_g=0.6/0.7 W/m²K
- n50=0.75 h^{-1}, ventilation with 85 % heat recovery
- Ground heat exchanger air
- Heat pump COP 4.5-5.0 / 3 probes with 95 m / floor heating system, but operation only as an exception
- Buffer storage 825 litres
- Control of the hours of operation of domestic appliances
- Consumption: heat pump 15 kWh/m²a, household 25 kWh/m²a

The domestic electricity has a high utilization rate (at least 50 %) by means of load-management and application of power surplus (20 kWh/m²a) for private electromobility (10,000-15,000 km/a) and battery storage (6-8 kWh).

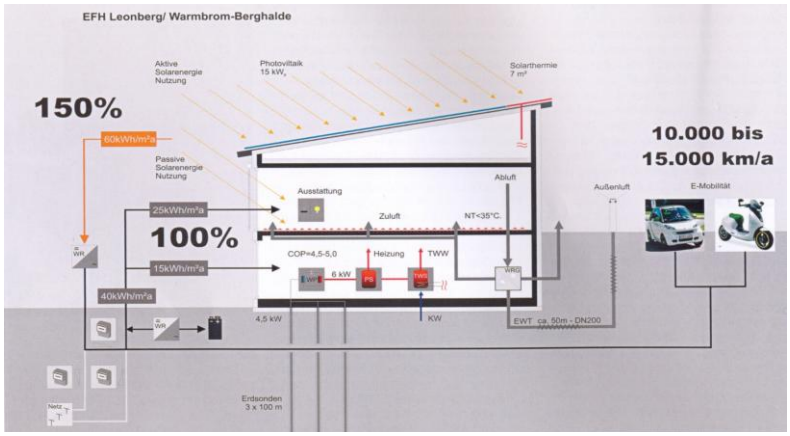

Fig. 6: Active house as power plant - system scheme [13]

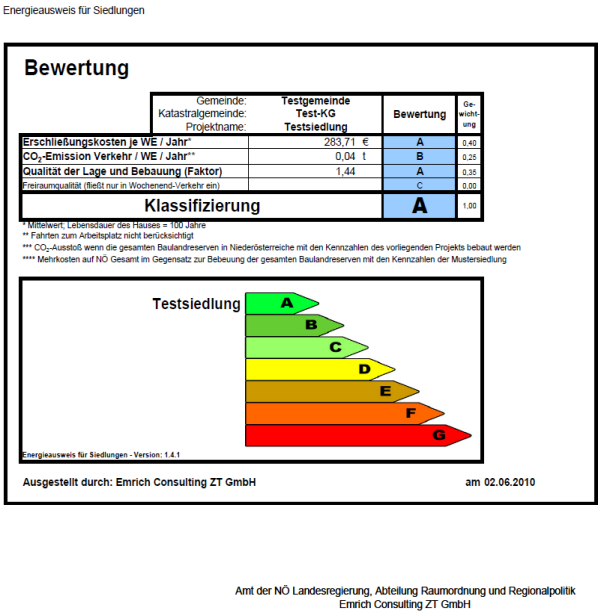
6.2 Energy Performance Certification for Settlements in Lower Austria



The Energy Performance Certification for Settlements in Lower Austria is not an Energy Performance Certification as usually, instead it assesses following aspects:

- Building land efficiency
- Transport infrastructure: examines internal and external transport infrastructure. Internal transport infrastructure means the pipe lengths of supply (water, district heating, etc) and the external transport infrastructure contains the distances to the connections to supply systems (drainage, electricity supply, noise barrier, etc.).
- Quality of open spaces: evaluates the total length of the road network and the length of ways which are particularly attractive for pedestrians, private green areas, noises, etc.
- Connection and transport: deals with distances to the next center, local supply, playground, stop of public transport, etc. on weekdays (from Monday to Friday) and on weekends

(Saturday, Sunday and on holiday)

- Situation and development: contains the topography of the building (whether it is situated on the northern/southern/… slope), the type of building and the orientation of the area, which is averted from the street.

The results are displayed like Energy Performance Certifications in categories A to G (see Fig. 7). Partial results are the development costs per dwelling unit and year in €, the CO2 – emissions per dwelling unit and year in tons, the quality of the situation and development (factor) and the quality of open spaces, which influences the transport of the weekend. Each partial result is displayed in a specific category A to G, too, multiplied by their individual weighting factor and summed up to a total category result [14].

Fig. 7: Energy Performance Certification for Settlements results [14]

6.3 Urban quarters

Portland is with 600,000 inhabitants the largest city in the U.S. state of Oregon and pioneer in the matter of environmental protection. Until 2050, Portland wants to reduce the CO_2 – emissions by 80 %. Heretofore the emissions are decreased by 26 % per head compared with 1990 due to their long-term comprehensive planning. The city addresses contemporary traffic, production and efficient use of energy, recycling and forestation. Additionally measures like standards, inducements and taxes are established. Moreover, the effects of urban sprawl are reduced with the improvement of the public transport and the expansion of the cycle network. More than 22,000 people go to work by bike, much more than in other cities in U.S. [15].

Based on the analysis of certification systems for residential buildings four certification systems for urban quarters, DGNB for new urban quarters, BREEAM for Communities, LEED Neighborhood Development and Green Star Communities, are researched. Fig. 8 shows the comparison between these certification systems with regard to criteria for infrastructure and density in relation to the total amount of criteria. LEED has the highest amount of criteria and the percentage of infrastructure and density criteria is with 30 % the highest compared with the other systems, too. Criteria in BREEAM achieve a share of 25 % of the total rating, in DGNB and Green Star 18 % [16].

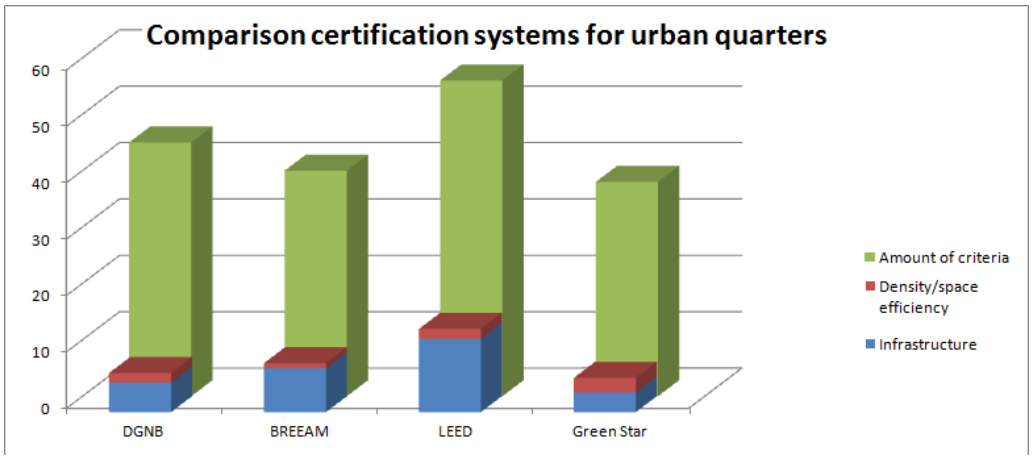

Fig. 8: Comparison between the certification systems for urban quarters [16]

7. Discussion and conclusion

Building certification systems serve as quality assurance and quality optimization of buildings. These criteria for energy efficiency are treated broadly coherent at least in Europe, whereas criteria for site and mobility are viewed different in various certification systems. In DGNB these criteria are not included in the overall assessment, which can be referred as a historic mistake as the total separation of building certificates and urban quarter certificates, since every building is not mobile and consequently inextricably linked with the site. Holistic orientated assessments do have to consider these factors, because the system boundaries redeploy off buildings to urban planning dimensions. The Austrian systems klima:aktiv and TQB already set very detailed parameters for accurate ratings as distances to public transport connections or to local supplies. Nevertheless, a scientific basis was missing so far for comprehensive assessments of mobility factors, even with unknown mobility of the user. These gaps are filled by the leaflet SIA 2039, which covers the building-induced mobility in the energetic overall consideration. Consequently, the leaflet and its calculation tool is currently the state-of-art tool for the interface of mobility and immobility. Precisely why, it has to be questioned, why they did not develop new criteria on the basis of SIA 2039 in the new version of the Swiss system MINERGIE ECO®, which was revised in July 2012. As a result of the comparison, all building certification systems have to be reworked until they achieve an ideal mixture of all aspects of mobility and until all their requirements are easily comprehensible and reasonable.

Short Summary

The focus of the research project “life cycle improvement of the building quality” (“LQG”), financed by the Austrian Research Promotion Agency (FFG) and six industry partners is to develop, analyze and evaluate methods to assess planning decisions with their consequences on the life time of a building [1]. The project has two main outputs. One is the creation of a common database on building life cycle data as well economical as ecological, the other is a comprehensive guideline on sustainable building.

The “Database of Quality” follows the initial idea that a holistic improvement of the quality of buildings over their entire life cycle can be achieved by adding quality assurance methods with one aim in mind, the contentment of the user of a building. Building certification systems are one possibility to get a higher level of quality performance [2]. From one partner in the project – FH Wels – a lot of quality assurance methods from different certification tools were tested. These studies are put into the comprehensive guideline.

The guideline is structured on the life cycle of a building and contains defined time slots, where decisions are necessary and what information will be helpful for a decision maker. The focus of the common database will lie on facts, which have to be estimated during the planning of the building. This comprehensive guideline is placed in an internet portal, which gives quick access to the scientific data that will be presented online.

Keywords: Building certification systems, Quality assurance

1. Introduction

As part of the research project “life cycle improvement of the building quality” (“Lebenszyklusorientierte Qualitätsoptimierung von Gebäuden – LQG”) a database is created. This is done to increase the approachability of the information provided and to spread the background and knowledge further. Especially landowners who plan to construct a building should know about the ecological impact and life cycle data. The usual interest concerns mainly investment costs and time as well as creating the building according to the owner’s wishes. Particularly quality over the whole life cycle is an argument that applies scientists and house owners [1].

With the Austrian Research Promotion Agency (Forschungsförderungsgesellschaft – FFG) financing the project, it runs for five years but ends in October 2013. Five Austrian Universities of Applied Sciences work together with six industry partners and the main output beside the database is a comprehensive guideline. The industry partners support the project with their know how.

Beside a rising demand for comfort the operating costs and expanses along the life cycle of the building should be kept low. High performance buildings combine this argument together with further advantages. To enhance a standard house, different topics need to be considered at subsequent time periods. At first the energy efficiency is used to reduce losses for example prevented with insulation. Secondly the energy optimization maximizes the profit by using solar power or else. With the calculation of life cycle costs substantial decisions can be reached at their best before the building ecology gives a statement about the impact on the environment. To reach the occupants satisfaction finally, the building biology and quality assurance along with certification should be considered.

2. Database of Quality

2.1 Formation

The structure of this database is built up as a dynamic matrix (see Fig. 1). The first vertical trace follows the five chronologic phases of the lifecycle of a building: concept, planning, construction, utilization, demolition/recycling. The horizontal succession of the columns is called “levels” and help to provide details on the topics. The second level allows the main phase to be more precisely described. With the third level topics like project-management, energy, building biology, building ecology and economics may be selected like a filter, while the fourth level provides additional information that serves as an overview for better understanding of the challenges inherent in building construction. The descriptions should be for people with lower levels of experience in planning sustainable buildings. The fifth level provides the detailed information on specific topics which arise within the project and continues deepening the knowledge. Here you can find LQG research reports and a variety of master and bachelor thesis done by the LQG partners. For example many guidelines on how to carry out quality testing methods from the FH Wels are placed here. The sixth layer provides the space for references, standards, important links and reports generated outside of this research project [1], [3].

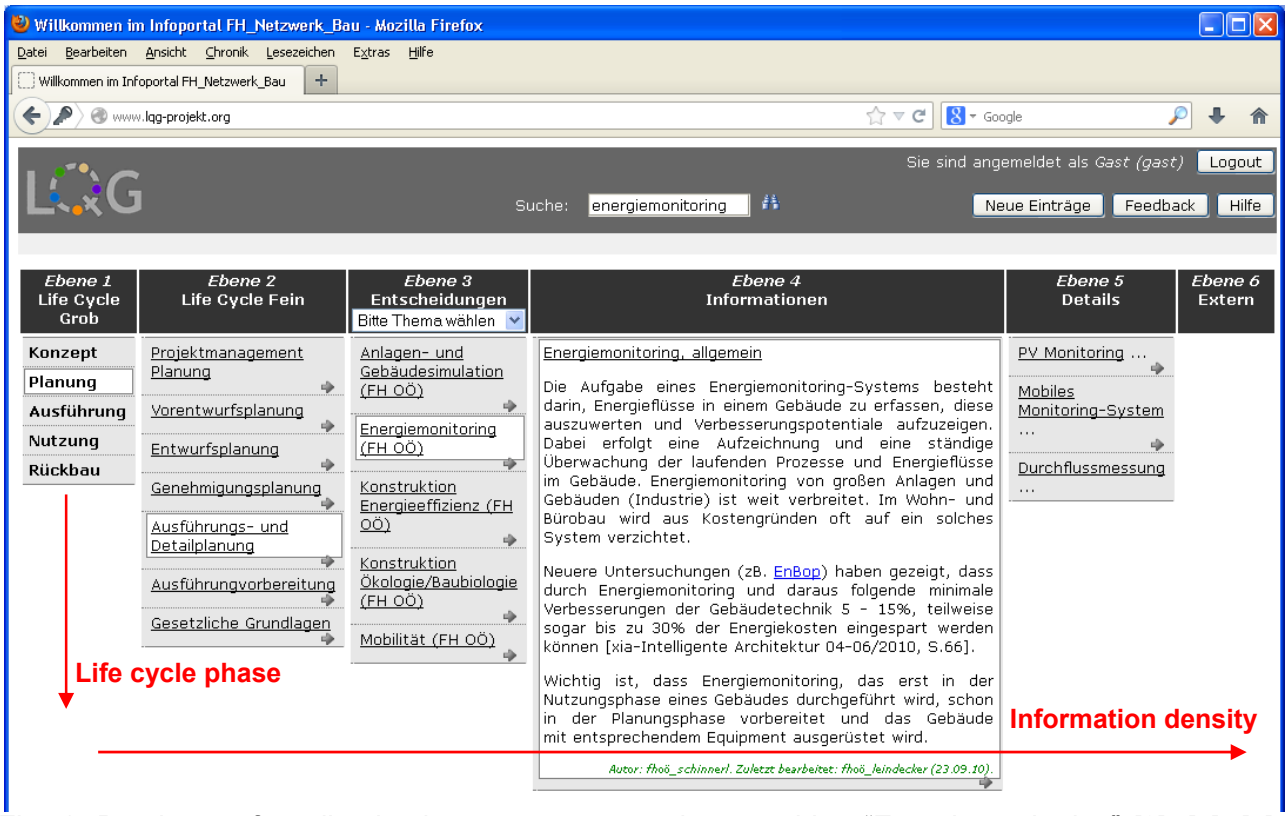

Fig. 1: Database of quality, basic structure, example: searching “Energiemonitoring” [3], [4], [5].

2.2 Expansion of the Database

The Database of Quality is filled with issues according to the relevant work package of each University of Applied Sciences (in German: Fachhochschulen – FH) involved in the project. The project management in addition to the development and the realization of the database is done by the FH Tirol Kufstein beside quality assurance energy efficiency and life cycle costing. The main topics of the FH Burgenland Pinkafeld are life cycle analyses and the database of quantity. Parallel the FH Kärnten Spittal contemplates life cycle costs among a tool for the early planning phase. From the FH Joanneum Graz LCA and LCC of facade elements come with a test in a concrete application. The FH OÖ Campus Wels is responsible for quality assurance particularly tools concerning energy efficiency, building biology, occupant satisfaction together with processing the database [3].

With the button “register as visitor” everyone can enter the database and read articles but has no rights to delete or add further postings. Only certain persons relating to the research project LQG can do so. Either the text is directly written in the database or a MS Word document is uploaded. Beside these possibilities one could upload full PDF documents or single pictures and diagrams.

2.3 Database of Quantity – “Energieausweis Plus”

Common competences should be used in the database of quantity called “Energieausweis Plus”. In comparison with an usual software for the creation of an energy performance certificate this should additionally provide data for LCA and LCC as an optimal planning tool. The first projection was already published [6] and further improvement is planned [3].

3. Examples

The database focuses on the fact of improving the quality of buildings enormously with quality assurance methods. This should happen along the life cycle to secure occupant satisfaction. One possibility is the certification of buildings with systems like TQB, DGNB, LEED or BREEAM [3], [7], [8].

3.1.1 Life Cycle Costs

Path to the issue life cycle costs:

- Level 1: Planning
  because LCC should be considered already at an early stage of the building’s life cycle
- Level 2: Basic design
  to achieve a result some facts have to be known so things can be adapted appropriate
- Level 3: related articles appear with the choosing the filter economy
  a variety of articles about LCC are available and described closer in level 4

One article called LCA/LCC explanatory notes offers the opportunity to choose between three sub-articles, where one again relates to LCA in the planning phase and explains two calculation tools. The Eco2Soft presents results about environmentally friendly facts like the acidification potential, the global warming potential and the primary energy index. With the MS Excel based tool “Econ Calc” comparative calculations were computed. This calculator is available at the klima:aktiv homepage. The aim is in principle given in figure 3 and can be reached with the econ calc.

With the correct decisions at the beginning of the life cycle of a building the operating costs can be minimized and this needs not to be done at the expenses of the customer comfort. The green line indicates the discretion in decision-making and decreases enormously in the first phases. The lines coloured red, orange and blue rise in contrary constantly with the decision about the angle α or β made already at the very first phases (see Fig. 2).

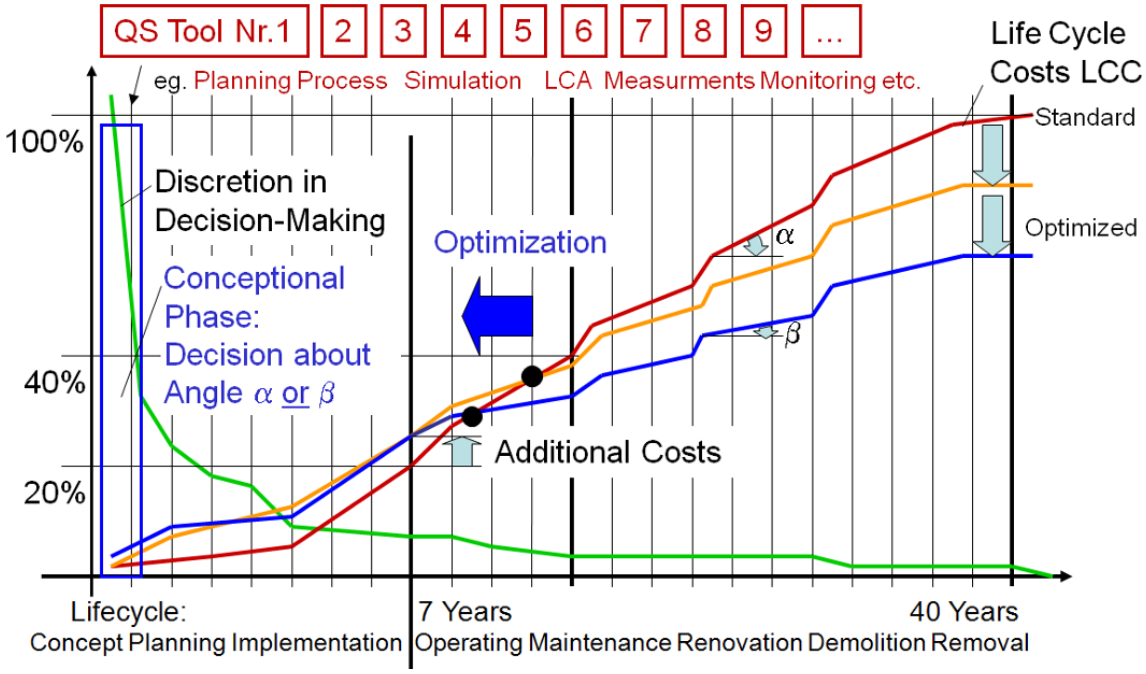

Fig. 2: Decision-making and costs according to the life cycle of a building [9]

3.1.2 Building Biology

With Austrians spending about 90% of their lifetime indoor the conditions in there are important for the wellness and health of peoples. Beside mold and carbon dioxide, radon is an issue concerning folks. As odourless inert gas radon is formed in the ground and is absorbed by humans. It can harm the respiratory system especially the lunge and cause cancer. Through leakages in grounding building elements the gas attains our houses, gathers and reaches serious concentrations [4]. The University of Applied Sciences Upper Austria Campus Wels did several measurements with interesting findings. In the context of a “Benchmark”-project and in collaboration with AGES radon measurements were done in passive houses. The results showed (see Fig.3) that when the ventilation system was switched off, the concentration of radon went up extremely [3], [10].

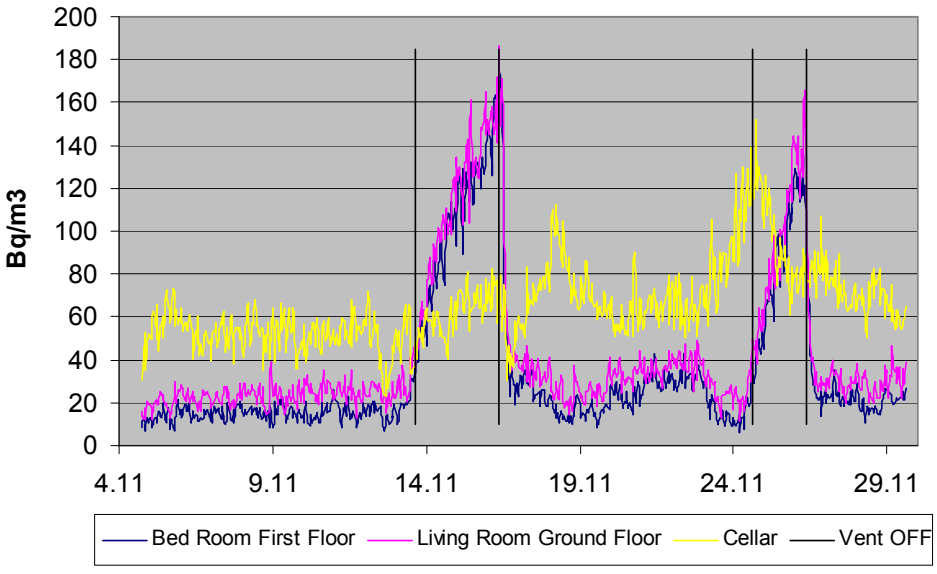

Fig. 3: Radon concentration measurement in a passive house in Haag, Austria [10]

Path to related articles about the issue occupant satisfaction (see Fig. 4):

- Level 1: Implementation
  issue about the used materials, quality assurance on the building lot
- Level 2: Approval
  inspection whether the materials are really applied, quality assurance of completion
- Level 3: Indoor air with the filter building biology (in German: Baubiologie)
  as typical building physics matter including thermal comfort
- Level 4: Indoor air quality
  concerning building biology with healthy building and living;
  a description of radon, formaldehyde and volatile organic compounds is given
- Level 5: further articles
  radon in detail, radon measuration and radon in low energy-buildings and passive houses

Because of radon being already important for building owner's when the choice of location has to be made, the articles can also be found under concept/initiation/location/building site analysis.

Fig. 4: Path to articles about radon [4]

3.1.3 Occupant Satisfaction

One of the most ambitious aim of projects is the well-being of occupants. Because of the complex opportunity to measure satisfaction, this issue often is neglected. Every person experiences heat and cold differently and that leads to very personal results.

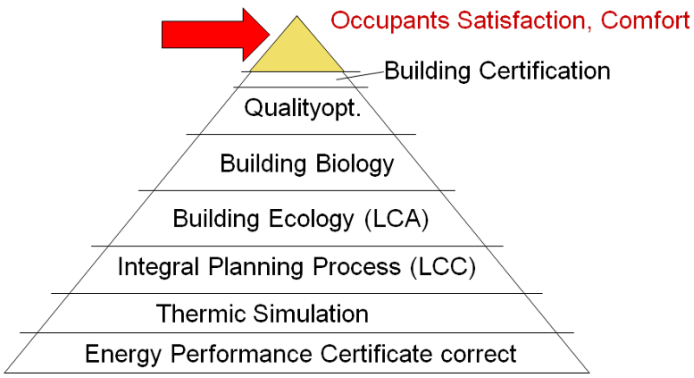

Fig. 5: Pyramid of quality of buildings [9]

The figure (see Fig. 5) indicates the building optimization assembled with energy optimization, building biology and ecology along with quality assurance [9].

With a questionnaire the satisfaction of house owners was requested. Several accommodation units were consulted and a ranking list with the most important facts was disposed. Beside the air quality, the acoustic conditions and the temperature also the current health was observed. Moreover the energy savings, safety, design and offers of public transport were scrutinized [11].

Path to related articles about the issue occupant satisfaction:

- Level 1: Usage
  to evaluate a building the residents have to experience the house and live in it, as figure six indicates this is, what the building is made for and when the occupants do not feel well, they will not want to live in the building
- Level 2: Utilisation phase
  as most suitable phase of a buildings life cycle to include occupant satisfaction beside energy monitoring, examples for the utilisation phase are the move-in, renovation works or a change of users
- Level 3: Occupant satisfaction
  this level offers three different articles to deepen the knowledge on level 4 and some more on level 5

3.1.4 Solar Monitoring

With the user name and the password given in the article about PV monitoring in level 5 the online data of the PV system installed on the FH Wels can be seen. Therefore the available link leads to the homepage for the “Solarportal FH Oberösterreich”. From a variety of days, month and years the previous measurement data can be checked. Fig. 6 illustrates the radiation colored orange and the produced energy in dark blue of the days in February 2013. Even for every hour of the day the data is given which can be seen for 11th.February 2013 in Fig.7.

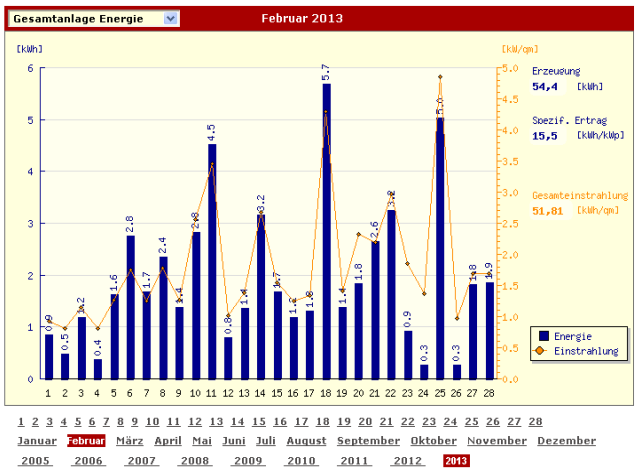

Fig. 6: Monitoring of PV system owned by the FH Wels for February 2013

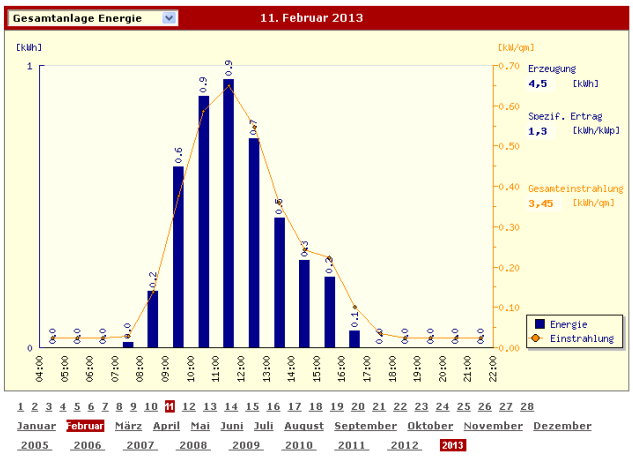

Fig. 7: Monitoring of PV system owned by the FH Wels for 11.February 2013

To check actual data of different PV module types in Wels the user can start with choosing usage in the first level. In the second level it concerns facility management and the filter energy for the third level. This offers the possibility to select energy monitoring and read the article about the general facts in level 4. The choice to read the information provided to this issue leads to a switch of the path in the database. This happens automatically and leads to a change in the phase of the building’s life cycle from usage to planning. Furthermore the subject in the second level changes and only in the third level the issue remains constant. In case the user knows the topic of interest or related key words one can always use the search function to reach a quick result.

Path to the online data of the PV monitoring system of the FH Wels (see Fig. 6 and 7):

- Level 1: Planning
  already at an early stage of the project quality assurance and control are important
- Level 2: Detail engineering
  a certain equipment has to be provided and included in the construction of the building
- Level 3: Energy monitoring
  for this issue the filter energy can be used
- Level 4: Energy monitoring in general
  with a short article about challenges and advantages of energy monitoring systems the user gets to know what it is all about
- Level 5: PV monitoring
  the provided article describes detailed costs, the measurement setup and results referring to the site in Wels

Beside the choice of the date, different types of PV modules and even errors can be seen on the homepage with the solar monitoring data. All information to check the functionality of the site can be viewed and so the maximum power output is ensured because in case something breaks or other problems appear in the monitoring data the response can be seen.

3.1.5 High Performance Buildings

Creating high performance buildings requires a variety of complex issues which can be split into seven main sections. Already included in figure 6 five out of seven topics are listed according to their importance and level of difficulty. In a students project each issue was examined more closely with interesting conclusions.

1. Energy efficiency (minimization of losses)
   In association with buildings insulation, air ventilation systems including heat recovery and a tight building envelope in combination with the avoidance of thermal bridges are important, just like a compact A/V-ratio [12].
2. Energy optimization (maximisation of gains)
   Beginning with a certain standard of energy consumption of the building the performance is improved with active components and energy storage systems. Beside these key components the user behaviour is an essential factor [13].
3. Life cycle costs
   For the calculation of costs over the life cycle of a building the tool Econ Calc was used. Four different building types were compared with the biggest saving potential in the renovation of old buildings to low energy buildings [14].
4. Building ecology
   Including life cycle analyses this provides the possibility to decide whether anything is environmentally friendly. For example the calculator Eco2Soft offers this potential with a big database in the background [15].
5. Building biology
   For a better indoor quality harmful substances should be avoided and the usage of natural resources focused for example with clay. Measurements of certain substances in the air can show positive the effect with only a little bit higher additional costs [16].
6. Quality assurance and certification.
   Declarations like TQB, DGNB, LEED and BREEAM can assure the quality of the building. Another possibility is the installation of a monitoring system or different measurement and instrumentation equipment with communication systems [2]. Although this can only assure mainly physical criteria, the connection with the occupants behaviour and satisfaction (see below) has to be mentioned.
7. Occupant satisfaction
   A closer description of this issue and results of this project part is given in chapter 3.1.3 Occupant Satisfaction.

4. Discussion and Conclusions

Up to now the database of quality has reached a certain grade of complexity and is already publicly available. With the adjustment according to the life cycle of a building the ordinary user can handle it easily and find one's way. For experts especially the deeper levels provide general reference work. To improve further development the database is verified by the industrial partners, who experience it in commercial practice. The spread competences of the different universities of applied science secure a diverse knowledge and approach [3].

With all the research done pursuant to the project "life cycle improvement of the building quality" ("Lebenszyklusorientierte Qualitätsoptimierung von Gebäuden – LQG") the network called "University of Applied Science_network_building" ("FH_Netzwerk_Bau") is an established partner. Beside declaration tools for buildings particularly life cycle costs and life cycle assessment can be comprehensively advised.

Assessment of an Office Building in Serbia by New Proposed Methodology - „OPEN HOUSE“

Prof. Dr. Djordje Djordjevic

Full professor at Faculty of Civil Engineering and Architecture Nis, Serbia

djoka@ni.ac.rs

Biljana Avramovic

Cluster general manager

Construction Cluster DUNDJER, Nis, Serbia

klasterdundjer@yahoo.com

Short Summary

The Construction Cluster „DUNDJER“ participates in the 7th FP European project entitled OPEN HOUSE (7th FP ENV - 2009.3.1.5.2). The overall objective of OPEN HOUSE is to develop and to implement a common European transparent building assessment methodology, complementing the existing ones, for planning and constructing sustainable buildings by means of an open approach and technical platform. OPEN HOUSE will develop a transparent approach able to emerge collectively in an open way across the EU. This approach will be communicated to all stakeholders and their interaction and influence on the methodology will be assured in a democratic way. The baseline will be existing standards (both CEN/TC 350 and ISO TC59/SC17), the EPBD Directive and its national transpositions and methodologies for assessing building sustainability at international, European and national level. This paper deals with practical assessment of an office building after reconstruction in Serbia.

Keywords: building assessment, sustainable building, european norms, ecologic building, energy efficiency, location

1. Introduction

Open house project involves 11 countries of the EU and the Western Balkans. Active partner at the project (FP7-ENV 2009) is a Construction Cluster Dundjer from Nis.

The scientific and technical objectives of the project OPEN HOUSE are:

• to define OPEN HOUSE approach: open and transparent european platform for sustainable construction,
• to promote OPEN HOUSE approach and define the mechanisms of interaction between the project and the decision-making factors,
• to build OPEN HOUSE platform: to support pan-european effort for a common view of sustainable construction,
• to consolidate the method of application and evaluation methodology: the choice of test examples and decision-making mechanisms,
• to evaluate and improve the methodology by using the results of the test examples and other similar cases, as well as other observations of decision makers,
• further development and use of OPEN HOUSE methodology.

Basics methodology consists of the following assessment:

• environmental quality,
• social-functional quality,
• economic quality,
• technical characteristics,
• process quality (design and construction),
• the position of the building (location).

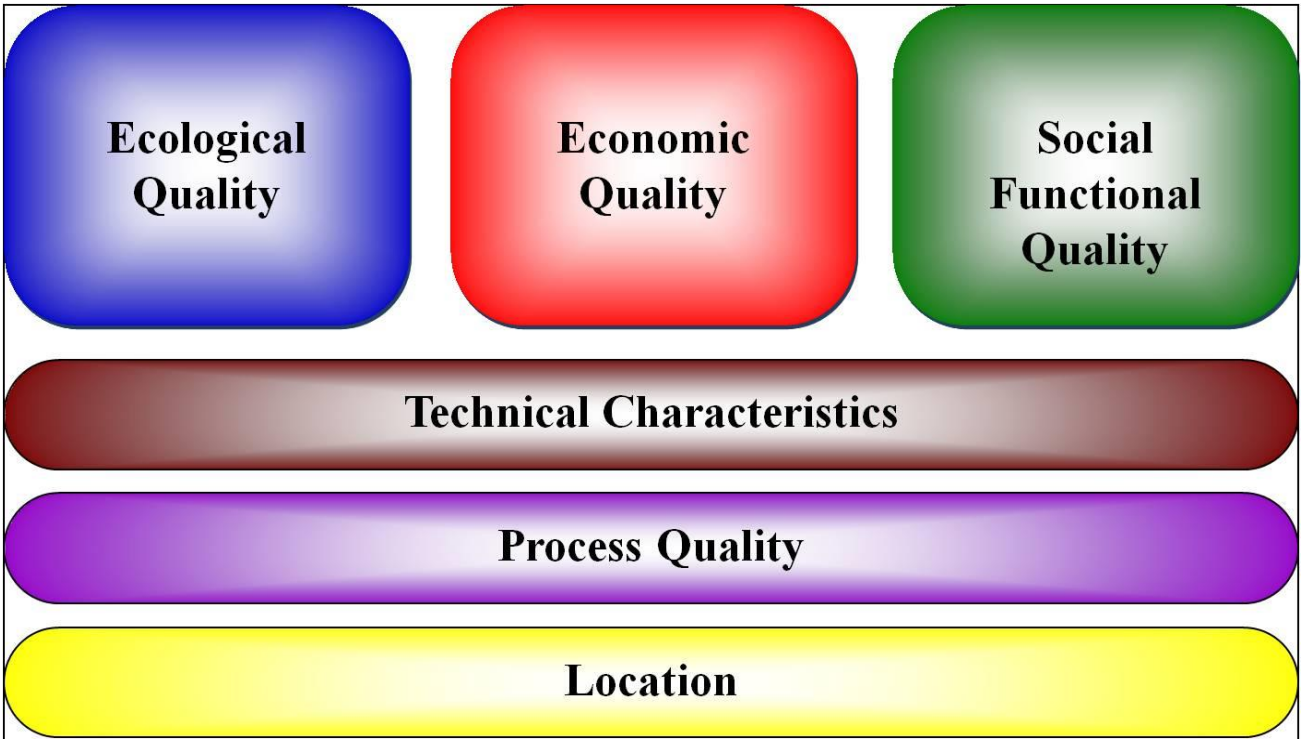

Fig. 1: **Open house shema**

Construction with emphasis on the cost during the building exploatation period is an economic method that aims to provide information before decisions making and to point out the savings when choosing the appropriate design solution including the cost of the product, service, energy efficiency.

During the analysis of the costs of the exploitation of the facility one should consider the costs that should be in accordance with the description and size of the object known in the evaluation. For the purposes of this analysis, the calculation period is limited to 50 years. The initial investment can be considered when the building is delivered to the investor, and is ready to use. This price includes the design of the structure, systems, installations, components, connections with suppliers and energy, and commissioning. These are costs that are presented to the investor.

When evaluating a particular attention has been given to the life cycle of the building - Life Cycle Assessment (LCA). LCA results of the building which is estimated, will be counted in a standardized manner and evaluated using benchmarking assessment. The goal of all LCA study is to analyze and subsequently evaluate the corresponding performance of "life cycle" of the building.

					B7 Operational Water use									

Fig. 2: **Building assessment information**

2. Project description

The case-study building hosts J.P. “Razvoj” (Public/Municipality Enterprise “Razvoj”). The Eterprise supports urban development of Municipality Knjaževac, and controls public investments, including design of major projects and objects. The Enterprise takes part in regional development and supports research in collaboration with research institutions, usually with University of Niš.
The building is located in the downtown of city Knjaževac, in pedestrian zone, close to main administrative municipality institutions. Face of the building is west-southwest oriented, without shadowing obstacles. The view from the building front side is to the small city central park and river Timok. The building has 3 main floors and an attic. In the 3rd floor are located offices, and in attic small conference hall, which is used also as a design studio for working team consultations.
The reconstruction of building was accomplished in the year 2005, with steady improvemen especially in energy consumption. This is the only office building with heating/cooling system based on heat pump. In addition, there is design of using solar energy (PV system) on the south oriented part of the roof. The design draft for using PV solar energy shows ability for using 200 m^2 (roof area) for PV panels. After completing, it would enable saving up to 15-20% of total energy consumtion.
Modeling the thermal energy balance of buildings is recently a challenging task for local architects and engineers. Directive EPBD (2002/91/ES) is recently enforced by local Energy Law, but in the time of building design and construction, the elements of design like glazing areas or windows thermal characteristics, the climate zone, the orientation, and the type of construction (e.g. high or low thermal inertia) have not been considered in a way to optimize their thermal contribution to the whole building’s energy balance. The measuring system, necessary for proper assessment and improvement, has to be realized in near future.
All the sustainability aspects (environmental, social/functional, economic, technical, process, location), are assessed “as is”, according to given scale. For Economic Quality assessment, the

bill of quantities is now out of date, due to unrealistic prices of some materials and works, and using some not any longer used materials (with not standardized quality) and equipment with not strictly defined efficiency, and, finally, local rate of inflation (over 10 %). Sensitivity analysis, being considerable politically dependent, is even more complex, and somehow rather unpredictable.
It is worthy to mention that this building was chosen, it seems, occasionally, and not as an example of good practice. The building is located in underdeveloped part of Serbia with all consequences to quality of building and, consequently, building sustainability. But, it is, in a way, representative case of construction technology in southeast Serbia.

Short Summary

Case study of the real life example where individual low-energy building in Maribor, Slovenia has been carefully planned, built, supervised and certified as low energy (LE) building. Consultants for sustainable construction where tightly involved in all stages, from the very beginning of the building design. Blower Door tests for air tightness and thermography have been used, not only for the proof of the sustainability of the complete building, but also for the quality checking during the building process. All phases have been well documented, from planning, via on site measurements until the acquisition of grants by Slovenian Eco Fund. Also similarity and differences of sustainable building sector in Slovenia and Austrian region Styria has been discussed.

Keywords: green building, certification, eco subvention, real life example

1. Green buildings in Slovenia, past and present

1.1 Comparison Slovenia vs. Styria

Despite Slovenia and Styria are comparable on forest coverage (over 50%), the share of the wooden buildings is significantly higher in Styria then in Slovenia, where over 80% of the new buildings are classical massive buildings. That means more difficulties to reach low energy (LE) and passive house (PH) standards and more embedded energy in the buildings.

For comparison here are some basic information, regarding the size and forest coverage, between Slovenia and Styria:

	Styria	Slovenia
Size:	16,387 km^2	20,273 km^2
Population:	> 1,200,000	> 1,900,000
Forests:	8.530 km^2	10.124 km^2

When Slovenia has joined EU a number of European directives came into force in the field of sustainable buildings. System of lending and granting subsidies has been successfully established for the construction of LE and PH facilities through Slovenian Eco Fund.

1.2 Design of LE and PH buildings

Professional basis for making well-insulated buildings in Slovenia are given with the norms and regulations. The main one is PURES and associated technical guidance TSG-1-004: 2010 [1], both from 2010. Based on those regulations, variety of software solutions for building physics calculations (Archimaid FIBRAN, Energija 2010-Knauf, Building Physics 4.0 URSA, etc…) has been offered for free, mainly by our main insulating materials companies.

Darmstadt Passive House Institute guidelines and PHPP software are used in planning and building of LE and PH buildings. Main low-energy criteria is computational energy consumption for heating (<25kWh/m^{2}a for LE and <15kWh/m^{2}a for PH). Additional demand is the minimal air tightness of the building that should be: <1.0 h^{-1} for LE and <0.6 h^{-1} for PH. Controlled ventilation with heat recovery is mandatory.

1.3 Slovenian Eco Fund

Eco Fund, the Slovenian Environmental Public Fund, is operating under the jurisdiction of the Ministry of Agriculture and the Environment. Data from the annual report of the Eco Fund [5] shows that the average annual Eco Fund subsidies for the construction is for approximately 80 individual buildings (the LE or PH implementation), with around 1.000.000 EUR. Eco Fund support only LE and PH buildings and the value of subvention diverse from type of building (payments are carried out after fully completed construction).

Bottom tables (Table 1 & Table 2) shows the accurate data regarding the years 2010 and 2011 and are summarized and taken from the annual report. [5]

Table 2: Eco Fund report 2011 [5]

Eco Fund main criterion for the allocation of subsidies, for the construction of houses, takes into account the energy consumption for heating per m^2 of net heated surface of the object. Surface and heat consumption is calculated according to the PHPP 07 [2].
Condition for LE is heat consumption per square m2 <25kWh/m^2a and for PH it should be <15kWh/m^2a. Additional criteria regarding carpentry (windows and doors), insulation and heating system with controlled ventilation that have the heat recovery included, usually originate from the PHPP calculation.

2. Role of SB experts during design and building process

Involving of SB experts in all phases is essential. Also the investor must fully cooperate and have in mind the goal of low energy or passive house consumption. A control measurement before final works was done, that included simultaneous inspection with thermography camera while the blower door test was being executed, to discover weak points --as it was for example bad sealing around otherwise PH certified attic door (Fig. 1) and sunroof windows (Fig. 5e). Weaknesses revealed by the measurements have been corrected before the final measurement, certification and the occupation of the residents.

3. Observed residential family building in Maribor

3.1 Description

The observed building in Maribor (Slovenia) has four floors, including basement, ground floor, first floor and attic with external dimensions 9.10 m × 10.10 m. The net area of the accommodation is 257m^2 and heating and hot water preparation is covered with the 8kW heat pump (air/water) and central controlled ventilation with heat recovery is included for all for floors. The outside wall, which is essentially clay hollow brick POROTHERM system DRYFIX thickness of 25cm, is surrounded

with 20cm of the EPS insulation with λ = 0.032 W/mK. The building is heated by floor heating system at all floors. Special attention has been made to the implementation of the air-tightness of the building. Certification and Funding has been successful. In the very article presents, the observed individual residential building, whose construction started by excavating works, began in July 2012. The investor is a family with two children that build it for their own needs. Construction is now finalized; and family moved into the house at the end of April 2013.
The building has 4 floors, including basement, ground floor, first floor and attic. It has hipped roof with brick cladding. External dimensions are 9.10 m × 10.10 m. Technical Area (heating and hot water, is done with a heat pump (type air/water SAMSUNG EHS) with the power of 8kW, controlled ventilation with heat recovery is performed centrally and located in the basement of the building. Living rooms are at the ground floor, sleeping and working areas on the first floor and children rooms are in the attic. The net area of the accommodation is accord. to PHPP 257m^2. The building is surrounded by a thermal envelope, where also the basement foundation slab and the external basement walls are covered with 20cm of XPS insulation with λ = 0.035 W/mK.
In the hipped roof, in addition to 4cm THD-Agepan plates, that serve also as back decking, insulation from cellulose flakes with λ = 0.039 W/mK in thickness from 40cm to 50cm was blown in.
The windows are all three-layer glass, in between filled with argon gas, where in the value of the thermal conductivity the glass part has Ug = 0.7 W/(m^{2}K). The total value of the individual windows (glass and plastic frame) does not exceeds the Uw = 1.0 W / (m^{2}K). Main door is also LE certified product intended for the construction of low-energy building with U_d <0.92 W / (m^{2}K)
The building is heated by under floor heating system at all floors. For controlled central ventilation unit of central ventilation system with heat recovery for all rooms, Systemair VR700 DCV has been chosen.
All built-in thermal insulation materials and equipment for heating and controlled ventilation are certified and carried out by authorized service providers. Special attention was paid to the implementation of the air-tightness of building, which is described below.

Figure 1: LE family house during construction [4]

3.2 Airtightness; execution and on-site control

Each investor is required to familiarize themselves with applicable laws, standards and regulations that must be followed in the construction of the building. One of those areas is the air tightness requirements, which are defined by PURES and technical guidance TSG-1-004: 2010 [1].

It is essential to pay attention to air tightness in the construction or renovation of the attic.

It is recommended to carry out two measurements:
• the first measurement is carried out at a stage when the eventual elimination of errors is still possible, for example after all installations, when all penetrations in the outside walls and the perimeter of the building are carried out and at least provisionally sealed, but still available for corrections,
• the final measurement is carried out prior to the occupation with residents, to confirm the final stage and get the final result, which is present in the results of measurements (so called Blow door measurement Protocol), that is to be presented to the Eco Fund

Costs of the measurements are minimal, compared to what awaits the investor if after a period of exploitation; defects are shown in the facility, due to inadequate air-tightness. The integration of a specialist for Building Physics is essential at the planning stage of the LE- or PH-house, when the construction details of which depends the air tightness, are done. Here is of a great help PHPP software tool (Figure 2), developed at the Passive House Institute Darmstadt-u [2].

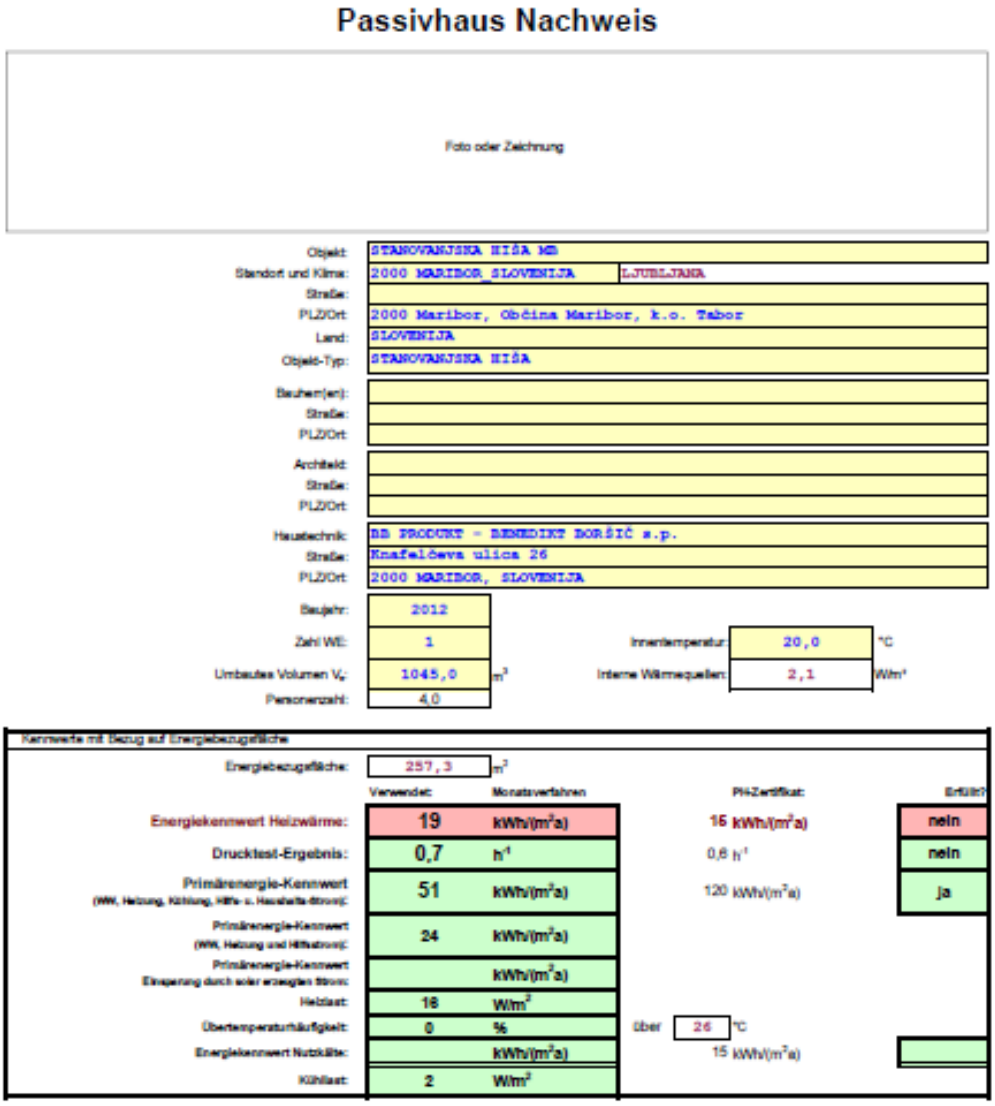

Figure 2: PHPP software - calculation of the observed object/first page results [4]

3.3 Why must the building be air tight

If the house is equipped with controlled ventilation and heat recovery (which is “must be” for LE-low energy house or PH-Passive House), then is generally known that better air tightness also mean the better energy efficiency of the building and lower costs for heating.

That is the reason, that the measurement of air tightness, so-called "blow door test", should primarily be understood as an aid in the construction phase and the way to the higher quality and as a tool to prevent subsequent problems in the maintenance of the building. It is essential to know that the air tightness of the building is not only in the domain of a single expert or craftsmen.

Coordinated work of all participants in the building process is obligatory.

Figure 3: Measuring device "Minneapolis Blower Door" [4]

Figure 4: Openings and penetrations must be properly sealed [4]

3.4 THERMOGRAPHY IN CONNECTION WITH "BLOW DOOR"

Experiences, when it comes to air tightness measurements on site, are showing the great potential of detecting hidden failures at the time of construction, immediately after the air tight layer is done. Especially using also the thermography camera at the same time the blower door test is in the progress.

Implementation is very simple. While the air tightness measurement is in the progress, the fan creates a vacuum. Simply by using the thermography camera on walk around tour in the building, we detect details where air is blow-in, while blow door fan creates a vacuum.

Pictures below are more than eloquent. They were carried out at the first measurement on the observed object, at the stage when the outside layer has been carried out and the errors were detected and after that with appropriate interventions successfully removed:

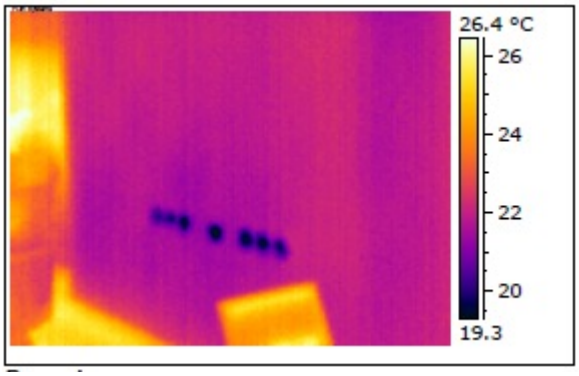

Figure 5a: Plain electrical boxes on the outside walls have been used (help: additionally sealed cans or by installing special air-tight cans) [4]

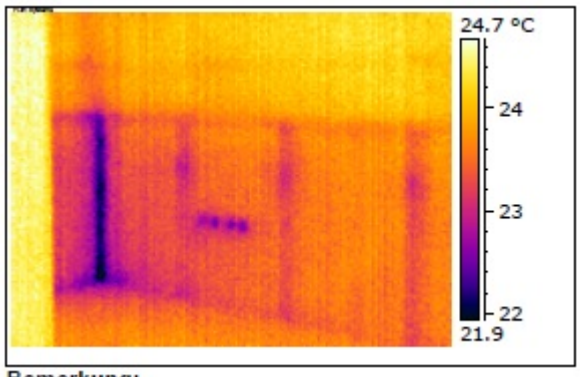

Figure 5b: on the picture visible lightweight substructure is shown in the attic on the outside wall external corner (no direct intrusion of air through the airtight envelope, further action is not required, the situation will be normalized after the façade EPS envelope is done) [4]

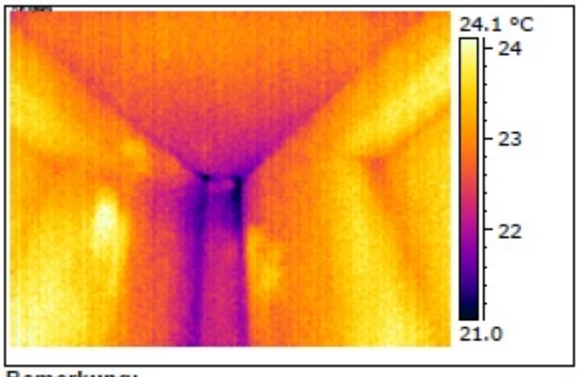

Figure 5c: Corner windows from PVC (the window manufacturer detail for corner windows should be better) [4]

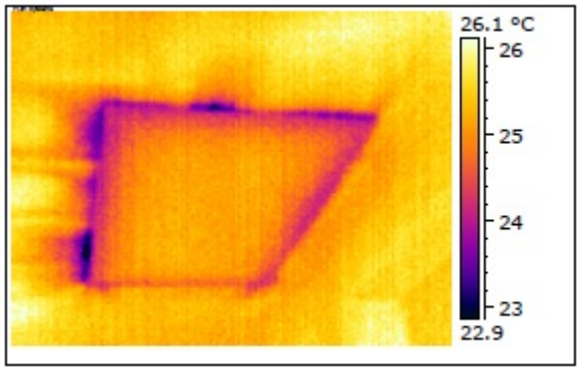

Figure 5d: pull-down stairs to the unheated attic part of the hipped roof (error: the lid does not close as it should, because it is a special type of pull-down stairs for passive houses; it was repaired) [4]

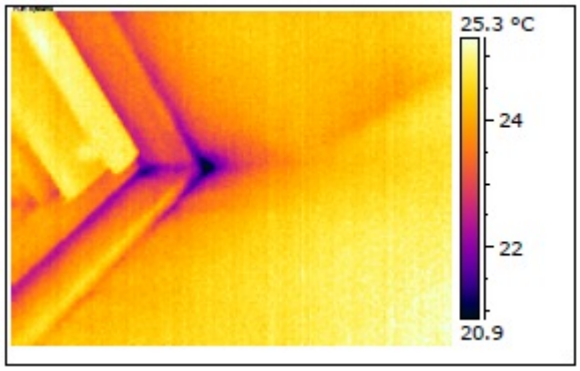

Figure 5e: sunroof window corner (error was detected after the removal of plasterboard: air tight layer was not properly sealed to the sunroof window frame) [4]

By proper use of a thermography camera in combination with the measurement of air tightness, errors can be easily detected. Errors are not visible with the naked eye because they are usually hidden in the structure. Here is an example of than significant contribution of an experienced construction professional to the correct assessment of the situation. Through the visualization of the status quo, using modern techniques and subsequently review the situation after the recovery, in the case of the use of thermography, we can really enjoy in those images.

In the case of Eco Fund founding [3] it is mandatory to submit the end measurement protocol of the air tightness. To get the LE house consumption among 15 – 25 kWh/m^{2}a the required level of air tightness is $n_{50} \leq 1.0\ h^{-1}$.

For the observed object, we planned airtightness in the PHPP $n_{50}<0.9\ h^{-1}$, but after the first measurement some improvements and repairs have been carried out and we were able to get even better result. Implementation of the two measurements was done in accordance with the European standard EN 13829, Method A.

For the observed object is the final measurement result, confirmed with the official protocol was:

$$n_{50} = 0.74\ h^{-1}.$$

4. Conclusion

Subsidiaries of the Eco Fund do not cover all extra cost of LE or even PH building, but they can certainly help investors in decision making “pro et contra” for LE or PH Building.

Benefits of LE and PH Buildings are not only in the lower cost of living and higher life quality in those buildings, but also in long-term sustainability for our society.

A construction of those buildings is forcing us (investors, the building experts and all the craft workers) in the detailed planning and detailed execution of planned details. And as the end result the residents get a more enjoyable and affordable place for living.

Extra effort and more attention in the design stage can ensure a comfortable stay for many years of the life cycle of the building.

Abstract

Appropriate energy efficiency and conservation strategies are essential for establishing optimal thermal comfort conditions in the buildings. In this regard, the building envelope has a major influence, and must be taken into consideration. In this study, the hourly variation of thermal comfort parameters of a building in Rasht (Iran), in warm seasons, is analyzed with Energyplus software. The walls of this building are made of horizontal hollow bricks, with a complementary thermal insulating layer from inside or outside. Natural ventilation based on the level of thermal comfort conditions has also been taken into consideration. The results make clear that high thermal inertia of the building envelope and natural ventilation with appropriate night purge sequence increase the thermal comfort level in all the floors of the building.

Keywords: Comfort condition; Building construction; Natural Ventilation; Thermal insulation.

1. Introduction

The thermal comfort depends on many parameters, such as the activity rate of persons, the indoor temperature, relative humidity, air speed and the temperature of surfaces surrounding the indoor space. Many investigations have been presented dealing with the thermal comfort condition.

E.S.Lee [1] investigated the effect of external overhang on the thermal comfort condition. Also, C.Huizenga [2] highlighted the influence of parameters related to the window. W.N.Hien [3] investigated the effects of double glazed facade with ventilation system on the energy consumption, thermal comfort and condensation in comparison with single glazed facade system, using TAS software. He showed that double glazed facade with natural ventilation were able to minimize energy consumption as well as to enhance the thermal comfort. G.F.Menzies [4] showed how to select the double pane glazing window based on thermal comfort. S. Atthajariyaku [5] presented an alternative methodology of real-time determination of optimal indoor-air condition for HVAC system in order to achieve thermal comfort. E.L.Olsen [6] evaluated the potential of energy savings of several different systems in a new building outside London, using EnergyPlus software.

In this paper, the hourly effect of using the thermal insulation and hollow bricks in the building external envelope exposed to natural ventilation at night, based on the level of thermal comfort conditions has been investigated for Rasht (IRAN). The simulation has been performed using Energyplus software in warm seasons. In the present study, the thermal comfort has been investigated in two configurations:

a) The effects of using thermal insulation and hollow bricks in external building, envelope on thermal comfort condition in sedentary and low activity rate condition,

b) The effects of using natural ventilation in the building on thermal comfort condition in sedentary and low activity rate condition,

The main objective of the current work is to determine how the thermal comfort condition can be

improved, without increasing the building cost using advanced building technology construction, such as hollow brick or insulation.

2. Simulation software

The building energy simulation program Energyplus™ was used in present study to predict the thermal comfort in a building in Rasht. Energyplus™ (version 1.2.3.031) is made available by the Lawrence Berkley Laboratory in USA. Energyplus calculates thermal loads of buildings by the heat balance method. This method takes into account all heat balances on outdoor and indoor surfaces and transient heat conduction through the building. The simulation results of Energyplus have been validated through numerous analytical, comparative, and empirical tests. Although Energyplus is capable of simulating heating, ventilation, and air conditioning (HVAC) systems, the details of HVAC systems are not modeled since the primary objective of the study was to examine the influence of windows on thermal loads of buildings. In Energyplus, the heat transfer by radiation, convection and conduction is calculated at each time step. The U-values are not constant through the simulation because the radiation and convection heat transfer is calculated by algorithms that take into account parameters such as temperature difference between the surface and the air [7, 8 and 9].

2.1 Weather data

Computer simulation software requires hourly weather data including dry bulb temperature, dew point temperature, solar radiation, air speed and direction. Since weather conditions can vary significantly from year to year, there is a need to derive typical meteorological year (TMY2) data to represent the long-term typical weather condition over a year [10]. In the present study the TMY2 data has been generated using two different software (Weathergenrator [11] and Meteonorm [12]). Afterwards, these data have been compared with the one measured by the meteorology office of Tehran, and have been validated [13].

3. Description of the building

The thermal comfort of a typical residential building including 4 floors has been evaluated by computer simulation. The building plans have been depicted in Fig 1. In this building, each floor has 4 similar zones. Different types of windows and doors have been used in the building. The thermal properties of materials used in wall, ceiling, floor and other components of the building are displayed in Table 1. The values are in accordance with ISO 12524-6, M19 [14, 15].

3.1 Internal heat gains

The rate of internal heat gains has been determined in accordance with M19 [14], as follows:
a) Number of persons
In this research the number of person has been determined, based on the area of the rooms: 3 people for rooms with area lower than 60 m^2, 4 people for rooms between 60 to 85 m^2 areas and 3 people for rooms with areas upper than 85 m^2.
b) Lighting
The lighting power is determined as follows:
- In the rooms 2, 3, 6, 7 and 8, 200 watts, and
- In the rooms 1, 4 and 5, 100 watts.

c) Electrical equipments
In each room, the thermal power generated by electrical equipments is as follows:
- 125 watt for appliances working constantly
- 150 watt for electrical equipments that are used during a fraction of time

The hourly variations of the internal heat gains schedules have been shown in Fig 2.

4. Calculating thermal comfort

First, the hourly inside temperature has been obtained using simulation by Energyplus software.

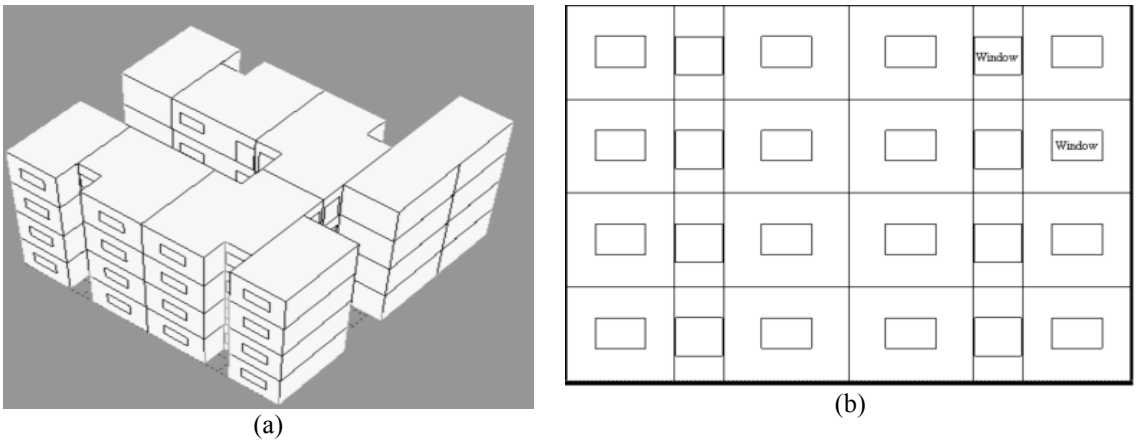

Fig. 1: Plan of the building (a) Isometric view, (b) Front view, and (c) Top view

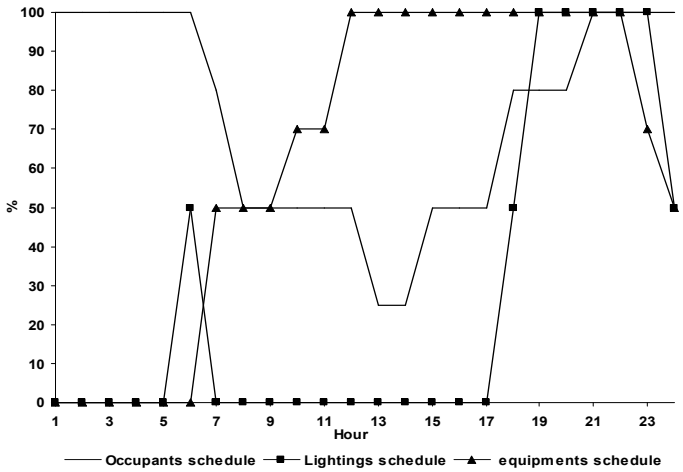

Fig. 2: Hourly schedule of internal heat gains

Afterwards, the thermal comfort has been calculated, based on method explained in the ISO 7730[15]. In this investigation, the people are assumed to wear summer dress and the hourly thermal comfort has been calculated in several air speed configurations, for sedentary and low rate activity, from the 5th (May) to the 10th (September) month.

The thermal properties of the clay block and hollow brick used in the external envelope of the building are shown in Table 2. and Fig 3. Also, during natural ventilation period with windows wide open, from 10:00 at night to 9:00 in the morning, the air change is assumed to reach 3 volumes per hour. The rest of the time, air change rate is taken equal to 1. Table 3 shows combinations in different models that are compared in this research. In some models used insulation as Table 4. All models have been simulated in different indoor air speed conditions: 0.5, 1, 1/5 and 2 m/s, for sedentary and low activity rate. The variation of the air speed can be provided using ceiling fans.

5. Results and discussion

5.1 Effect of building construction materials

The simulation have been performed for the models with 1 m/s air speed and air change rate equal to 1, in sedentary activity (models 3, 4, 5, 6, 7, 8, 9 and 15). The results have been compared with model 1 (Reference model) to determine the effect of building construction materials on the thermal comfort. The compared results have been showed in Fig 4 for room 6 in the first floor. The result shows that in the first floor, the thermal comfort condition in the rooms 6, 7, 2, 3, 5, 4, 8 and 1, changes respectively from best to worst. The change of the wall construction material leads to variations lower than 4%, in comparison with the reference model.

	Case 15	Case 10	Case 9	Case 8	Case 7	Case 6	Case 5	Case 4	Case 3

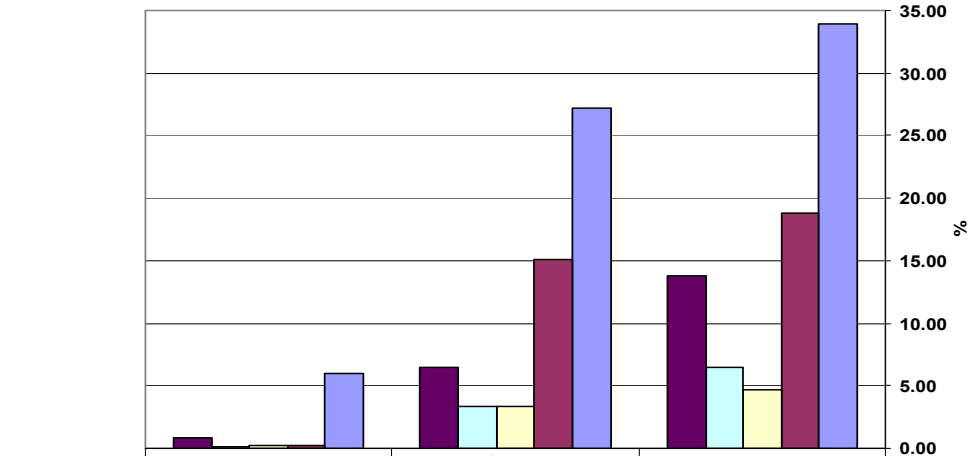
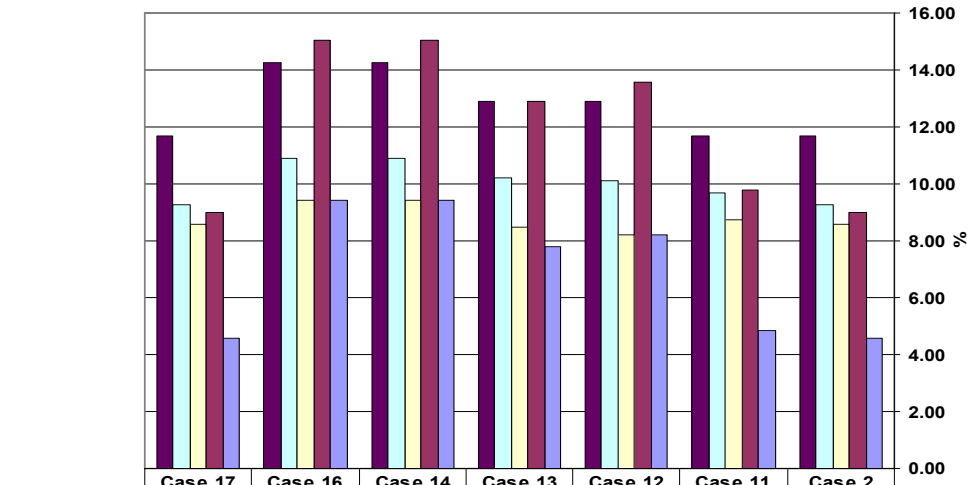
Fig. 4: Improved percent of thermal comfort with changing the building construction in comparison with model 1 (Room 6 floor1)



5.2 The effect of room orientation

The simulation have been performed for the first floor of the model 1, with 1 m/s indoor air speed, and an air change rate equal to 1, in sedentary activity condition. The results have been compared between rooms to determine the effect of orientation on the thermal comfort condition. Fig 5 shows the comparative result in the different orientations in the first floor. It can be seen that the thermal comfort condition in the north of the building is better than other parts, especially in comparison with the eastern rooms.

5.3 Effect of night-time natural ventilation (night purge)



In this part, the simulation has been performed for the room 6 in the first floor, which in best thermal comfort condition, according to the results of part 5-1, with 1 m/s air speed in sedentary activity, for models 2, 11, 12, 13, 14, 16 and 17. The night air change rate, between 22:00 and 9:00 o'clock, is taken equal to 3. The results have been compared with model 1 (Reference model with air change rate equal to 1) to achieve simultaneous effect of building construction and night natural ventilation on the thermal comfort. Fig 6 shows the comparative result for Room 6 in the first floor.

The results put into evidence that the thermal comfort condition in the north part is better than other parts. The result shows that improvement caused by high rate of air change during the night is about 4-11% for the hot season, during the summer.

Fig. 6: Improved percent of thermal comfort using night ventilation with different building construction in comparison with model 1 (Room 6 floor1)

5.4 Effect of air speed

The simulation has been performed for room 6 in the first floor with best thermal comfort condition, with an air change rate equal to 1, in sedentary activity . The room has been compared in four air speed conditions: 0.5, 1, 1/5 and 2 m/s. The results have been compared with model 1 (reference model with 0.5 m/s air speed) to achieve the effect of increasing air speed from 0.5 to 2 m/s on the thermal comfort. Fig 7 shows the comparative result for room 6 in the first floor. It can be

concluded that using a ceiling fan to increase air speed improves more efficiently, from 10 to 65%, the thermal comfort during the hot season.

	2 m/s	1.5 m/s	1 m/s
May	49.87	46.57	34.14
June	65.26	55.85	29.64
July	48.92	33.06	6.72
August	54.37	39.78	10.69
September	46.37	43.82	34.14

Fig. 7: Improved percent of thermal comfort by increasing air speed in comparison with 0.5 m/s (Room 6 floor1)

5.5 Effect of activity level

The simulation results for room 6 in the first floor, with an air change rate equal to 1 (reference model) have been compared with the model 1 with sedentary and low activity level. Fig 8 shows that, by changing the activity level from low activity to sedentary, the thermal comfort change is more noticeable.

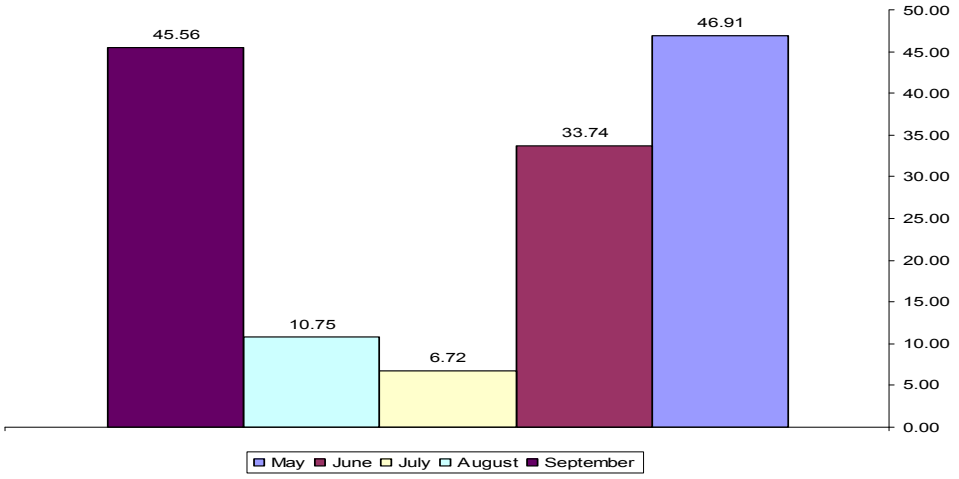

Fig. 8: Improved percent of thermal comfort by changing the activity level from low to sedentary activity (Room 6 floor1)

6. Results and discussion

In this paper, the hourly effect of using the thermal insulation, with hollow brick external walls, accompanied with natural night ventilation, based on the level of thermal comfort conditions has been investigated. Based on the results, the following conclusion remark can be formulated:

1- The best thermal comfort condition is achieved in the first floor of the building, in rooms 6, 7, 2, 3, 5, 4, 8 and 1 (descending order).
2- In cases without night ventilation and without air speed increase, changing the building construction material of the reference building has not a noticeable effect on the thermal comfort condition (maximum 4%), despite the increase of the build cost.
3- In case with night ventilation, without air speed increase, changing the building construction of the reference building has a more noticeable effect on the thermal comfort condition (4 to 11%).
4- In case without night ventilation, with air speed increase, the thermal comfort change is more noticeable (about 10 to 65% in all month).
5- The change of activity level, from low activity to sedentary, leads to a more noticeable change of the thermal comfort.

In consequence, using night ventilation with ceiling fans (to increase air speed) is suggested to improve the thermal comfort condition. This change is cost effective, and can be suggested for new and existing buildings in Rasht and other regions with similar climate.

Integration of Zero Energy Standards into Student Accommodation: Demonstrated through a Case Study of Lancaster University Residences in the UK

Hasim Altan
Director/Lecturer
BEAU Research Centre
of Sheffield University
United Kingdom
h.altan@sheffield.ac.uk

Summary

The paper aims at the possibilities of converting the student accommodation of University of Lancaster (UK) into zero energy building. The analysis has been carried out on the typical student accommodation unit and an evaluation has been completed on the amount of energy saved, carbon emission reduction and energy produced by renewable sources. The paper also provides results of a study of climatic conditions of Lancaster and its influence in the design, based on which zero energy building techniques have been used to make the building energy efficient. In the study, the thermal efficiency, daylight factors, artificial lighting and energy production are considered to make the units sustainable. Series of computer simulations have been completed on the unit to assess the impact of thermal insulation on space temperature and energy uses, window openings to admit in the required light and use of solar collectors to produce energy. This particular building and site has been selected as it could become the template of student accommodation in the UK. As per statistics, there has been an increase in the demand for student accommodation with the increased flow of foreign students coming to the UK. This phenomenon has forced mainly university to expand their accommodation infrastructure and the University in conjunction with the University Partnerships Programme who were able to develop accommodation with standards of Ecohomes. The study looks at the possibility of achieving zero energy standards for the Ecohomes so that it could be used as design template to build greener student accommodation around the country to answer the demand.

Keywords: Eco Residences, Zero Energy Building, Student Accommodation, Building Simulation, Photovoltaic Cells, Energy Consumption

1. Introduction

With the existing energy crisis and increasing global warming around the world, designing buildings which are energy efficient have become a prime importance for developed countries like USA, Germany, and many others which consume major part of the world energy. In most developed countries, energy efficiency standards are incorporated into the building regulation in order to reduce the overall energy consumption. Zero energy buildings are a breed of buildings which help to produce energy from green sources and reduce energy consumption. There have indications all around that the climate is changing and it is the human beings who are majorly responsible. Predominantly because of the emission of greenhouse gases, particularly carbon dioxide has added to the deterioration of nature. It is important that all nations join hands together to make our earth free from carbon emissions.
Approach towards Zero Energy Buildings (ZEB) will be a big step to achieve the same. A ZEH combines state of the art, energy-efficient construction techniques and equipment with renewable energy systems to return as much energy as it takes on an annual basis. It is a known fact that a

normal bases renewable energy cannot fulfil the energy requirement all round the year. That is in case of nights in absence of solar energy, it has to depend on the national energy grid. At the same time, there are occasions when solar energy is not used by the occupant and therefore the energy produced is supplied back to the grid. This is used by the public utility giving the occupants the full retail value of the energy. In this context, the paper presents recent developments in how the UK is planning on moving towards energy-efficient building standards and ultimately towards zero carbon levels.

2. Moving Towards Energy-Efficient Buildings in the UK

2.1 Recent Developments

The 2003 Energy White Paper demanded for more energy-efficient buildings as part of energy policy of UK [1]. This was very well reflected in the years 2006-2008 with the tightening of energy efficiency within the building sector. It has a long term goal of cutting down carbon emission by 80% by the year 2050. It aimed at cutting down energy consumption by 80% in comparison with a building which have been built by 2002 building standards. The other major rating system is the Code for Sustainable Homes which has been introduced by the government in 2007 replacing the Ecohomes [12]. This is used to rate housing in the public sector and buildings which undergo major refurbishment or new buildings. Ecohomes look out for a wide range of sustainable issues in which energy efficiency is only one. Requirement for good practice and advanced practice is set by the Energy Trust for achieving low energy buildings [2].
In addition, Association for Environment Conscious Buildings' (AECB) CarbonLite program specifies silver and gold standards, the latter approaching a zero energy building. In housing particularly, in order to improve the efficiency of all the residential accommodation, local authority had been given the responsibility of considering measures as per the Home Energy Conservation Act 1995. It was projected that between 1996 to 2010 there will be a cut down of 30% in the energy usage, but as per reports to Department for Environment Food and Rural Affairs (DEFRA) [3], there have been only 14.7% of cumulative improvement by the end of March 2004 and most of it was achieved without the Home Energy Conservation Act [4]. As for the present day, the goal is to achieve the 2016 target of making all new housing zero carbon and follow that by the 2019 target of making all new non-domestic buildings zero carbon in the UK. Even if the goal is fulfilled, it is important to address the existing building sector and particularly residential sector which also has to be energy-efficient [9].

2.2 EU Zero Energy Building Legislation

"All the buildings build after 31st December 2018 will have to produce as much energy as they consume on-site, says the European Parliament, amending the 2002 Energy Performance of Buildings Directive (EBPD). MEPs also call for the more public investment in energy-efficient buildings." [5]. The target is that an EU member state must ensure that by above date all the newly constructed buildings will consume as much energy it can produce on-site. Again, MEPs defined a Zero Energy Building (ZEB) as a building, where as a result of very high level of energy efficiency, the overall annual primary energy consumption is equal to or less than the energy production from the renewable energy source on-site [5]. The proposal will lead to high insulation of buildings so as to reduce the energy consumption and to meet the remaining energy demand by effective incorporation of appropriate renewable energy into the building including all type of residential buildings.
In the present scenario, on-site energy production does not work out to be cost effective. That is when we compare PV power stations and large wind turbines to small PV panel and wind power respectively. To make it more economically sustainable for the consumers, they must be given the freedom to produce energy off-site. This is possible in the form of community wind farm or solar farms for which the local authority has an important role to play. Majority of the European citizens live within the urban setting and in such situations it is difficult to install ground source heat system and roof spans are also limited. Zero energy is achieved by producing energy in the summer and

utilising it in the winter or the reverse of it. The very nature of zero energy makes it limited to a set of buildings and the application of the idea in a massive scale is still not very clear.

2.3 Zero Energy Building Concept

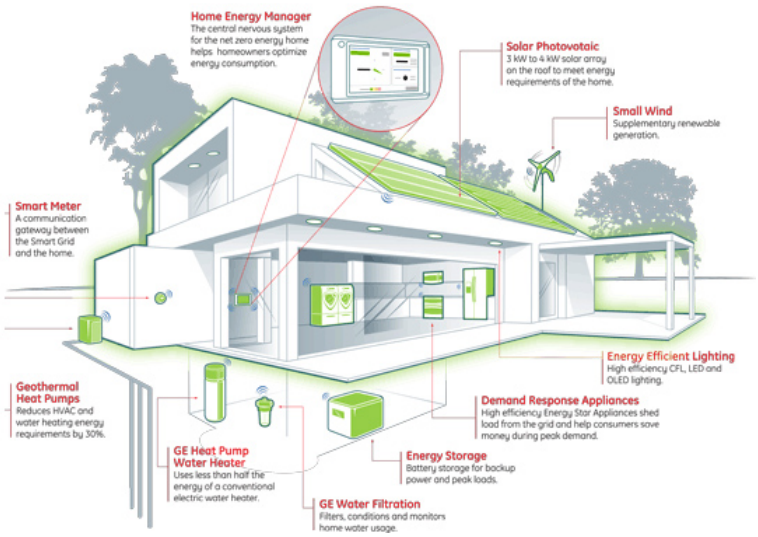

Fig. 1 Zero Energy House Concept

A Zero Energy House combines state of the art, energy-efficient construction techniques and equipment with renewable energy systems to return as much energy as it takes on an annual basis (see Fig. 1). If you see on a normal bases renewable energy cannot fulfill the energy requirement all round the year. That is in case of nights in absence of solar energy it has to be depended on the national energy grid. At the same time, there are occasions when solar energy is not used by the occupant and the energy produced is supplied back to the grid. This is used by the public utility giving the occupants the full retail value of the energy.

"Zero is the cross over point between a building that consumes the resource and one that produces the resources. Conceptually building has no impact. First on the definition front –the word "zero" is really "net zero". The sum of the flows is equal and opposite. This does not imply zero consumption from the national grid." [6]. The emphasis is on the amount of consumption (demand side) or on the various ways on alternate energy could be produced (supply strategies) and whether the methods used meet the zero energy standards. There are four aspects of ZEB which are as follows: Net zero site energy; Net zero source energy; Net zero energy cost; Net zero energy emission [7].

In the paper, the study is based on the assessment of the amount of energy that could be saved by means of passive design solutions. It aims to explore how far the definition of zero energy homes is practical and cable of producing desired result .The present ZEB definition does not adapt to the idea of producing energy off-site. Residential sector does consume a good percentage of national energy. It is therefore important that residential sector meets the ZEB standards and that the load on the national grid is reduced and energy used is greener. A question therefore arises how a house meets a ZEB standard? How different will be the outlooks of the zero energy houses in comparison with that on non-zero energy houses?

The definition of Net Zero Energy Building (NZEB) used by the industry committee is: "...where, as a result of the very high level of energy efficiency of the building, the overall annual primary energy consumption is equal to or less than the energy production from renewable energy sources on site". [6]. Torcellini et al (ACEEE 2006) identified the following main definitions of zero energy buildings (ZEB) [8]:

- Net zero site energy- A site ZEB produces as much energy that will be equivalent to the amount required by it in a year.
- Net zero source energy- A site ZEB produces as much energy by the renewable source whose total will be equal to the primary energy used to generate energy.
- Net zero energy cost- In a cost ZEB, the amount of money which the utility pays to the owner should be equal to the money paid by the owner for the energy services used in a year.
- Net zero energy emission- Building which produces as much emission free renewable energy as that of the consumed emission produced by the energy sources.

3. Case Study

3.1 Eco-Friendly Student Accommodation at Lancaster University

Fig. 2 Exterior view of student accommodation

In the year 2008, BREEAM rated the Eco Residences at Lancaster University with an 'Excellent' rating. Carbon footprint per student was said to be of 25% less than targeted carbon emission rates required by building regulations (see Fig. 2). The Eco Residence is a template for easily constructed sustainable university accommodation. It marks the last phase of the agreement between University Partnership Programme (UPP) Ltd and University of Lancaster dating 2003 in which redevelopment of student accommodation was one of the main goals. It has been one of the largest projects undertaken. The project has delivered 4347 rooms over three phases, with an investment of £180 million [10]. The final stage of the scheme has provided 963 additional students rooms which are completed as per UPP eco accommodation model. The eco accommodation reduces the carbon emission by 30% by using timber from sustainable sources. Energy and water saving features have been integrated into the accommodation. The students are encouraged to live in a sustainable environment by providing online monitoring system of their utility consumption and by integrating recycling schemes into their residences.

3.2 Design Solutions

Ground Floor

First Floor

Fig. 3 Residences' layouts

Town houses and cluster houses were the two layouts developed by UPP Ltd and Lancaster University for the Eco Residences (see Fig 3).

Town house: It consists of a large kitchen with dinning along with living room at the ground floor. A unit accommodated about 12 students and each floor, starting first floor four bedrooms and two bathroom/toilet facilities included. The town house is grouped in residences of 3 to 5 units together were each unit measured 6m wide and 12 in lengths. These dimensions made it possible to span the floor without the support of the load bearing walls. Therefore it gives it a possibility to reconfiguration of the floor plan in the future [11].

Cluster flat: It contained six en-suites flat with sharing kitchen/dining and living. The flat is approximately 12 wide and 24m long. It has a central staircase which is shared by two flats in each floor and each unit is four storied. For the future reconfiguration, the floor has been spanned between the external wall and the central corridor. Great care has been taken into the insulation of the accommodation. The insulation is 50% better than stated in the current building regulation [11].

3.3 Sustainable Features

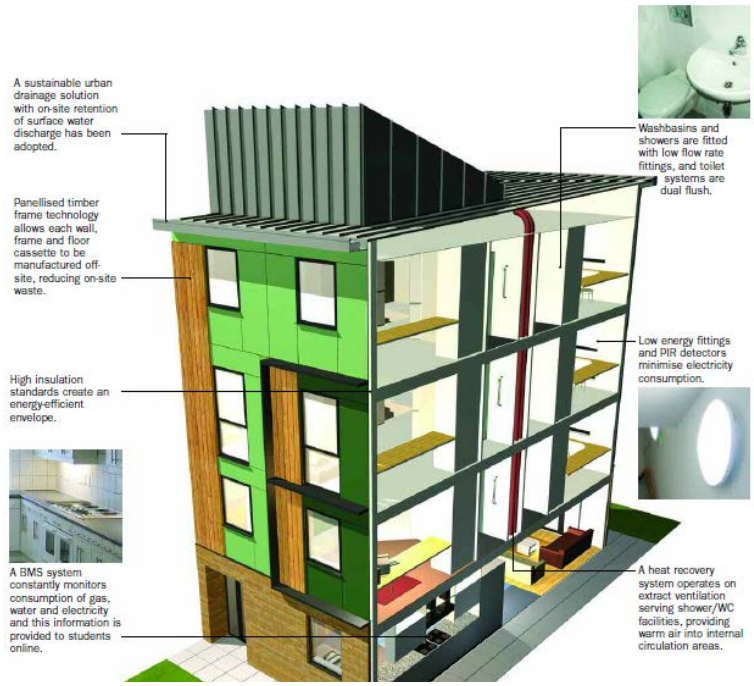

Fig. 4 Eco residence

The Eco Residences had the following features in terms of an eco-friendly construction technology implemented to make the building sustainable and a superior services used to cut down energy consumption [11] (see Fig. 4):

- It has been constructed out of panelised wooden frames which make it possible to construct the door and window off-site hence reduce onsite waste and also speed up the building process. The which is been used has been sourced from the FSC (Forest Stewardship Council). When it comes to shower heads, wash basin and toilets are delivered in prefabrication, which is fully tiled and needs only to be fitted in the correct position and connected.
- Care has been taken to look into the fact that the materials used for construction are non-toxic.
- Lower level of the building is exposed with the brick work and the higher level is gladded with cement cladding and cedar cladding panels.
- A very high energy efficient envelope is achieved by providing high insulation standards.
- Each room is facilitated with a small radiator which is controlled by a thermostatic radiator valve.
- Communal areas are installed with PIR (passive infrared sensors) detectors to ensure lights are switched on only when it is needed and also the lights are of low energy.
- Unexpected use of high wattage appliances is prevented by implementing mini circuit breakers into the study room.
- Heat from the waste water is tapped by using heat recovery system which is connected with the shower, washbasin and toilet facilities which is later used to heat the internal space.
- Toilets are installed with dual flush systems and low flow rate fittings are used to washbasins and shower heads.
- On-site retention of surface water discharge has been adopted to have a sustainable urban drainage solution.
- BMS systems are installed which enable the students to keep track of their energy consumption in terms of gas, water and electricity.

3.4 Simulation Studies

In order to make an effort to understand whether energy is effectively used or wasted, a monitoring is essential. Most of the student accommodation uses energy more than what is required due to improper planning. For example designing a passage space which can be lit up by natural light can save considerable energy for lighting. At the same time, students must be aware of the consequences of energy wastage and possibilities of energy conservation in today's lifestyle. Designing an energy-efficient accommodation will enable them to improve their outlook of students towards energy conservation.

The building which has been selected for simulation studies is an eco-friendly student accommodation at Lancaster University. The aim of the study is to use an existing building considering a particular unit and later projecting the results on the building blocks with similar

features. Moreover, it will explore the possibilities to make eco-friendly buildings zero energy buildings by using renewable sources of energy sources.

The building: County field flats are four stories high, with the entire one bedroom flats are arranged along the east- west axis and the two bedroom flats are aligned perpendicular to the one bedroom flats. One bedroom flats are arranged in blocks containing 3, 4 and 7 flats in a block. Breakup of the blocks provides space for passage which used as disability access to ground floor rooms. This helps to reduce the wind pressure on to the buildings and again to blow in wind into the courtyard which blocked from other sides. Each single room flats consist of the following spaces: Lobby; Ground floor bedroom (designed for those with disabilities in certain cases); Kitchen; Living; Staircase shaft; Passage spaces; Bedrooms (12 rooms); Toilets (6 in total) (see Fig. 5).

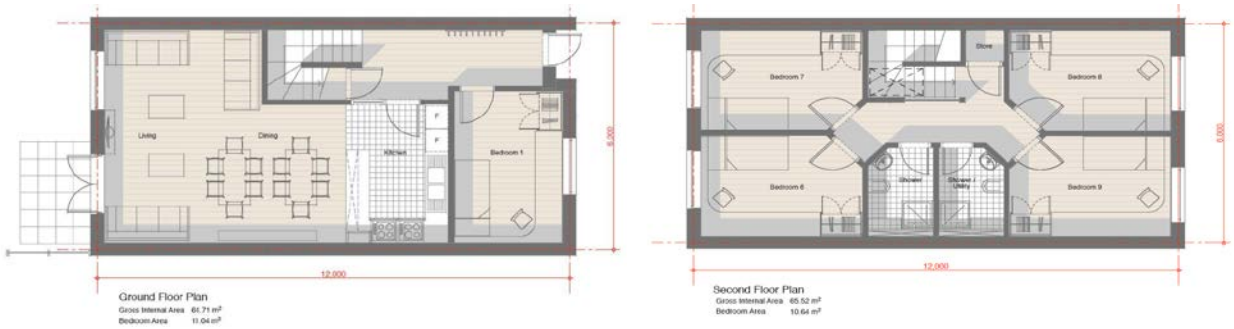

Fig. 5 Ground floor plan (left) and typical upper floor plan (right)

3.5 Energy Consumption and Internal Spaces

In order to make the student accommodation a zero energy building using renewable sources, it is important to comprehend the amount of energy required to run the accommodation units. Energy required to run the units has to be calculated and verified with the readings obtained to cross check the definiteness of the findings. Energy consumption is calculated using the chart obtained from the carbon footprint website. It gives the average value of the number of times a particular appliance will be used in a year. This data used to project the yearly consumption by correlating it with the watts of the corresponding appliances. The results have been obtained are explained in the form of graphs and its interpretations are illustrated in the paper.

Lobby/Staircase: These are spaces which are used round the day. The major requirement is lighting and space heating. This has been provided with glass door in order to maximise daylight whereas for staircase shaft there is no openings and as result, it demands artificial lighting. Motion sensors are installed for efficient lighting in the passage spaces.
Living room: It is basically used in the morning for casual sitting in the morning for breakfast or become communal spaces for the students from 6pm to 10.30pm.
Kitchen: This is a space which is used without any fixed pattern from morning to evening as different students has different timings for cooking. More or less this space is heavily used from 6pm to 10pm. Kitchen space contributes to the energy consumption by the usage of appliances, hot water for cooking and dish washing and space heating requirement.
Bedroom: The spaces where students spend majority of their time in a student accommodation. During the time activity that involves energy consumption are lighting, use of laptops and space heating. In normal weekdays, a student spent about 12 to 14 hours of a day in the room which is normally from evening to morning.
Bathroom/Toilet: The prime usage time will be 7.00am to 8.30am. This space contributes to the energy consumption by the lighting and greatly by the hot water requirement.

Table 1 is showing a typical single unit and its energy consumption.

Table 1 Energy consumption of a single unit

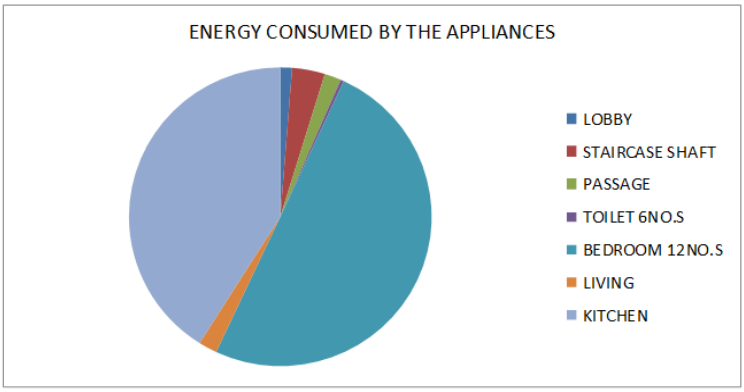

Fig. 6 Energy consumed by different rooms

Fig. 6 clearly shows that maximun energy is used by bedrooms when summed together followed by kitchen. Energy consumption by the appliances when 12 bedrooms are put together constitutes half of the energy consumed by the entire unit excluding the energy consumed for heating. Lobby space, staircase shaft, passage, toilets and living rooms when together only consumes a small portion of energy. The reason behind this is that in all other spaces within the unit, energy is consumed only for lighting and energy required for it can be reduced drastically by using an energy-efficient lighting system. Moreover, these are the two major spaces in which students spent their most of time, and which involves utilisation of appliances which consume the most of energy. The energy consumed for appliances sums up to 4979.62 kWh of energy excluding the energy required for heating.

3.6 Energy Consumed for Heating

The model of a single unit is developed in Ecotect software and it has been simulated to perform the thermal analysis. The analysis has been carried out by providing selected materials with appropriate u-values as specified by the Code for Sustainable Homes.

External fabric: Constructed with thermal efficient timber cassette shell that has a u- value of 0.14W/m^2 K.
Roof: Engineered I beams were used, filled with recycled newspaper insulation with 100mm wood fibre with OSB top and bottom and an internal vapour control large to the underside of the OSB. U-value of 0.12 W/m^2 K.
Floors: Constructed from concrete planks with 150mm foam insulation under a 50mm screed with 50mm edge upstand. U-value of 0.15 W/m^2 K.

Doors and Windows: Windows with triple glassed FSC certifnied with U-value of 1.2 W/m^2 K. External doors U-value of 1.1 W/m^2 K [12].

The design standards have been integrated with the architectural design as specified by the code. The PassiveHaus design certifies the building when the heating energy spent on heating is not more than 15kWh/m^2/year [13]. After simulation, the value obtained is approximately 33 kWh/m^2/year which is double to the value set by the standards of PassiveHaus.

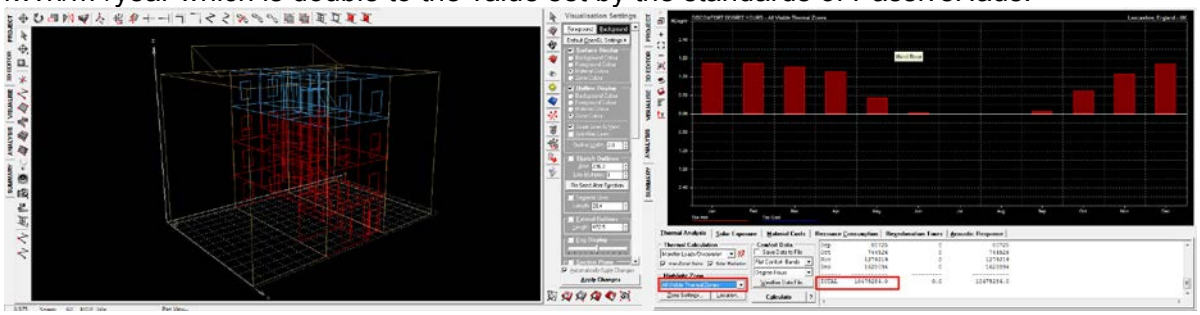

Fig. 7 Ecotect model (left) and total heating loads of the entire unit (right)

Thermal analysis has been carried out considering comfort band between 18-23°C with occupancy rate of four per zone and internal air change is taken to be as still air. Operational hours are set from 18pm to 8am. Each floor has an internal floor area of 78.37 m^2. Simulation studies have shown that there is a gradual increase on the loads from first floor to third floor. At the same time, heat required for ground floor is greater than the first floor. The ground floor layout has less inetrnal walls. Third floor plan has the highest annual consumption of 41.79 kWh/m^2 and first floor has the lowest which is 29.14 kWh/ m^2. Considering all other zones together, the annual energy spent is 10475.28 kWh with an average of 33 kWh/m^2 of energy is spent on heating. Summarising both the energy required for heating and for appliance adds up to 15454.9 kWh as per the rates of British gas, 1kWh cost 15.3 pence on an average [14]. Thus cost £2364.57 a year and £197.04 a month.
The goal was to find the amount of energy that can be produced by wall mounted or roof mounted photovoltaic (PV) panels that can help to cut down the energy consumption from the national grid.

4. Conclusion

In order to demonstrate the energy generation, a comparison of the two sets of model has been carried out; the model with wall mounted PV panels has given a better result. The reason being that southern wall gets more solar radiation compared to the roof as the sun stay very low in the sky for the major part of the year. In the other model, the PV panels were overshadowed by the neighbouring panels which resulted in providing the more space in between which in turn resulted in less productivity per unit area. The vertical stacking of PV panels on to the wall has proved to be more effective than arranging PV panels on to the flat roof when it comes to energy produced per unit area.
By using a wall mounted Crystalline Silicon cell module (15% efficiency), it can achieve 20.45% of annual savings whereas a roof mounted can only save up to 8% on the energy consumption. For the very same reason wall mounted reduces electricity bill by £483.6 which is double of the amount saved by roof mounted systems. The same is reflected in the case of CO_2 reduction. Roof mounted reduce CO_2 emission by 1.8 tonnes annually whereas wall mounted cut down CO_2 emission by 2.8 tonnes annually.
CIGS cells with increased efficiency (19%), a much better performance than crystalline silicon cell module were achieved. The difference between powers generated by both the models is not as significant. Annual generation by the wall mounted is 3159.06 KWh and the energy generated by roof mounted is 2634.24KWh. Roof mounted CIGS cells helps to cut down CO_2 by 2.5 tonnes annually whereas wall mounted cut it down by 3.05 tonnes. Wall mounted cut down 24% of annual energy cost whereas roof mounted is only capable of cutting it by 17%.

Using a CNT based cell module (50% efficiency), more than the total sum of the energy generated by the other two cells were achieved. It cuts down CO_2 emission by 7.7 tonnes in the case of wall mounted and 5.04 tonnes when it comes to roof mounted system. The most important part is that it can generate more than 50% of total annual consumption by the wall mounted systems and the energy consumption cost is reduced to half the total annual amount.
Today, 85% of the UK market consists of crystalline silicon. The reason is that the UK market is dominated by the smaller roof top application. Compared to crystalline silicon, the market of tin film photovoltaic has increased from 7% to 17% over the recent years but only 10% and 12% efficiency module is available commercially. CNT based cells module technology is not available in the commercial market. They are supposed to dominate the market of solar power by the year 2020. The cost will be less than half the price of crystalline module available in the present market. Therefore, the Eco Residences can meet zero energy standards by CNT based cells alone in the future. However, for the present day only the combination two or more renewable energy is required to meet the zero energy standards. By using 19% efficient CIGS based cell can produce enough energy for the unit to offset the energy requirement for appliances. It is best to combine solar power with ground source heating system which can substantially cut down the energy requirement for heating and meet the standards of zero energy building.

Short Summary

This is a basic study on developing an assessment technique to objectively measure environmental loads of recycling building materials throughout their life cycle. At present, the building materials industry does not have any detailed procedures and standards necessary in estimating greenhouse gas emission caused by manufacturing and utilization of products developed using waste materials as ingredients. Therefore, it is necessary to develop an assessment methodology with which to measure in advance the environmental loads that can be lowered at waste recycling. This study aims at proposing a life-cycle assessment method to quantitatively assess potential environmental load reduction of recycling building materials by each stage, such as manufacturing, use and disposal of building materials made using recycled materials.

Keywords: Carbon emission reduction; Life Cycle Assessment; Environmental impacts; Avoided Impacts; Recycling Building materials.

1. Introduction

The amount of waste generation in Korea's construction field is displaying a continuous trend of increase from 26% to more than 51% over the last ten years. The actual rate to recycle construction wastes as cyclic aggregate is approximately 22%. This means that most construction wastes are simply recycled for soil banking or covering and that the rate of recycling for concrete and subbase, the highly economical uses, is very low at around 14%. In addition, as demand for new building construction and reconstruction increases rapidly, the problems associated with insufficient amounts of natural aggregate collection are worsening and an enormous national budget loss is incurred due to land damage and natural environmental destruction resulted from development of aggregate supply sources. Accordingly, it has been necessitated for the construction industry to make efforts for preventing waste of natural resources and reducing environmental load and greenhouse gas emission caused by resources development and use by turning wastes into resources. In other words, it is required to suppress generation of construction wastes by developing technologies for efficient recycling and reuse of waste resources and to implement a low-carbon resource recycling system by turning wastes into resources in the building products fields.
However, building materials fields are currently lacking detailed procedures and standards necessary for estimating the amount of greenhouse gas emission generated by production and use of building materials. Therefore, it is difficult to establish objective environmental load reduction plans through improvement of product applicability or reusability by assessing potential environmental impacts and analyzing processes in which greenhouse gas emission is concentrated. In addition, a methodology to estimate life cycle greenhouse gas emission specialized to the construction industry is not yet established and implementation of national LCI

DB(Life Cycle Inventory Database)[1] to represent each material is insufficient. This results in a shortage of basic data for $LCCO_2$ assessment of carbon reduction-type building products using recycled resources. Therefore, it is required to develop standards for assessment technologies to measure in advance the environmental loads according to materials used in production, the manufacturing process and utilization of the manufactured products.

2. Objectives and Scope

2.1 Objectives

This is a basic study on developing an assessment technique to objectively measure environmental loads of recycling building materials throughout their life cycle. At present, the building materials industry does not have any detailed procedures and standards necessary in estimating greenhouse gas emission caused by manufacturing and utilization of products developed using waste materials as ingredients. Therefore, it is necessary to develop an assessment methodology with which to measure in advance the environmental loads that can be lowered at waste recycling.
Recycling building materials are produced using mainly waste and, thus, the ratio of natural resources content is low. As much as so, different assessment scenarios must be applied to measuring environmental impacts by life cycle and a methodology to estimate carbon dioxide emission according to each scenario must be established in detail. This study aims at proposing a life-cycle assessment method to quantitatively assess environmental impacts of recycling building materials by each stage, such as manufacturing, use and disposal of building materials made using recycled materials.

2.2 Scope

Although there can be various methods of quantitatively assessing environmental performance depending on the points of view, this study uses an analysis method based on $LCCO_2$ (Life Cycle CO_2) in relation to climate change agreements, which are emerging as an international issue. Building materials undergo numerous processes during their life cycle, ranging from production and use to disposal. Using the $LCCO_2$ assessment method, data on the inputs and outputs in each stage can be gathered, and data on environmental load generated during the product life cycle can be developed.

3. Methodology

3.1 Definition of the $LCCO_2$ assessment

$LCCO_2$ is defined as a technique of quantitatively assessing potential environmental impacts during the product life cycle ranging from production to disposal based on CO_2 equivalent (CDE). A typical technique of quantitatively measuring the environmental load generated by the use of products and services is the LCA (Life Cycle Assessment) methodology set forth as an international standard. By applying this methodology, the environmental load of natural resources, human health, and ecosystem according to the production and use of a target object can be evaluated quantitatively. With greenhouse gas (GHG) becoming an issue nowadays due mainly to the advent of climate change conventions and certified emission reduction (CER), the $LCCO_2$ technique -- which takes into account only the global warming potential (GWP) among the LCA results -- has been brought to the fore. In other words, $LCCO_2$ complies with the LCA methodology based on the international standard ISO 14040. With regard to the environmental impact in the life cycle of products and

[1] LCI DB (life cycle inventory database) is the database that has listed waste discharged from the resources, energy, and system inputted into the environment during the life cycle ranging from the extraction/gathering of raw materi-als required for production, processing, transport, and use of a product to the disposal of the product.

services, however, the $LCCO_2$ technique is defined as the environmental impact assessment method expressed as GWP index.

3.2 Process of the $LCCO_2$ assessment

3.2.1 Functional units and reference flow

LCA is carried out targeting the final products or services having main functions. Therefore, it is very important to set functional units. The purpose of a functional unit is to quantify the services offered by a product. The reference flow of materials and energy is then set by interpreting the functional units based on the performance of the targeted product. Here, reference flow indicates the number or quantity of products required to carry out functional units.
In the product $LCCO_2$ assessment, the method of setting functional units is based on the unit product sold in the market. When the functional units are unclear, or to aid in a third party's understanding, a separate functional unit for the product concerned can be set as necessary. When the production process of products released in the market is the same, but the sales type and size of the products differ according to consumer requirements, units such as 1kg and 1ton of a product can be used as basis.

3.2.2 System boundary

A system refers to an aggregate of a series of activities that carry out clearly defined functions. In a broad sense, a system covers the acquisition of raw materials up to product use by industrial companies or consumers and final disposal of the product. The system boundary is decided by the unit processes included in LCA, and the scope, by intended use, limitations of data, expenses, assumptions, and intention to apply the research results.
In ISO 21930, an international standard on the building products' environmental declaration, the products' environmental information from cradle to grave should be drawn based on the information modules described in ISO 14040 and ISO 14044. Accordingly, the life cycle of building materials can be divided into 4 stages: production, construction, use, and disposal stages.
The environmental impacts according to the flow of materials and energy in each stage can be calculated based on CO_2 emissions. The following describes the system boundaries for the building materials' $LCCO_2$ assessment:

A. **System boundary of material production:** This boundary includes all the processes of pro ducing the building materials to be inputted into a building by consuming the resources and energy required for production, such as the extraction/gathering of natural resources and re cycled resources and manufacture of products into finished goods or semi-finished goods. T he data to be collected in this stage are activity data related to natural resources extraction/g athering, intermediary and final product production activity data, and transport data between raw material extraction/gathering and manufacturing workplace or between manufacturing w orkplaces.

B. **System boundary of construction:** This boundary includes the process of transporting ma terials constituting a building from the material production site to the construction site and the stage of completing the building by inputting building materials, energy, and various mac hines by construction techniques. The object of data collection in this stage is the data on th e transport means, distance, and cargo in the transport process and data of raw materials u se volume of machines inputted in the site construction process.

C. **System boundary of use and maintenance:** This boundary includes the process wherein a user maintains a gradually wearing and tearing building through additional repair and main tenance while the user resides in the building until the completed building is demolished. Th e types of activity data to be collected in the use stage are the quantity of materials and ener gy volume inputted for maintenance and transport activity data of the transported materials.

D. **System boundary of disposal and recycling:** When the use of a building ends, this bound

ary includes the following, i.e., when a building is demolished using equipment, the building waste is transported to a building waste materials processing plant for reclamation or incineration or recycling as raw materials of other products. In this stage, data derived from demolition activity, data by reclamation, incineration, and recycling according to disposal mode, and transport activity data from the demolition place to each processing place are collected.

$LCCO_2$ in the building materials can be calculated as the total of the values of activity data in each stage of the life cycle multiplied by the relevant basic unit of CO_2 emission. As set forth in the building products' EPD criteria or carbon emission assessment guidelines, the system boundary or information module in each stage of the life cycle is decided. Likewise, unit processes within each boundary are defined, with each carbon emission according to the activities in the unit process subsequently calculated.

3.2.3 Data Collection

It is important to know what is connected and what flows in each stage of the life cycle, since LCA is the process of quantifying the flow of materials and energy. To prevent the omission of data on various inputs and outputs generated during the building's life cycle and to collect quantified data, the category of data to be collected should be set, and the relevant parameter list should be made in advance.
The data collection scope is divided into field data collection scope and general data collection scope. General data include disclosed general data including national LCI data and selected foreign database. Field data include the data preferentially collected from the participating companies' workplaces. The general data collection scope differs depending on the collection scope of site data. For example, general data disclosed with the consent of participating companies can be used in relation to raw materials, utilities, and external process facilities having difficulties in collecting data.
In principle, activity data needs to be collected based on field data. When field data cannot be collected, however, general data can be used. System boundary for data collection is divided into 4 stages in line with the building materials' life cycle; the data collection method of each system boundary can be summarized as follows (table 1):

Table 1: Data collection method of each system boundary

System Boundary	Information Module	Input data	Output data	Types of Activity data
Material Production Stage	Raw material supply	Material, Energy	CO_2 eq	Activity data related with raw material and energy production
	Transport	Energy	CO_2 eq	Transport data between manufactories
	Manufacturing	Material, Energy	CO_2 eq	Activity data related with end product manufacture
Construction Stage	Transport	Energy	CO_2 eq	Transport data between product manufactories and construction site
	Construction – installation process	Energy	CO_2 eq	Activity data related with construction machinery
Use & Maintenance Stage	Use	Energy	CO_2 eq	Activity data related with energy consumption of end product
	Maintenance	Material, Energy	CO_2 eq	Activity data related with product maintenance
	Transport	Energy	CO_2 eq	Transport data between product manufactories and building
End of life Stage	Disassemble	Energy	CO_2 eq	Activity data related with dismantling product
	Transport	Energy	CO_2 eq	Transport data between building and disposal facility
	Recycling	Material, Energy	CO_2 eq	Activity data related with waste treatment for recycling or reuse
	Disposal	Energy	CO_2 eq	Activity data related with waste landfill or waste incineration

4. Proposal for measuring CO_2 reduction

4.1 Expanding System Boundaries

The model in life cycle assessment to describe resources and energy flow in the ecosystem is basically divided into an environmental sphere and a technical sphere. Environmental sphere is where natural resources and primary energy before the stage of artificial processing exist and technical sphere is where human activities take place. The system boundaries for life cycle environmental impact assessment on a target are generally limited to the acts of processing, construction, utilization and disposal that take place within technical sphere. Environmental impacts are calculated by collecting the relevant data and applying the corresponding LCI DB by each input substance.
However, in case a waste substance discharged within specific system boundaries inside technical sphere, such as recycling building materials, is processed and utilized as a recycling resource or biomass within another system boundaries, it is necessary to add a new circulatory sphere so that to explain the phenomenon of a cyclic closing that takes place within technical sphere. This special circulation of recycling materials is illustrated in figure 1. As for recycling resources, collection and disposal of the resources take place within technical sphere. Accordingly, by expanding system boundaries to include collection and disposal of materials, both carbon reduction occurring in the stage of collection and potential environmental load reduction occurring in the stage of disposal must be taken into consideration.

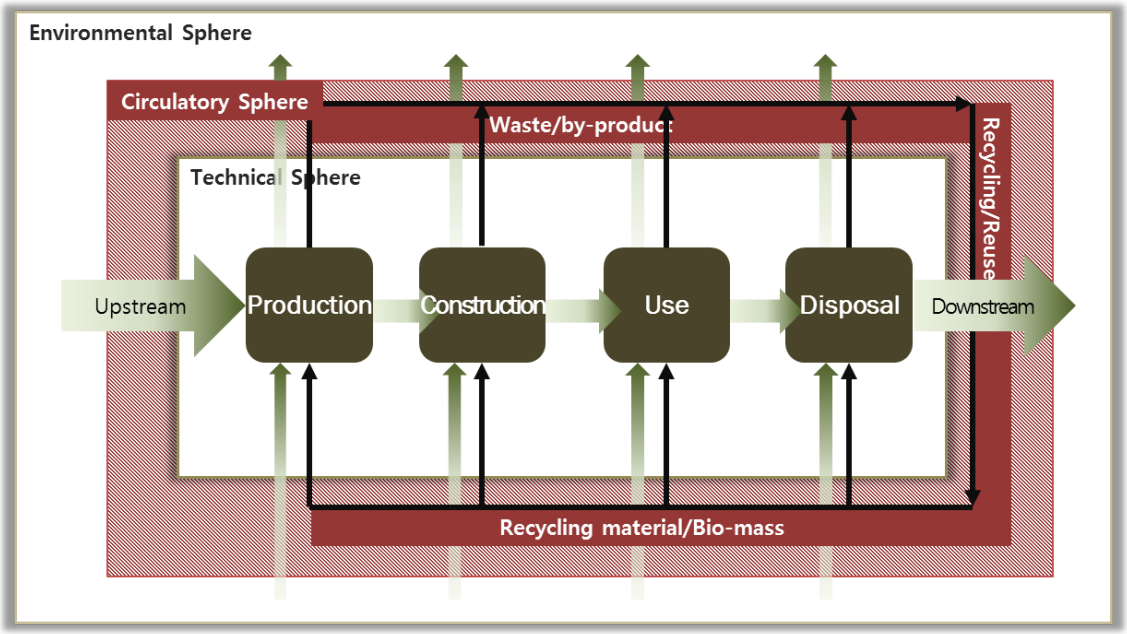

Figure 1: Illustration of circulatory sphere for the recycling materials

4.2 Considering Avoided Impacts

In life cycle assessment, avoided impacts refer to considering potential environmental impacts occurring before or after an assessment period established with life cycle of an assessment target within the system boundaries. As system boundaries changed according to assessment period expanding to be longer than the life cycle of an assessment target, the quantitative environmental impacts estimated are expressed as relative values in this study. Figure 2 explains how different the system boundary is to consider the avoided potential impacts by materials recycling.

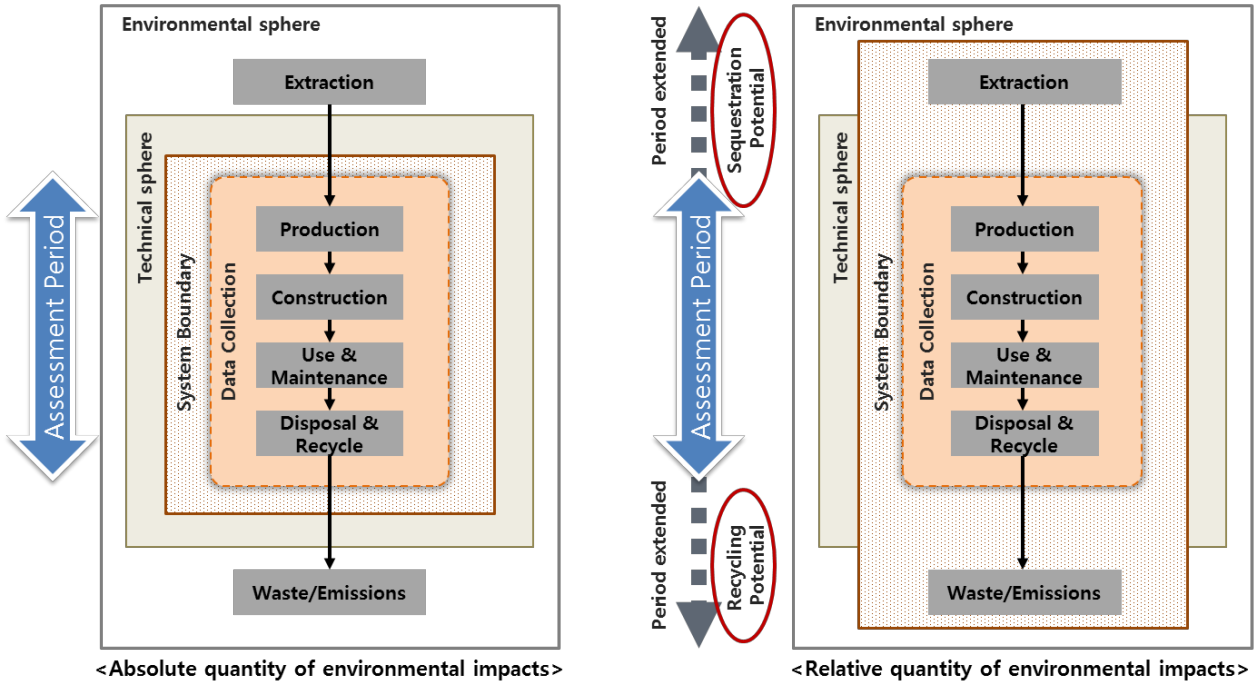

Figure 2: Comparing the system boundary for absolute quantity and relative quantity

An example of considering avoided impacts in an environmental impact assessment is the carbon sink effect acknowledged in the Kyoto Protocol. As Kyoto Protocol acknowledges afforestation and farming land development as carbon sink activities, for carbon-based products that absorb carbon in the materials stage, the amount of carbon absorption is deducted from the total carbon emission. Likewise, additional natural resources and energy consumption can be prevented by recycling or reusing waste. Considering potential environmental impact reduction effects as such within the system boundaries of an assessment target, the avoided impacts can be calculated quantitatively.
The potential amount of carbon reduction in the stage of materials collection and the potential amount of carbon reduction in the stage of disposal can be called sequestration potential and recycling potential respectively. In this study, the avoided impacts by resource recycling, potential carbon reduction in the stage of materials collection and the potential carbon reduction in the stage of disposal were expressed as reduction potential, sequestration potential and recycling potential respectively. Figure 3 is the formula for calculating the relative quantity of carbon emissions during entire life cycle of recycling building materials.

- $LCCO_2 = C_P + C_C + C_{U\&M} + C_{D\&R}$
- $C_P = C_E + C_M + \sum C_{ti} - C_{Sequestration}$
- $C_C = C_I + \sum C_{ti}$
- $C_{U\&M} = C_U + \alpha(C_E + C_P + \sum C_{ti} - C_{Sequestration})$
- $C_{D\&R} = C_D + C_R + \sum C_{ti} - C_{Recycling\ potential}$

- C_P = carbon emissions during material production stage
- C_M = carbon emissions from final product manufacturing
- C_E = carbon emissions from raw material and resources excavation
- C_P = carbon emissions from final product manufacturing
- C_T = carbon emissions from transportation of raw material, products or waste
- $C_{Sequestration}$ = carbon reduction by using carbon-sink materials or carbon-based materials
- C_C = carbon emissions during construction stage
- C_I = carbon emissions during building construction or assembling building parts
- $C_{U\&M}$ = carbon emissions during building operation and maintenance
- C_U = carbon emissions from building operation
- α = coefficient of maintenance cycle, (=assessment period/durability period of material)
- $C_{D\&R}$ = carbon emissions during building demolition, waste disposal, recycling and reuse
- C_D = carbon emissions from building demolition
- C_R = carbon emissions during recycling or reuse process
- $C_{Recycling\ potential}$ = carbon reduction by substituting recycled material for virgin materials

Figure 3: The formula for calculating life cycle CO_2 of recycling building materials

4.3 Case study

Figure 4 is case studies of carbon reduction potential which applied the $LCCO_2$ formula. In the first assessment, the absolute amount of carbon emission was estimated using the same system boundary model as the one used in the existing carbon labeling system. In the second assessment, calculation was carried out by expanding system boundary to the stages of materials collection and recycling in order to take into consideration the potential carbon reduction amount generated by recycling of resources.

		Production	Construction	Use & Maintenance	Disposal & Recycle	Reduction Potential	Total
Fumed silica insulation board 	Absolute quantity	1.43	0	0	0.0641	X	1.5 kgCO2e/ea
	Relative quantity	1.43	0	0	0.0641	-1.23	0.265 kgCO2e/ea
Stone dust artificial marble 	Absolute quantity	21.5	0	0	0.254	X	21.7 kgCO2e/ea
	Relative quantity	21.5	0	0	0.363	-20.2	1.65 kgCO2e/ea
Stone dust concrete panel 	Absolute quantity	33.2	0	0	0.683	X	33.9 kgCO2e/ea
	Relative quantity	33.2	0	0	0.975	-31.2	2.97 kgCO2e/ea
WPC window profile 	Absolute quantity	1.12	0	0	0.0143	X	1.13 kgCO2e/m³
	Relative quantity	1.12	0	0	0.0086	-0.913	0.215 kgCO2e/m³

Figure 4: Case studies of carbon reduction potential of recycling building materials

5. Conclusions

The life cycle of recycled building materials consists with the stage of production, the stage of construction, the stage of application and maintenance and the stage of disposal. The sum of emission amounts resulted from activities in each stage is the life cycle carbon emission amount.

A. **Production stage:** The sources of carbon emission activity in production stage include raw materials for production, energy collection, manufacturing process and transportation of raw materials and energy. If raw materials are the source of carbon absorption, according to the carbon reduction effect generated by carbon sink, the amount of carbon emission can be lo wered as much as the amount of absorbed carbon.

B. **Construction stage:** The sources of carbon emission activity in construction stage are largely divided into activity to transport building products to a construction site and activity to assemble the building products using construction equipment. The amount of carbon emissions is calculated by adding emission amounts caused by each activity.

C. **Use and maintenance stage:** The sources of carbon emission activity in application stage are divided into an activity to use building products and an activity to repair the products in o rder to maintain their performance during the period of use. The amount of carbon emission generated by the application of building products can be calculated based on the amount of

energy use and the amount of carbon emission generated by maintenance activities can be calculated by estimating repair cycle based on the product lifespan in comparison to total application period and then multiplying the repair cycle with the amount of product input in the initial phase.

D. **Disposal and recycling stage:** The amount of carbon emission generated by disposal of building products is calculated by adding the amounts of emission from dismantling the products and recycling activities, and then deducting the amount of carbon reduction resulted from production of natural resources that are substituted with reused or recycled materials.

The results of this study can be used in deriving detailed procedures and standards of an assessment to measure environmental loads in relation to recycling materials used in processing of building materials, final products developed using the materials and their manufacturing processes. Further studies can be implemented in a direction to specify applicability and suitability of the assessment methodology in identifying causes of environmental loads, which are generated due to unique characteristics of recycling products, such as recycling and transport of waste, and also of other environmental loads occurring internally in manufacturing plants.

Summary

Sustainability requires the development of new economic frameworks and business models for a better management of materials and energy. For example, the performance economy (as well known as product-service system) proposes new function-based business models instead of product-based business models. Performance economy can be applied by companies through dematerialization of their offers and rental of a service. In this case, companies keep ownership of materials involved in the service provision over their life cycle, which gives a strong incentive to optimize resource efficiency.

This study aims to rigorously quantify environmental impacts of the performance economy in the case of industrial storage, by comparing the rental of metal-textile storage structures with classic storage solutions (like warehouses). To accurately take into account the management of materials and the reuse cycles (e.g. logistics, stock management), a material and energy flow analysis (MFA) is carried out, using the Umberto® tool. Based on representative demand profiles, various use scenarios are defined and analysed. A Life Cycle Assessment (LCA) is then carried out to compare this service provision with plausible alternatives.

Over five environmental indicators (primary energy consumption, climate change, abiotic depletion, photochemical ozone formation and water consumption), it has been shown that rental of metal-textile storage structures can have a lower environmental impact than classic storage solutions. Environmental benefits of metal-textile structures are even higher when storage of non-standard pallets occurs (due to the modularity of the structure) or when stock turnover is high (due to the proximity of the structure). However, benefits can be lower whether the pallets are stored for a short time, or the supplier of structures is far from the need of storage.

To conclude, thanks to its lightness and the reuse of materials, as well as the modularity of the design, metal-textile structures could be lower environmental impact solutions for industrial storage and could bring flexibility and reactivity compared to classic storage systems.

Full Paper

1. Context and objectives

Sustainability requires the development of new economic frameworks and business models for a better management of materials and energy. For example, the performance economy (as well known as product-service system) proposes new function-based business models instead of product-based business models. Performance economy can be applied by companies through dematerialization of their offers and rental of a service. In this case, companies keep ownership of materials involved in the service provision over their life cycle, which gives a strong incentive to optimize resource efficiency.

Performance economy has been experienced in different sectors (e.g. printing, transport ...) and is nowadays considered as a way to reconcile economy and sustainable development. This observation is mainly due to the fact that in a performance economy system, added value of a product or service and natural resources consumption are decoupled. In some case a reduction by 30% to 50% of raw material and energy consumption per unit of service have been observed by shifting from classic business model to performance economy business model. An explanation for this reduction is that this new business model is intrinsically opposed to planned obsolescence business model. Indeed, as the added value of a system is measured by the performance of the system, companies involved in a performance economy business model have a high interest to reduce their consumption of raw materials and energy per unit of service, driver for the product price.

Industrial storage is a sector in which performance economy has been developed for a long time. Indeed, instead of building a shed, a company which have some storage need can rent a logistic service or rent a metal-textile structure in order to insure merchandise storage. These two types of service have been developed mainly because of:

- Technical issues: Reactivity, modularity ...
- Economic issues: Risk management, financial investment ...

Nowadays companies are less and less interested by building their own warehouse. Indeed, this classic solution for industrial storage is not flexible for companies because:

- It needs a high investment and have a long return on investment
- It is not well sized for seasonal activities
- It consumes time to build
- Companies need a high visibility on their storage need and evolution
- It is considered as fixed assets

Even if performance economy of storage sector has not grown first from environmental drivers, the Serge Ferrari Company was interested to assess the environmental impact of different storage solutions. More than a classic environmental comparison, a specific analysis has been realized on the rental system of metal-textile structures to make possible interaction with environmental performance of industrial storage. Indeed, metal-textile structures show interesting properties like:

- Obsolescence risk management: unlike simple warehouse or logistic platform, there is no risk of obsolescence in the case of metal-textile structure because if a company do not need storage space anymore, metal-textile structure can be disassembled and use in another place.
- Proximity: Metal-textile structure can be assembled on-site where the need of storage is required. This specific feature permits to reduce the use of trucks to transport merchandise between storage place and need.
- Modularity: Metal-textile structure can be adapted to merchandise that have to be stored and in particular when merchandise is stored on non-standard pallets. Indeed, in classic logistic platform, when non-standard pallets are used, racks cannot be used so logisticians need to store on the floor (they cannot store in the whole space of the warehouse).

This study aims to rigorously quantify environmental impacts of the performance economy in the

case of industrial storage, by comparing the rental of metal-textile storage structures with classic storage solutions (like warehouses) on realistic storage need scenarios. To accurately take into account the management of materials and the reuse cycles (e.g. logistics, stock management), a materials and energy flow analysis (MFA) is carried out, using Umberto® tool. Based on representative demand profiles, various use scenarios are defined and analysed. A Life Cycle Assessment (LCA) is then carried out to compare this service provision with plausible alternatives.

This study has been performed using two types of data:
- Primary data : specific data collected from industrial companies
- Secondary data : generic data available in Life Cycle Inventory databases

According to its lightness and modularity, metal textile structures are foreseen to be interesting solution for industrial storage compared to classic warehouse and logistic platform. In this comparison perspective a best case/worst case approach have been used. This means that:
- Favourable hypothesis have been chosen for classic warehouse and logistic platform (Best case)
- Unfavourable hypothesis have been chosen for metal-textile structure (worst case)

This point of view allows robust conclusion if metal-textile structure presents better environmental performances than other solutions.

The different storage solutions analysed in this project are presented in Figure 1.

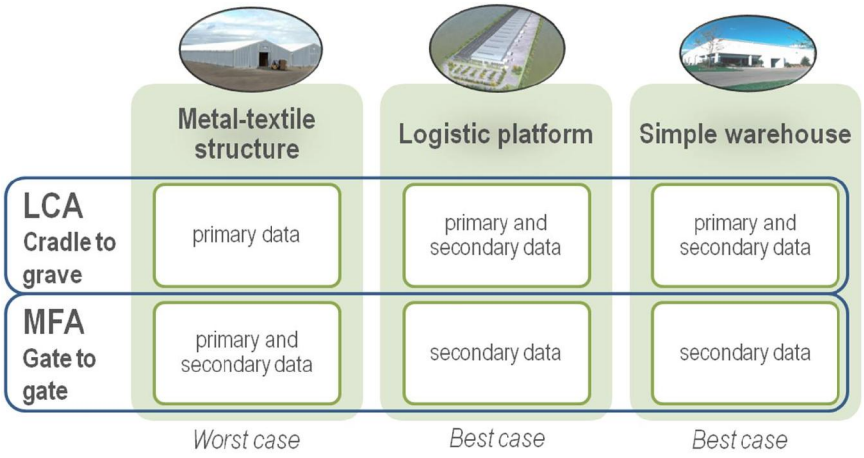

Fig.1: Storage solution analysed in the project

In order to compare these different storage solutions, 2 specific scenarios have been defined, based on case study, and are presented in figure 2.

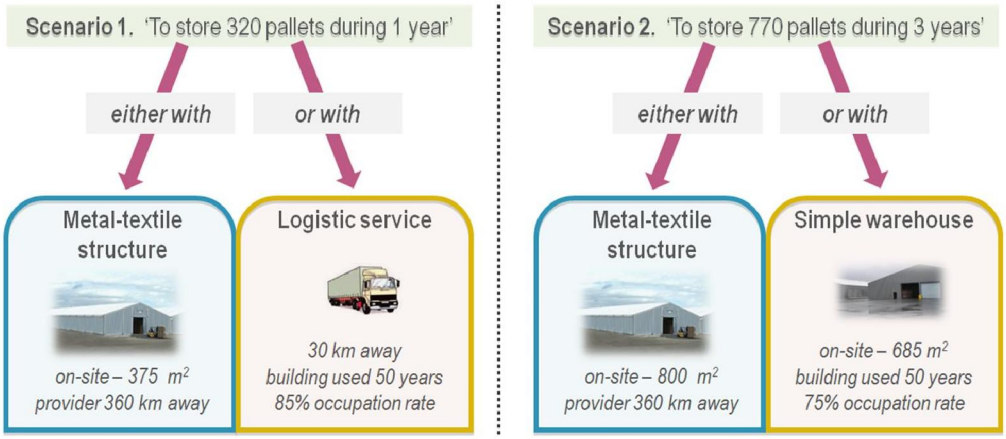

Fig.2 : Scenarios analysed for industrial storage solutions comparison

2. Methodology

The rental of metal-textile structures has some specificity compared to simple warehouse or logistic platform. Indeed, this type of system needs a material management of parts (storage, repair, reuse loops ...). According to this complexity, Material and Energy Flow Analysis has been carried out in order to evaluate “gate to gate” results of this system. Then, Life Cycle Inventories have been used in order to add upstream and downstream flow and going to a “cradle to grave” Life Cycle Assessment.

2.1 Material Flow Analysis

Material flow analysis (MFA) is a comprehensive assessment of the flows and stocks of materials within a system defined in space and time. It connects sources, pathways, as well as intermediate and final sinks of a material. Because of the law of conservation of matter, inputs and outputs have to be balanced on different levels of the system (unit process, part and whole system). MFA is mainly used as decision-support tool in resources management and wastes management and more generally in environmental management.

An MFA delivers a complete and consistent set of information about all flows and stocks of a particular material within a system. The term material stands for both substances and goods, depending on the system modelled and objectives of the MFA. Materials can be chemical elements, substances, mixtures of substances, commercial products, etc. Through balancing input and output, the flows of wastes and environmental loadings become visible, and their sources can be identified. The depletion or accumulation of material stocks is identified early enough either to take countermeasures or to promote further build up and future utilisation. Moreover, minor changes that are too small to be measured in a short time scale but that could slowly lead to long-term damage also become obvious.

In MFA, systems (defined in space and time) are modelled using 3 elements:
- Places: physical or conceptual location which is source or sink of materials
- Processes: natural or man-made phenomenon which lead to modification of material or energy. Processes are defined by the relationship between input and output.
- Flows: Material or energy transfer per unit of time from a place to a process (input flow) or from a process to a place (output flow).

MFA methodology is complementary with other tools like Input/Output analysis or Life Cycle Assessment. The objectives of MFA are:
- Delineating a system of material flows and stocks by well-defined, uniform terms
- Reducing the complexity of the system as far as possible but based on robust data and usable for decision making
- Presenting and assessing the relevant flows and stocks of a system in a reproducible, understandable and transparent way and revealing sensitivities and uncertainties
- Using the results as a basis for managing resources, the environment and wastes

MFA model for metal-textile structures rent is presented in figure 3.

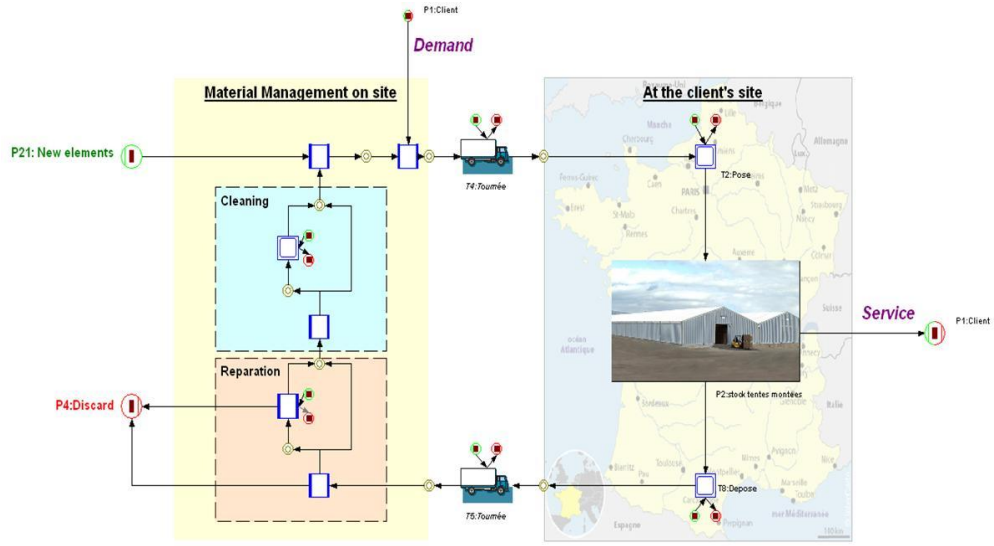

Fig. 3: MFA model of a metal-textile structure rent for industrial storage using Umberto® software

2.2 Life Cycle Assessment

According to ISO 14040, Life Cycle Assessment is a method to assess environmental aspects and potential impacts associated to a product, by:

- Compiling an inventory of relevant inputs and outputs of a product's system;
- Evaluating the potential environmental impacts associated with those inputs and outputs;
- Interpreting the results of the inventory analysis and the impact assessment in relation to goal and scope.

The goal and scope govern the way these three steps are conducted; this approach is named "goal dependent". From this initial definition, four phases are identified:

1. Goal and scope: this step defines exactly why and how the study will be performed. An important aspect is the way in which methodological choices are to be made.
Examples of such decisions include how the system's boundaries are used, allocation procedures, and the way impact assessment procedures are applied;

2. Inventory: phase where the life cycle of TFE's product is carefully modelled as a set of interrelated processes. The emissions and the use of resources for each process are compiled, and the result is a long list of emissions and consumed resources;

3. Impact assessment: the inventory result cannot be evaluated without a good understanding of environmental relevance of an emission or resource extraction. In impact assessment, inventory results are therefore grouped together or classified into a number of impact categories, such as climate change, ecotoxicity, and depletion of fossil resources. By using a set of characterization factors, an impact category indicator result can be compiled. This results in an environmental profile of usually 10 to 20 impact category indicator results. As optional procedures, these indicator results can be normalized and weighted to get a better understanding of the meaning of the impact category indicator results.

4. Interpretation: the inventory and impact assessment results are interpreted in relation to original goal and scope of the study. A number of procedures are used to check the validity of the conclusions of the study. These procedures include uncertainty analysis, sensitivity analysis, consistency checks, and issues relating to impact assessment.
LCA is an iterative methodology, that's why each phase is interrelated.

The LCA methodology is standardized at the procedural level of the ISO standards 14040 (AFNOR, 2006) and 14044 (AFNOR, 2006).

There are two essential principles in the LCA methodology:
- The multi-criterion approach (a set of environmental impact indicators is studied);
- The multi-step approach (every life cycle step is part of the study, from raw material extraction till end of life).

The multi-criterion and multi-step approach of LCA is presented in figure 4.

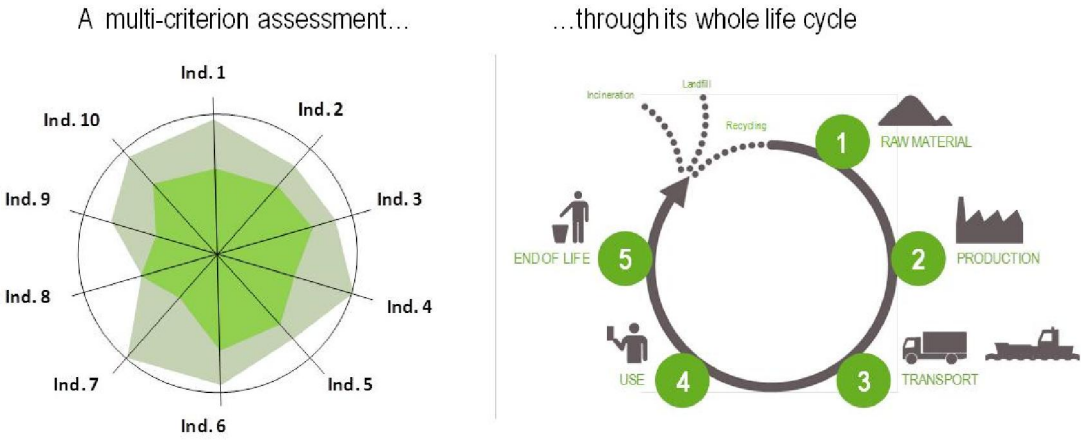

Fig. 4: Schematic representation of a life cycle assessment

3. Results

Five environmental impact indicators have been analysed:
- Total energy consumption (in MJ)
- Climate change (in kg CO_2 eq)
- Photochemical ozone formation (in kg C_2H_4 eq)
- Abiotic resource depletion (in kg Sb eq)
- Water consumption (in m^3)

Comparative results of two basic scenarios analysed are presented in figure 5.

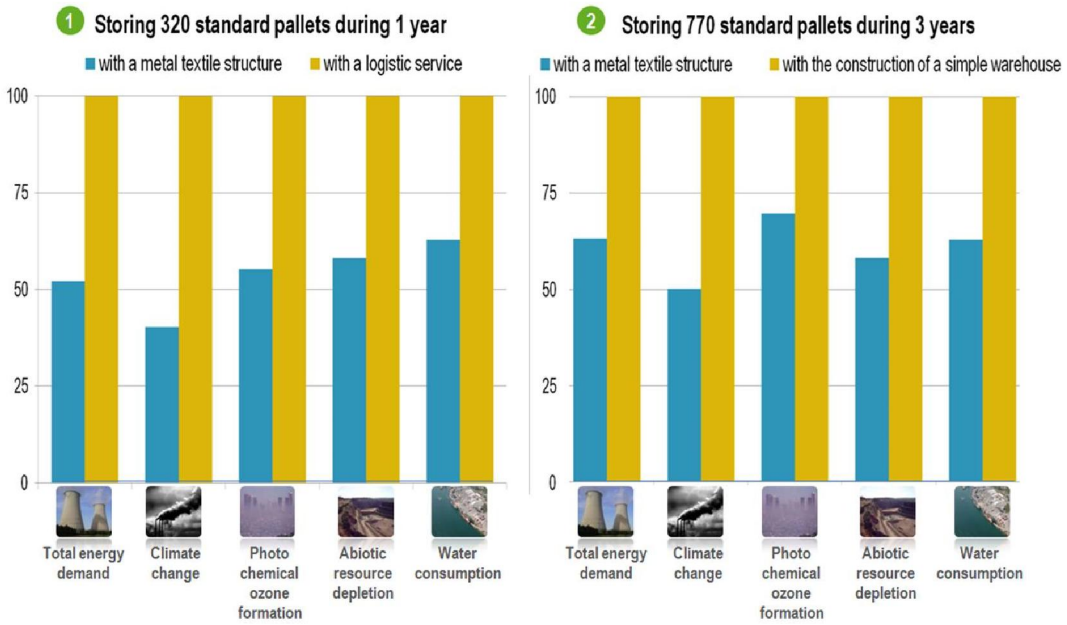

Fig. 5: Comparison of the two scenarios

Starting from these basic scenarios, a succession of sensitivity analysis has been performed with two objectives:

- Test data robustness
- Highlight some specificities of metal-textile structures (management of materials obsolescence risk, modularity ...)

Due to the risk of obsolescence, the effective lifetime of a warehouse can be only about 30 years instead of 50 years (lifetime generally used in LCA). In this case, environmental burdens per unit of service of the logistic platform increase.

Therefore, a sensitivity analysis on effective warehouse lifetime has been performed and results are presented in figure 6.

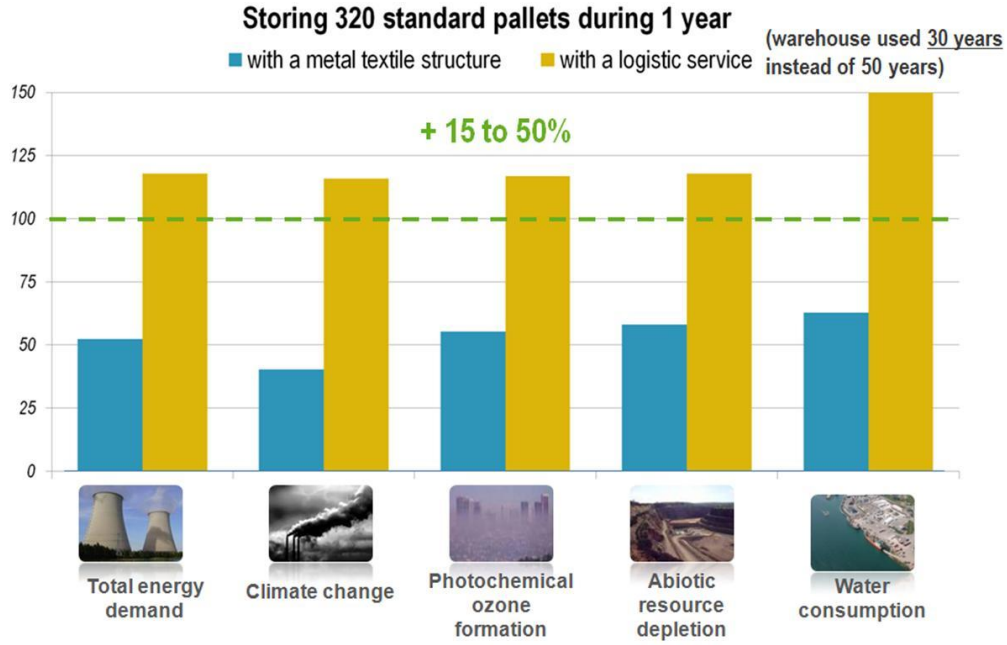

Fig. 6: Sensitivity analysis on the effective warehouse lifetime

Another specificity of metal-textile structures is that they can be adapted to specific pallets contrary to logistic platforms which generally need to store these non standard pallets on the floor (instead of using racks).

Therefore, a sensitivity analysis on the pallet type has been performed and results are presented in figure 7.

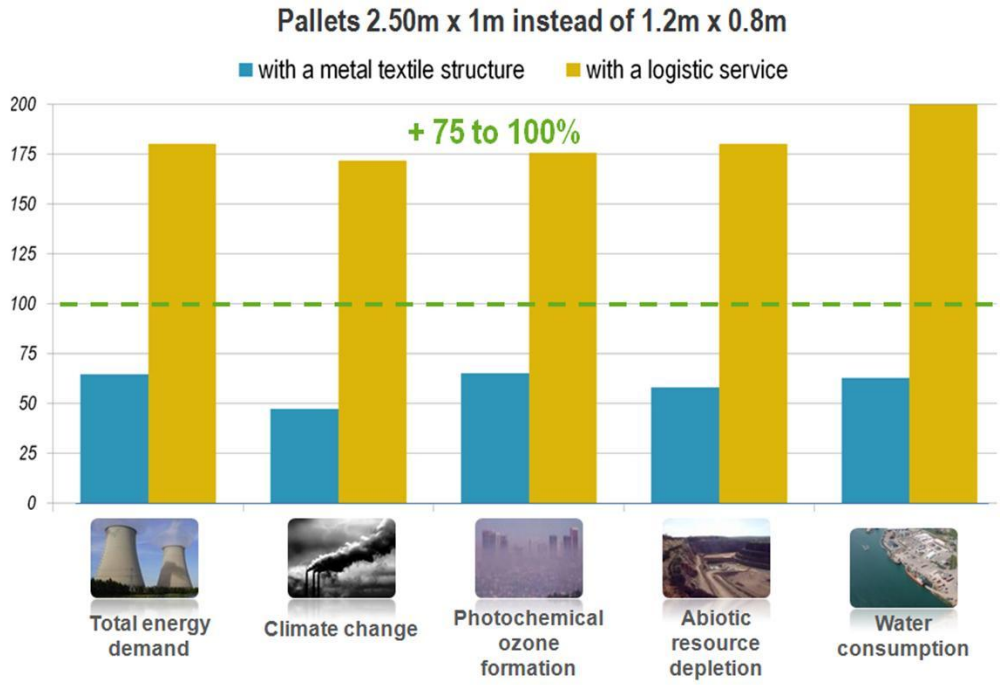

Fig. 7: Sensitivity analysis on pallet type

4. Interpretation and discussion

Comparison between different storage solutions shows that over five environmental indicators (primary energy consumption, climate change, abiotic depletion, photochemical ozone formation and water consumption), the rental of metal-textile storage structures can have a lower environmental impact than classic storage solutions (logistic platform and warehouse).

Thanks to its lightness and the reuse of materials, as well as the modularity of the design, metal-textile structures could be lower environmental impact solutions for industrial storage and could bring flexibility and reactivity compared to classic storage systems.

Environmental performances of metal-textile structures compared to other storage solutions are mainly due to:

- The lightness: reduction of material input per unit of service
- The proximity: reduction of pallet transport by truck
- The modularity: adaptation of the storage solution volume (no oversize needed)
- The efficient management of material (wastes reduction): reusing, repairing, remanufacturing and finally recycling

Moreover, this performance economy business model shows interesting properties which lead to higher benefits than the standard case. Indeed, thanks to the modularity, metal-textile structure can be adapted to non standard pallets, unlike logistic platform which are efficient for standard pallets (storage on racks) but less efficient with non standard pallets (storage on the floor). Metal-textile structure is also a solution which manages the risk of material obsolescence by reusing materials in another place where there is a storage need. Indeed, in the case of classic warehouse or logistic platform, if there is no longer storage need at proximity, the building becomes obsolete and most of materials involved in the building will not be used in another building.

However, this study shows that metal textile structures are not always better than other solutions on an environmental point of view. Indeed, when the storage need is far from the metal-textile structures supplier and when the storage time is low, environmental burdens per unit of service due to transport, assembly and disassembly of the structure is high.

Nevertheless, metal-textile structures are not destined to replace logistic platform or private warehouse which present other function that cannot be meet by metal-textile structures (thermal and phonic insulation, resistance to breaking in, etc). Moreover, environmental argument is not leading the choice of industrials for their storage solution because the decision in mainly based on technical and economic arguments.

Finally, this project shows some environmental benefits of technical textile in one specific application (metal-textile structures for industrial storage) but these types of textiles have many applications (in substitution to other materials). For example, technical textile can be used for:

- Frontage protection
- Dividing wall
- Signage
- Ceiling
- Specific architecture
- ...

Based on this project, thanks to its resistance and its lightness, technical textile may present environmental benefits compared to other materials. Technical textile presents many applications which need to be assessed on an environmental point of view.

Specific application of technical textile in events sector (e.g. Olympics Games) is presented in figure 8.

Fig. 8: Example of technical textile used in the building sector: The 2012 London Olympics Games

Identification of climate neutral buildings using LCA – Case studies from the project ÖKOPLUS-KOMPLEX

Short Summary

The paper summarizes main findings of the Austrian research project “ÖKOPLUS-KOMPLEX”, which investigated technical, ecological and economic pre-conditions for the implementation of plus energy and climate neutral building concepts. The paper focuses on the results concerning the technologies, which can be used to produce more energy on the buildings surface than needed by its residents in the operation phase, how life cycle assessment (LCA) was used to determine climate neutrality of the building, and the impact of setting different system boundaries on the results.

Keywords: Plus energy building, climate neutral building life cycle assessment (LCA) greenhouse gas emissions

1. Introduction

The construction and operation of buildings contributes significantly to the Austrian greenhouse gas emissions (GHG-emissions) and energy consumption. In the recent years so-called “plus-energy-buildings” were developed and first demonstration buildings installed, to reduce GHG-emissions and energy consumption in the building sector. In general the term “plus-energy-buildings” is used for buildings which generate more electricity than is needed by its resident within one year. However, there is no commonly accepted definition of “plus-energy-buildings”. Therefore in the project ÖKOPLUS KOMPLEX the concept of climate neutral buildings was investigated. Climate neutral buildings are defined as buildings which reach at least zero GHG-emissions over the total life-cycle of the building (including construction, operation, and demolition), due to the compensation of GHG-emissions with surplus energy (Figure 1). If climate-neutral-buildings are possible, and which technical, environmental and economic requirements are necessary for such buildings, was investigated in this project.

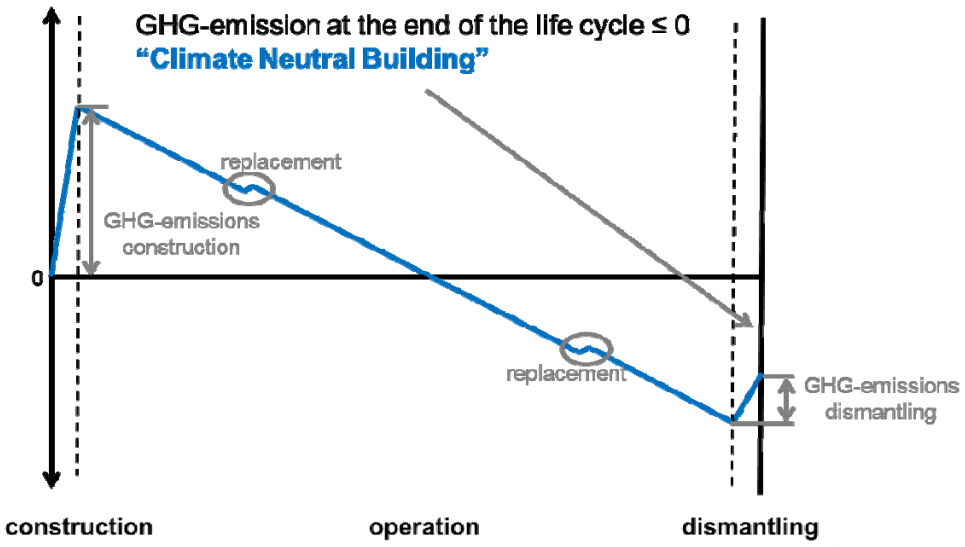

Fig. 1: Concept of a climate neutral building

2. Content of the project ÖKOPLUS KOMPLEX

Content of the project was the investigation of the possibilities to reach climate neutral buildings, with real existing buildings as starting point. In the first step GHG-emissions and non-renewable primary energy demand for construction, operation and demolition of the buildings was determined. Subsequently all relevant technologies for energy production on the building surface and within the building were identified. For the most promising technologies combinations of buildings and "technology options" were investigated. For selected combinations a technical, environmental and economic assessment was performed.

3. Results

Results are the GHG-emissions and non-renewable primary energy demand of the investigated buildings for the actual condition, identification of relevant technologies for plus-energy-buildings (technology options), an electrical energy balance for different technology options, and the environmental and economic assessment of buildings and technology options.

Starting point for the assessment was the selection of six existing buildings: three single family homes, one multi-story building, an event-building, and a housing complex.

The investigation of GHG-emissions and the non-renewable primary energy demand for the actual condition showed:

1. In the construction phase of the investigated buildings the potential to reduce GHG-emissions and non-renewable primary energy demand is rather low. Nevertheless, using insulation material with low GHG-emissions and low mass (amongst others by using "light" construction material e.g. "hollow concrete construction") GHG-emissions can be reduced.
2. The operation phase of the building has a significant influence on the GHG-emissions and the non-renewable primary energy consumption. A high energy efficiency of the building, minimizing the use of fossil energy carriers and maximizing the use of renewable energy carriers leads to a significant reduction of GHG-emissions during the operation phase.

Relevant technologies for heat and electricity production with renewable energy carriers in plus-energy-buildings are:

- photovoltaic (PV)
- small wind turbines
- small hydro power plants
- heat generation and combined heat and power generation with biomass

- solar thermal heat plants
- heat pumps

All these technologies, with the exception of small hydro power plants (due to the site specific and limited usage options), were examined more closely.

For the combinations of technology options and buildings, which resulted in a “plus-energy-production”, an environmental assessment was performed. The development of GHG-emissions and non-renewable primary energy demand for the total building life-cycle (construction, operation, demolition) was estimated. The economic assessment was performed for two buildings in combinations with technology options, which lead to climate neutrality. Economic aspects of electricity and heat production were investigated and the additional investment costs for plus-energy-buildings estimated.

Based on the results of the technical, environmental and economic evaluation, the following conclusions are drawn:

- Electric “plus-energy-production” is for all investigated buildings possible. In the planning phase, however, optimizing the system design and minimizing the energy demand is important.
- Suitable technologies for electric energy generation are photovoltaic and small wind turbines. Photovoltaic plants have a high building surface area demand, which is a disadvantage for multi-story buildings. The energy output of small wind turbines is strongly site specific. A detailed technical and economic planning based on the geographic and legal framework is necessary.
- Suitable technologies for thermal electricity generation are heat pumps, pellet boiler and solar thermal plants. Pellet boilers show an advantage for electric “plus-energy-production” due to the significant lower electricity consumption compared to the heat pump. Solar thermal plants are in competition for buildings surface space with photovoltaic plants.
- The environmental assessment showed that climate-neutral-buildings are possible. The investigated technology options are environmental optimized alternatives, which demonstrated the maximum GHG-reduction potential.
- The results of the environmental assessment are strongly influenced by assumptions, which are basic for the assessment (e.g. are GHG-emissions investigated or the primary energy demand, which energy carrier is substituted by the surplus electricity of the buildings).
- The building site is crucial for the mobility behavior of the residents. If the GHG-emissions for transport are included in the assessment, none of the investigated buildings reaches the status of a “climate-neutral-building”.

Short Summary

This paper presents a system to incorporate the economic benefits of sustainability into the valuation of real estate project developments. The impact is provided through the consideration of quantified sustainable qualities of buildings in the determination of the interest rate in the valuation process. Furthermore, it highlights the added value that sustainable features and the relevant certification systems bring to a project development. Using a catalogue of parameters, key parameters are identified for the specific project development to be valuated. These parameters are then quantified by means of distribution functions and checked for interdependencies. This analysis, and with it the results of a sustainability valuation, are incorporated into the calculation of the market value and the Internal Rate of Return. Results are communicated according to the input data through distribution functions. The valuation system makes investment decisions easier to understand and emphasises the positive impact that sustainable features can have on the economic success of real estate projects.

Keywords: project development, sustainability, valuation, real estate industry, certification systems, profitability, integral

1. Introduction

The prolific use of the term “sustainability” by the media and even more so by the advertising industry has turned it into a word which for many people has become no more than a marketing tool or a catchphrase. Yet the basic values that stakeholders, especially in the building industry, ascribe to the term are vital to the continued existence of our society: sustainability describes actions that do not compromise the ability of future generations to meet their own needs. The real estate industry has recognised this fact and has developed a number of certificates designed to help measure and implement sustainability. Nevertheless, the economic success of a property will always come first for investors.
The foundations for this success are laid at the start of a project, in the project development phase. Decisions taken at this stage are often not based on actual data, but on the experience and the intuition of the project developer. This makes it hard later for the stakeholders to understand the reasons behind those decisions; the process appears opaque. It is important, therefore, to find a way to include the sustainable features of real estate in the early stages of project planning and at the same time to achieve a balance between the sustainability and the economic success of a project. Other aspects that are often neglected in favour of investment costs are the follow-up costs and the life-cycle costs. When evaluating the estimated costs of a project in the early stages of

planning, each cost assessment relies on forecasts. However, people often forget that forecasts are not always accurate; instead, they tend to treat those numbers as deterministic values.
This paper aims to propose a model for the valuation of project developments under consideration of sustainability issues that provides the basis for informed decisions. The result is a systematised and transparent valuation model for project developments which will help to provide a sound and comprehensible basis for investment decisions and optimizations in the planning process. As a basis for the valuation model, a sustainability evaluation created for the project in addition to the data relevant for the project development is used. All project-relevant parameters from the sustainability certificate are contained in the valuation – including “soft”, not directly measurable factors. Another intention of this paper is to show that sustainability adds value for all stakeholders. A positive correlation between the economic success of a single project as part of the real estate industry and the fulfilment of sustainability criteria will be illustrated, which constitutes a win-win situation for all stakeholders.

2. Sustainability in project development

Sustainability and sustainable development are today firmly anchored in politics, society and in the minds of the people. Efforts are being undertaken in many areas to implement the idea of sustainability. This is also true for the construction and real estate industry, which is at the forefront when it comes to topics such as the responsible use of resources, waste management and other issues relevant to sustainability. The following quote clearly illustrates the importance of sustainable building:

Sustainable building means ... constructing and preserving buildings which, instead of being an inherited liability, will prove to be an asset for generations to come. [1, p. 221]

As the real estate industry produces objects that will be in use for at least decades, if not centuries, it must carefully assess the whole life cycle or usage period of any building being constructed [2, p. 48 ff]. Building sustainably, in a way that makes a building fit for the future, means fulfilling all ecological, economic, sociocultural, functional and technical requirements now and in the near future, cf. [3, p.8].

2.1 The significance of sustainability in the real estate industry

Over the past years, sustainability has become an integral part of the real estate industry. However, the added value of sustainability is different for each of the stakeholders. From an economic point of view it is important to ensure low operating costs and good value retention, while a positive ecological performance is seen as an intangible additional asset. Others, especially international investors, increasingly view property certificates as a good way to assess the quality of the object. Marketing provides another incentive for building sustainably. Recent studies have shown that sustainable properties have a higher sales potential than other buildings. In February 2012, the German bank “Deutsche Hypothekenbank” published a paper entitled “Sustainability in the real-estate industry”, which discussed the significance, the goals and the implementation of sustainability. The paper calls sustainability a social “megatrend” which influences people’s living conditions and behaviour. It cites mass production, electrification and globalisation as megatrends of the past. Sustainability has developed into a competitive factor due to its positive economic impact, its efficient use of resources and the eco-friendliness of sustainable buildings. This constitutes an advantage for investors, owners and users at the same time. All the above-mentioned factors have led to the establishment and growing recognition of sustainability certificates in the recent past, cf. [4, p. 5 ff].

2.2 Sustainability certificates

2.2.1 Objectives of sustainability certificates

The aim of sustainability certificates is to transparently and publicly detail the sustainable features of a building as well as to create economic advantages for property developers and investors. When it comes to direct competition and to decision making in the course of a project, it is important to be able to measure individual sustainability aspects [5, p. 6]. As well as serving as indicators for sustainability, certificates also act as important planning and optimisation tools.

2.2.2 The ÖGNI/DGNB system as a valuation basis for project developments

Valuation systems and their certification labels are now used on an international level, with some of them also catering to differing national standards. The most widely known of those systems are the British BREEAM system and the American LEED system. In German-speaking countries, the most popular system is ÖGNI/DGNB. It is also referred to as a "second generation system" because of its holistic approach to both time and topics. Most certificates divide the valuation areas into three main groups: ecology, economy and social issues. With three additional groups – technical quality, process quality and quality of the location – the ÖGNI/DGNB system provides a comprehensive set of data for valuation, which for example already includes life-cycle costs.
By looking at individual criteria, it becomes clear that there is a lot of common ground with the goals of project development, mainly when it comes to the economic criteria of life-cycle costs and value retention. But also other criteria linked to the topic of functionality play an important role, such as space efficiency and conversion capability. At the same time, the valuation system enables us to rate so-called "soft factors", for example the flexibility of use, using checklist points.

2.3 Implementing sustainability aspects in the course of the project development

New concepts and measures will be necessary in the future in order to implement sustainability effectively in project developments. Some of these are integral approaches which are already being used for the development and planning of projects. Integral planning means a simultaneous development of concepts in the different design disciplines [6, p. 42 ff] as opposed to the usual way of consecutively working on one project after the other.
The authors believe that for an effective implementation and coordination of the concept of integrated planning, we need an additional concept, namely the concept of *integral project management* or *integral project controlling*.

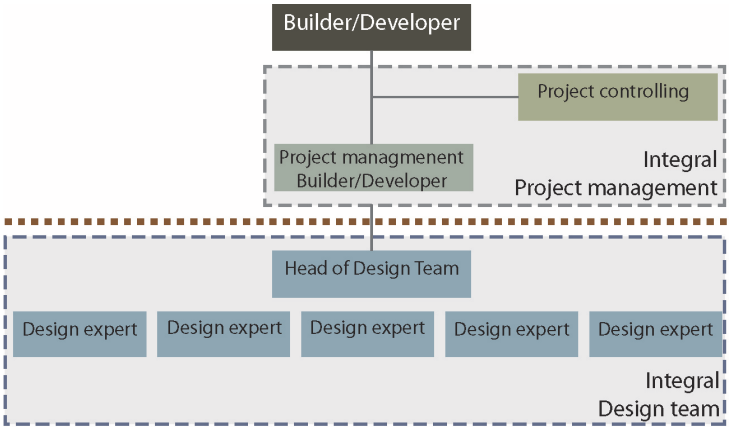

Fig. 2: Organisational structure for integral processing. [7, p. 87]

Integral project management thus meets a need arising from integral planning, namely to coordinate all stakeholders in the project as well as the design team in a holistic way. Integral project management differs from traditional project management in its focus, which lies on finding holistic and life-cycle oriented solutions and in implementing sustainability. The valuation model can be used in integral project management as a tool for improving planning and developing processes.

3. Valuation methods for project developments

The valuation of real estate, unlike the valuation of project developments, can draw on numerous standardised procedures. This kind of valuation serves various purposes and is carried out for many different reasons, but it is always a way of quantifying the economic benefit of an object without taking into account the subjective value for the stakeholders [8, p. 43].

3.1 The valuation method: basic requirements

In order to be able to choose or to draw up a valuation model for project developments, at first there has to be taken a look at how this kind of valuation differs from the valuation of real estate. Other than the pre-investment analysis, which would be useful for the valuation of project developments, traditional valuations are carried out on existing objects already in use. The valuation of preliminary designs happens much earlier, on the basis of much less information.

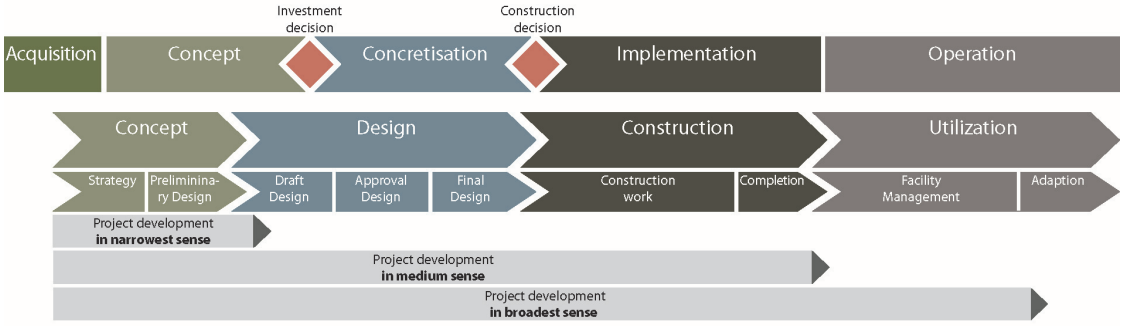

Fig. 3: Phases of project development. [7, p. 25]

The input parameters needed for the analysis, especially cost and benefit, are only available as forecasts. The range of fluctuation for those forecasts is still very wide, because many factors involved, such as dimensions and quality, cannot yet be determined [7, p. 24 ff].
Moreover, the valuation model has to be able to include the sustainable properties of the object into its market value. This can happen [3, p. 12] either by adding to or subtracting from the final market value or through an integrated approach, which directly influences the market value. In the valuation method the second option was chosen, because an integrated approach promises a more exact forecast through its direct effect on the value.

3.2 Creating a valuation model for project developments

The requirements specified above can only be fulfilled by the dynamic methods [9, p. 642] of a pre-investment analysis. From this group, the method most suitable for the valuation of project developments is DCF analysis. This allows for the inclusion of the life cycle, is very customisable when it comes to the periodicity of payments, and offers a high degree of transparency. In order to include the monetary impact of sustainable properties in the valuation of an object, it is indispensable to include the life cycle or the respective usage phase.

4. Valuation model

Using the aspects and requirements outlined in chapters 2 and 3, a valuation model was developed based on the DCF method, and the analytical interdependencies of the main project-specific parameters from the sustainability certificates and the project development were implemented. The valuation method comprises two sub-processes:

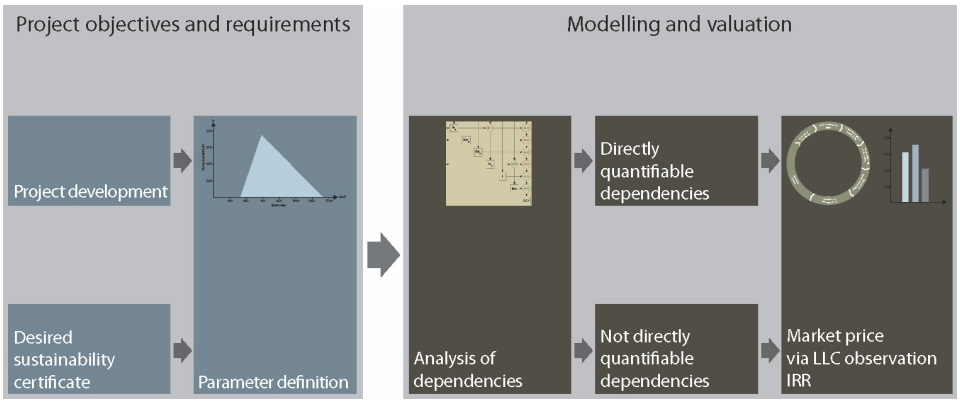

Fig. 4: Valuation process under consideration of sustainability issues

4.1 Input parameters and their quantification

The valuation model based on the DCF method requires a certain number of input parameters, mostly comprising revenue, expenses and general data. The input parameters are themselves influenced by input variables and preconditions, which were summarised in a parameter catalogue specific to the project development, cf. [7, p. 121 ff]
For example, rent prices not only depend on the features of the property but are also influenced by other variables. Within the valuation system these variables are referred to as project development parameters, and they also reflect the objectives established for each project. Occasionally these parameters can also be found in the sustainability certificates, for example when it comes to user satisfaction. In order to rationalise the evaluation process, the parameter catalogue is built up based on the individual project development [7, p. 122], with the relevant parameters being specially selected for each project.
Since it is not always possible to directly quantify the “soft factors”, parameters are divided into those that are directly quantifiable and those that are non-directly quantifiable. Directly quantifiable parameters can be incorporated via specific mathematical interdependencies, meaning their value can be clearly described. On the other hand, non-directly quantifiable parameters do not have a clearly identifiable impact on the result of the evaluation and define themselves via an indirect benefit – it is, therefore, not possible to establish a clear value. However, by using the ÖGNI/DGNB criteria it is possible to award so-called “checklist points” if certain criteria are fulfilled or if a building has certain features. Depending on their weighting, these points are then integrated into the sustainability evaluation. This option of using a catalogue of questions makes it possible to put into numbers parameters that are in themselves not quantifiable.
The actual quantification of the input parameters is carried out via distribution functions, since using probabilistic methods increases the general objectivity of the result. Indicating deterministic values creates the impression of a certain level of certainty, although in reality there is a margin of fluctuation. However, by processing the margins of fluctuation as distribution functions it is possible to predict the probability of a certain value actually being achieved. The investor can then use this information to take decisions on investments or construction projects and to determine budgets, thereby actively shaping his risk policy, cf. [10, p. 372].

4.2 Valuation process

The first sub-process shown in Fig. 4 describes the project objectives and requirements, which form the basis for identifying and quantifying the main project-specific parameters. The second sub-process is where the actual valuation takes place within the framework of the valuation model. Through this valuation the dependencies of the parameters are analysed and divided into directly quantifiable and non-directly quantifiable parameters. Finally, the distribution functions of the input parameters are aggregated using a Monte Carlo simulation.

4.2.1 Analysis of dependencies

The valuation model is primarily based on the DCF method. While the dependencies and mathematical connections of the input data within the DCF method are sufficiently defined, the way in which the input data for the DCF method is provided is not determined. In chapter 4.1 it was pointed out that the project-specific parameters influence this input data. These two areas (the DCF method and the provision of input data) are combined to form one single system, resulting in an overall system with inherent feedback effects and multiple interdependencies from single parameters.
The *N² chart* [11] method was chosen for quantitative analysis of the connections between the individual parameters. As well as information about how the parameters are linked, this method also provides data on changes in the value of the components that are influenced and on the relativity of the interaction. This analysis is carried out separately for each specific project in order to identify the respective interdependencies.

4.2.2 Quantification of dependencies

In order to incorporate the previously analysed dependencies into the evaluation model, it is first necessary to determine the quantification process. Directly quantifiable interdependencies are characterised by the fact that one value in the valuation system exercises a clear mathematical influence on another. Therefore, changing the value of the respective parameter has a direct influence on the resulting value.
For those correlations that are not directly quantifiable, the question is how to integrate the abstract checklist points from the sustainability certificate into the resulting value. In this paper, non-directly quantifiable correlations are understood to be a *mathematically non-obvious influencing of the independent parameters*.
For the purposes of the evaluation process it was decided to incorporate sustainable features, which are not directly quantifiable parameters, through the DCF method's interest rate and also in the risk situation. This interest rate shows not only the possible interest generated by an alternative investment but also the project-specific risk, cf. [12, p. 84 ff]. Therefore, the interest rate is formed using a base interest rate and a risk premium linked to the property. One of the hypotheses of this paper is to illustrate how checklist points can be used to include sustainability evaluations in the risk premium of the interest rate. Generally, a low interest rate means a low project-specific investment risk compared with a riskier project. Assuming that sustainable real estate can achieve a higher yield [3, p. 28 ff], a large number of checklist points improves the project's economic situation and reduces the investment risk [13, p. 14].
The WACC method [14, p. 85] was selected to determine the interest rate in the DCF process, since it provides the most practice-oriented approach. This method uses the interest rate as a weighted rate comprising interest from equity capital and debt capital. This approach can be used in all projects and is based on real interest rates that are easy to calculate.

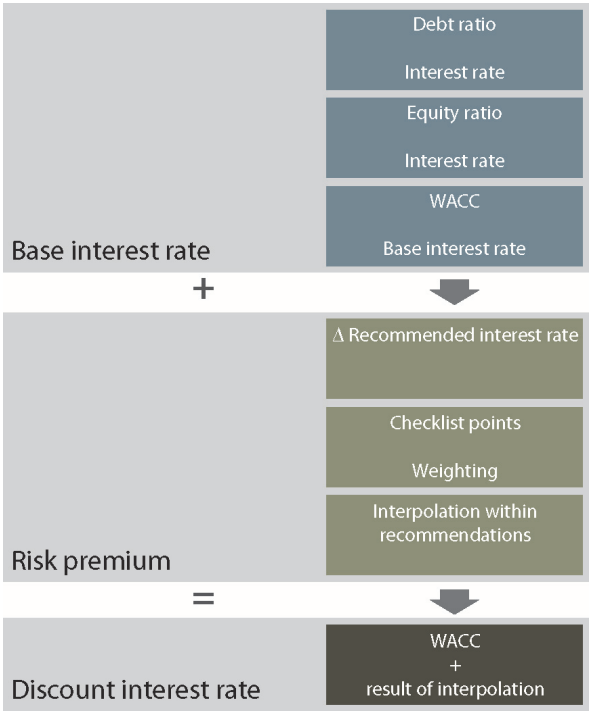

Fig. 5: Method for calculating discount interest rate

Since it is very difficult to determine the effect of non-directly quantifiable correlations, in practice it helps to calculate the risk premium using empirical data. At the time of writing this paper such research data were not available. Therefore, information from the *Austrian Association of Sworn and Certified Court Experts* was used. Included in this information are recommended interest rates divided into bands according to use and location [15, p. 97]. These interest-rate bands are set out by the Association's committee, meaning that they document the empirically calculated bandwidths found in real estate valuations. After limiting the bandwidth for the risk approach, the next task is to judge the situation within the bandwidth. This is carried out using checklist points from the selected

parameters based on the sustainability criteria. Using half the value of the bandwidth, the weighted average in applied in such a way that 0 checklist points result in an increased risk and, as such, form the upper value of that half of the bandwidth; vice-versa, 10 checklist points result in a low risk and form the lower value of that half of the bandwidth. The idea behind using only half of the value of the bandwidth is that sustainably valued real estate, as is the case with every new building project, conforms to the legal requirements and the state of the art. Assuming that the bandwidth covers the interest rate from good to bad real estate, and that the real estate to be valuated is no worse than average, only half of the bandwidth in the risk premium of the interest rate can be considered. The reasoning behind this is that it improves marketing possibilities of sustainable real estate and, as a result, improves the risk situation.
The following example is designed to illustrate and clarify the process. The WACC base interest rate was set at 4.9%. According to the recommendations, the total margin of fluctuation is 2.5%. This results in a bandwidth of +/- 1.25% and, therefore, a possible improvement of 1.25%. In this example the weighted average of checklist points gives a value of 6.4. For the interest rate this means a reduction of 0.8% from the basic interest rate, resulting in an interest rate of 4.1%.

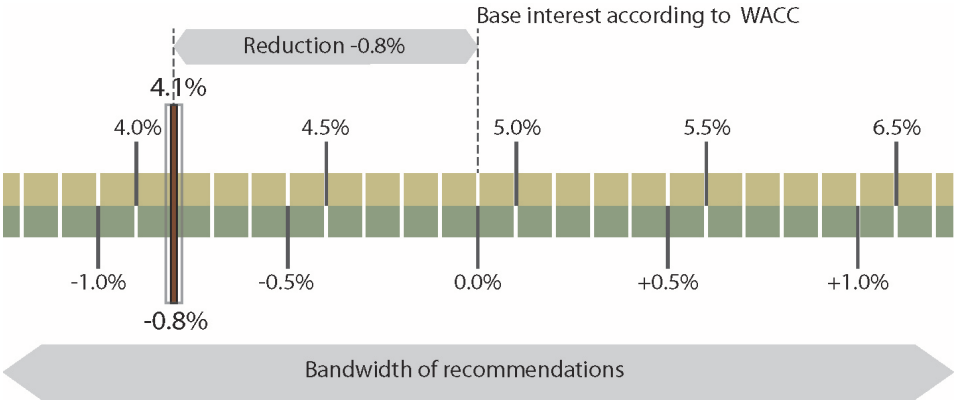

Fig. 5: Fluctuation range of discount interest rate
To provide a better correlation between sustainable features and the discount interest rate in the DCF-valuation method greater empirical research throughout the years has to be done. Results from this research would improve the quality of the outcome of the developed valuation system. Although for the demonstration of the functionality of the system the present available database is sufficient.

4.2.3 Discussion and evaluation of the results

Two different sources of data are available: the specifications / real estate data resulting from the project development; and the data from the sustainability evaluation (pre)certificate according to the ÖGNI / DGNB criteria.

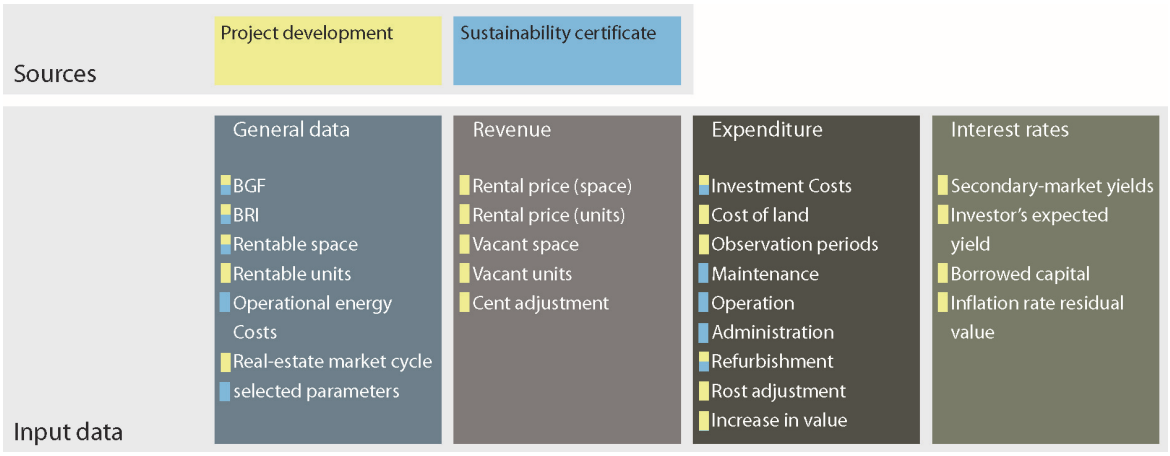

Fig. 6: Input data for valuation (including source)

Whenever the assessor believes it is necessary, input data are entered using triangular distribution. This will especially be the case in situations where future developments are subject to an understandably quantifiable margin of fluctuation.
The next step is to implement the interdependencies that have been assessed. Directly quantifiable correlations are entered into the valuation system as conventional calculations via a table calculation programme. Non-directly quantifiable correlations whose values have been calculated using checklist points are incorporated into the discount interest rate using the method described.
The necessary calculation steps are carried out using the table calculation programme Microsoft Excel. The triangular distributions entered are processed via the application @risk and aggregated using the Monte Carlo simulation method integrated into the programme [7, p. 145 ff]. The terminal value is also calculated by extending the DCF method through to the end of the expected end of life. However, in this case the increased forecasting uncertainty means that a different discount interest rate is calculated for the residual value using the method described in 4.2.2.
The valuation leads to a distribution function of the market value calculated on the basis of market rental prices. Absolute profitability [16, p. 630] of the investment is given as soon as the DCF-based value exceeds the value of the investment costs. This method can, for example, also be used to calculate minimum rent prices with a predetermined interest rate or to calculate discount interest rates with predetermined investment costs.
In general, yield figures are generated in order to determine the profitability of developing a project. Parallel to the holistic approach represented by the sustainability evaluation, the Internal Rate of Return (IRR) is calculated as a property-specific dynamic yield. The IRR shows the average interest return during the periods observed and can be compared in its interpretation with the initial yield [17, p. 293].

5. Evaluation

For validation purposes a sample project was selected from the author's work as an auditor at the ÖGNI / DGNB. The project in question has already been put into operation. Indeed, this was one of the reasons why it was selected, as valuing a real-life building offers interesting comparisons with model-based valuations.

5.1.1 Sample project

The sample project is an office complex in Austria with a gross volume of around 52,000m³ and around 10,300m² of rentable space. During the design process one of the main focuses was to make the complex as multifunctional as possible while also taking into consideration the concept and atmosphere of modern offices. The building comprises five floors made up of office space and, to a lesser extent, business premises. It is accessed via a central atrium that can be used for a range of purposes.

5.1.2 Input data

The input data were taken from the sustainability evaluation and are complemented by information provided by the operator / developer according to the method described in chapter 4.2.3. For the discount interest rate a value of 5.4% has been determined. The bandwidth is 2.0% and was taken from the recommended interest rate of the Austrian Association of Sworn and Certified Court Experts. The relevant and identified checklist points of the sustainability assessment for the sample project are indicated at 7.6 CHP. By performing the interpolation in the indicated bandwidth, a deduction of 0.76% from the base interest rate results. This implies a discount rate of 4.64% for the DCF valuation.
This practical valuation experiment confirmed the added value for the project development and the potential alternative use of data from the sustainability certificate.

5.1.3 Valuation and results

After gathering the input data in a careful and comprehensible way, the valuation itself was carried out using the method described in chapter 4.2.3. The results are shown as distribution functions in

Fig. 6 and are interpreted in the following way.
There is a 95% probability that the market value will not fall below €19,963,170. The most likely market value is €21,486,036 (the modal value). There is a probability of just 5% that a market value of over €23,956,129 can be achieved. A deterministic valuation carried out at the same time produced just one single value of €21,435,779. While this figure is roughly the same as the modal and median value, the probability of it actually being achieved is only around 50%. An independent valuation commissioned by the developer gave the property a value of €23,000,000, though this is optimistic.
There was also a good level of correlation regarding the Internal Rate of Return. The calculations indicated that there was a 95% probability that the IRR would not fall below 4.72% and not exceed 5.70% – very similar to the value of 5% given by the developer based on building operations.

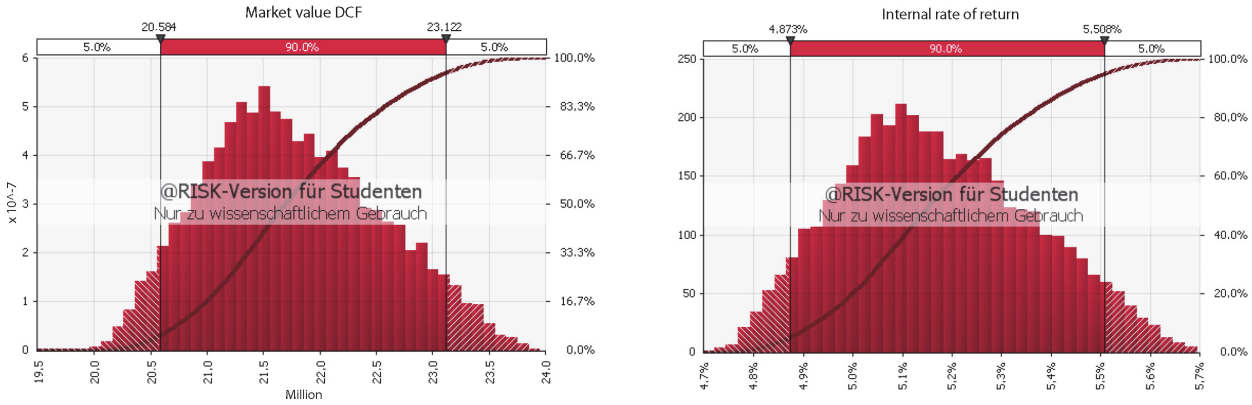

Fig. 6: Results of sample project valuation

6. Limitations of the valuation

This valuation method provides systematic and sound access to the real-estate project development process. At the same time, it does not claim to treat the topic exhaustively or to take into consideration all aspects and interdependencies. Successful project development cannot be planned down the very last detail and cannot be calculated using digital building models. So what are the limitations of this valuation method?
As the project development valuations are forecasts, it cannot be assumed that the forecasted values will actually be achieved. In particular it is important to remember that *each forecast is only as good as its input data*, cf. [18, p. 764]. That makes it clear which area we must focus on for the valuation. There is a vanishingly small probability that the forecasted value will be 100% identical to the actual value. As a result, valuations only make sense if they are used to compare different planning variants and/or to judge potential improvements. In such cases the absolute, forecasted values are of secondary importance – instead, it is the differences between the valuations of the variants that are of greatest interest. Provided these requirements are adhered to, it can be assumed that the best possible decision was taken using the information available at the time of the valuation. Processing the input parameters via distribution functions also contributes to making the result as objective as possible.
All valuation methods show their limitations when it comes to creative and aesthetic aspects. However, there is no doubt that excellent architecture makes buildings more attractive and, ultimately, increases their value on the market. One appropriate and recognised way of ensuring such excellence is by launching an architectural design competition. In doing so it can be assumed that, at least concerning the design, the best possible result will be achieved. However, it is more than questionable whether this assumption holds true in all cases. The same goes for valuations of functional aspects, though in this case compiling operational processes or spatial and functional programmes make it easier to produce an accurate valuation.
It is also very difficult to calculate how the synergy effects of a project development will influence nearby properties, the surrounding area or even the wider region. A good example of this is the attempt to make an area more attractive by developing individual properties like urban entertainment centers. The actual effect of these properties is difficult to predict, since it depends

on a large number of boundary conditions that cannot be controlled. In practice we also commonly see the opposite effect – making one area of a city more attractive drives down property prices in neighbouring areas. All of these processes have an impact on the social fabric and, consequentially, the purchasing power of the population. A drop in purchasing power makes an area less attractive and leads to falling prices. The result is an increase in the number of vacant properties, which again leads to a further drop in property prices. Developments such as these cannot be predicted and, as such, cannot be taken into consideration when carrying out a valuation.

7. Conclusion

This paper describes a system for valuing property developments that gives sustainable features the recognition they deserve, through consideration in the discount interest rate. The valuation system itself is divided into two processes. In the first process the main project-specific parameters are identified and quantified using division functions. In the second process the parameters are analysed for dependencies (divided into directly quantifiable and non-directly quantifiable dependencies), which then are incorporated into the valuation as risk-minimising influencing factors. The incorporation is carried out through a reduction of the discount interest rate. The extent of this reduction is determined by an empirical bandwidth of the interest rate and the amount of check list points resulting from the sustainability assessment. The final step is to calculate the market price and the Internal Rate of Return as distribution functions using an adapted DCF method via a Monte Carlo simulation. The system was validated using a practical example. The results of this validation were very similar to those achieved using alternative valuation methods used in the real estate industry.
The method developed in this paper represents a practical valuation tool that can be used in all phases of real estate project development, right through to the final design phase. For decision makers this tool significantly improves the process of investment decision making through easier comprehensibility and, as a result, the optimisation process. This is because the results achieved are based on actual data and, at the same time, incorporate both sustainability and profitability requirements. Compared with deterministic methods, this valuation system paints a more realistic picture and provides superior levels of information by carrying out quantification using probabilistic methods and thanks to the probabilities integrated into the division functions. One key advantage of the tool in practical situations is that it creates a highly transparent system that is easy to understand, especially for investors and financing institutions. Through the paper it was also possible to highlight how fulfilling sustainability criteria adds value to a project development. All in all, this valuation system can make a significant contribution to risk management in project developments.
One possible way of further developing the valuation system would be to transform it into an independent IT tool that would standardise the input parameters as far as possible. Greater empirical research is still needed into the correlation between the sustainable features of a building and the discount interest rate in the DCF process. Further work is also needed on integral approaches in both project management and project development, especially concerning operational processes.
By developing this valuation method it has been possible to illustrate a positive correlation between the economic success of a project and the fulfilment of sustainability criteria. This constitutes a win-win situation for all stakeholders.

Short Summary

This study addresses the role of ÖGNI in the Vienna real-estate market and puts a more detailed focus on members and auditors as part of the stakeholders to identify innovative impulses in the Vienna real-estate market to analyse the linkages between economy, politics, and society.
The real estate sector is one of the most dynamic economic sectors which contributes negatively to the environment and society in many ways (e.g. inefficient use of materials, water, land, etc.) and can therefore be seen as one of the major threats to sustainability in the future. This contribution investigates the dynamic development in the green building market in Austria and specifically in Vienna and focuses on the non-state market driven environmental governance processes led by the green building councils. The role of these non-profit oriented councils within the internationally powerful real estate and construction market appears to be a quite specific one. There are a lot of critical voices among scholars which alert us that such industry dominated environments are mainly serving the market while neglecting public interests. But we can also think of arguments, however, why it is extremely important to create networks being managed by non-governmental organizations (NGOs) in order to fill the gap between public and private interests. Therefore the role of different kinds of organizations in fostering sustainable development has become a broad field in governance related research [1]. Within this research the role of NGOs as governance actors for sustainable development is becoming increasingly relevant. Since NGOs are involved in processes aimed at raising quality standards in different areas, e.g., forestry management, marine protection, the scientific community can build upon a growing empirical basis.

Keywords: Governance, Green Buildings, NGO, networks, ÖGNI, third-party certification

1 Introduction

The goal of this paper is to identify innovative trends in the Vienna real estate market which have been activated by the Austrian Green Building Council (ÖGNI). Furthermore the analysis of the council and its third-party role has provided insights into its ability to act as a bridging institution between the state, the market, and the public. The analysis focuses on the council's network and its activities. This contribution is following a case study approach in order to analyse the ÖGNI and its effects on the real estate market in more detail. For this purpose we conducted an online survey and interviews both addressed to ÖGNI and its network members. The first preliminary results have already shown that the real estate environment in Vienna has shifted its interests towards sustainability and that the dynamics of the network actively contribute to new developments in the building sector.

The overall goal of the study is to analyze non-state market driven governance, by taking ÖGNI as a basis for a case study. In this respect, we looked at the role of this organisation as an independent and external institution in the area of real estate certification. By analysing the entire network of the organisation, different roles inside ÖGNI became more apparent. The study is combined with already existing findings from the international analysis from the World Green Building Councils (WGBCs) 2011 [2]. Therefore the organisational structure, the defined goals and activities of the councils were taken and processed into a questionnaire.

The study has been structured along two parts: A theoretical part that illustrates the concepts of non-state market driven governance and the international application. The second part consists of a case study analysis about ÖGNI by putting a detailed focus on its members and auditors.

2 Non-state market driven governance processes

Non-state market driven governance is embedded within a framework of existing sub-levels (i.e. regional governance, global governance, corporate governance, economic governance, see [3]). All these concepts are representing the obliteration of borders between politics and society. They have a normative entitlement of increased participation of various stakeholders that is manifested in policy networks and public-private-partnerships.

Some authors see the development of non-state governance regimes in weakly regulated and inefficient policy areas [4]. However, these regimes do not exist apart from political regulations. Moreover decision makers take part in governance networks by having a central role [5].

The enforcement of complex areas that are difficult to overcome through ordinary measures (governing) over a long period of time can be seen as an important contribution to non-state market driven governance regimes [6]. Simply spoken, these governance regimes are wisely taken, if ordinary political processes act inertially and ineffectively. The role of NGOs in these governance regimes is of increasing importance. The independent role of these organisations, which seem to act apart from political- and market structures, makes them more effective in dealing with certain problems. [7] argue that NGOs as non-state actors still have an influence in political decisions. Especially in the environmental and sustainability sector NGOs became more and more integrated in decision making processes. This can be seen in international negotiations, where NGOs represent certain groups of society. Contribution of NGOs in political discussions is traced back to the mid-19th century [8].

As discussed before NGOs are often acting as third parties. Dixit [9] argues that third parties remain in a neutral outside position that allows independent decisions. Contribution of NGOs therefore allows new forms of decision making that is decisively marked through a good

cooperative situation between state and non-state actors. Consequently, NGOs fulfil a bridging function between public and private actors.

The real estate sector is also organised internationally by NGOs that share the common goal to create worldwide more sustainable buildings (labelled as blue or green buildings). The foundation of the WGBC in 2002 made a progressive step to form an umbrella association that includes all regional green building councils that are organised as an NGO. The overall goal of this association is the improvement of building standards that are provided via certificates. The ÖGNI is one of 93 of such regional NGOs that pursue common goals in an international network. All regional NGOs act independently in their countries and exchange themselves through the WGBC. These links can be seen as a learning network with the central aim to exchange knowledge and experience about building certification. Especially in this sector, powerful real estate enterprises are driven by increasing their profits that could make the observer sceptical about the added value for society. This study tries to identify strengths and weaknesses of these new non-state market driven governance regimes by investigating the case of ÖGNI.

3 ÖGNI's contribution to the green building market in Vienna

ÖGNI was established in 2009 through an initiative of a number of active players in the Austrian real estate industry. ÖGNI is a non-profit organization and does fit into the category of non-governmental organizations (NGOs). As mentioned it is part of the 93 WGBC members with the status of a 'prospective member'. The office of the NGO, headquartered in Linz, is supported by a team of ten people. The duties of the office are the support of experts and projects, the organization of events and the management of the website.

ÖGNIs objectives are defined in the form of key performance indicators. The growth in membership to 500 members in the next three years is at the forefront, followed by an increase in the number of certified buildings. Therefore important strategies are the on-going recruitment, open and transparent communication, a permanent event management, as well as continuous public relations by media campaigns.

The research project was designed as a single case study, which falls in principle within the qualitative research paradigm, but it takes both qualitative and quantitative sources for analysis of the selected case. In this case, the organization ÖGNI is the research object to be identified and its role in contributing to sustainable real estate market is analysed. Case studies are used in a variety of disciplines, especially in areas where it is important to analyse complex social phenomena (Yin 2003).

The case study was embedded in a conceptual framework that provides the basis for the case study analysis. The empirical part was preceded by an extensive literature and Internet research on ÖGNI. This research formed part of the basis for the subsequent interview with the founding president of ÖGNI and also served as the basis for the development of the online questionnaire. The questionnaire was designed together with the management of ÖGNI, who supported the research team with data from the members and auditors database. It became clear fairly soon after the start of the study that the online questionnaire would be addressed to different stakeholder groups. Originally a mere member survey was planned. As a result of the initial research it was decided relatively quickly to interview the auditors as well. As a matter of fact the third group had to be taken into consideration - those who are both members and auditors.

For the online survey, ÖGNI has provided the research team with a list of 239 email addresses. Out of them 206 people could be contacted and received an invitation for the online survey. A total of 90 people completed the questionnaire. Out of them 27 people are exclusively members, 30 auditors and 33 auditors, who are also members of the ÖGNI. This corresponds to a response rate of 43.7%. Parallel to the online survey, the research team decided to create a list of project participants of those buildings in Vienna, which were certified by the DGNB certification system.

The case study is designed as a target group specific analysis and therefore we were interested in the different stakeholders' perceptions. The questionnaire focuses on members and two different types of auditors, the ones being members and the others who do not belong to ÖGNI's member network. The final part of the questionnaire was targeted at all respondents and focused on the general perception about the organisation ÖGNI and its activities. Thus members and auditors listed in the ÖGNI member directory were contacted and invited to participate in the online survey. A total of 90 people completed a questionnaire. The majority are male respondents (80%). The age distribution of respondents is normally distributed between 25 to 50 year old, with the exception of the most represented age group of 40 to 44 year old, which is extremely over-represented with about twice as many people in this age group compared to the neighbouring group of 30 to 39 year old. In the 55 + age group an uneven distribution can be seen in the sample. It represented more 60-64 year olds than 55-59 year olds. Overall, it can be said that the survey in terms of age groups covering a very broad cross section of age.

Having a look at the educational level it becomes clear that most of the respondents have an academic background (82%). Profession shows an enormous variety, but can be summarized to be located in the construction sector in general. More clusters can be identified in the project development-, architecture-, consulting-, as well as in engineering area. On the management level there are a few nuances across divisional or departmental managers. Overall, people are consistently well educated and most of them in leadership positions. This result could be expected in the field of sustainable building development. Therefore, we can infer that the network of ÖGNI consistently includes representatives in leadership positions and academics.

This study is dealing extensively with ÖGNI, to find out if this organization, founded in 2009, occupies a governance function as a mediator between business, politics and society, and how it makes an active contribution to the implementation of sustainable development in the property sector. The underlying hypothesis is focused on the role of ÖGNI as independent and external ('third party') organization for building certification, which can be defined as a part of a non-state market-driven governance regime by having an important bridging role inside complex stakeholder groups. Here, the organization as a NGO is assumed to have a comparative advantage in the area of moderation and mediation between business, politics and society. The situation in Austria is so mounted that the Austrian Climate Strategy (BMLFUW 2007), especially the issue of energy efficiency in buildings, is more addressed than the issue of the development of sustainable buildings. Consequently a market-driven initiative like ÖGNI would have a great potential to initiate innovative market impulses towards sustainable buildings. Especially auditors in the sample see a big potential in having ÖGNI as a coordinating institution holding the position of a third party institution. Certification is seen as the key for improving the standards of buildings and to make the market aware of these standards. They see the network as a valuable asset for improving their own businesses and to share and exchange knowledge. Auditors do see a big potential at the Austrian but specifically at the Viennese market for sustainable buildings whereas members are more sceptically. Members do see ÖGNI as an information provider and they see the network as a possibility to keep them informed and integrated. It can be interpreted as a knowledge receiver function whereas auditors share knowledge with other auditors and actors in the network. Altogether this can be interpreted as a valuable non-state market driven governance mechanism which has room for improvements but has already initiated dynamic developments on the real estate market.

4 Results and conclusion

The aim of the study was to provide new impetus to the real estate market specifically in Vienna. Although ÖGNI operates nationally, it has to be mentioned that its main activities could be identified in Vienna. A second aim was to analyse and evaluate the role of ÖGNI as a governance actor. Strengths and weaknesses were analysed having a look at the network. The results are

presented in the following analogy referring to the case study analysis presented along different respondents, namely members and auditors of ÖGNI.

The members use ÖGNI as a networking platform, where they are primarily focussed on networks in the context of their own profession. This can be clearly seen as an advantage, since the network activity has direct relevance to developing a sustainable building industry. Moreover, the members who participated in the survey largely come from industry. It can be stated that ÖGNI provides a platform for the exchange of industry-specific activities and is described by its members as a valuable networking instrument as reflected in the literature on non-state market-driven governance.

The main strength is seen in the increased media presence of ÖGNI. The real estate market moves more and more towards sustainability and related activities are demand driven from the customer (investor) side. The active public relations are seen as an awareness instrument that is used in the entire real estate industry. An additional strength is the certification. It is described as a long term investment by investors and customers (owners) are demanding certificates as found in interviews.

The weaknesses generally refer to the information provided and in particular to the lack of structure of this information. It can be subsumed that ÖGNI provides information, but too much in terms of volume, or in an unstructured way. This is an important issue for an organization that provides information in addition to the general public, especially for its own members. As the number of activities is relatively large in relation to the size of the organization, structuring problems are quite common. Non-profit organizations in general have a comparative disadvantage towards private organizations with respect to the availability of resources.

The second identified weakness is focused on certification. According to the members certification could be improved. The DGNB certification system however provides ample space for improvement and sees itself as a learning tool. As such it will be continuously adapted in order to make it more effective. One area that was rated ambivalently is transparency. The result shows that transparency is a sensitive topic that is barely recognized by individuals, because transparency has been called both strength and weakness. It can also be associated with excessively existing information or the lack of structure of this information, as this may also lead to non-transparent process.

Members see a benefit in their membership. It is mainly the building certification, which has a high priority to them and can be seen as "the strength" of the ÖGNI. However certification strengthens the position of ÖGNI and thus the quality of the organization. Membership is the opportunity to actively participate in this area. This can be interpreted as a win-win situation for the members of ÖGNI and considering its activities in the field of certification also for ÖGNI, especially in Vienna where there is high recruiting potential due to the vast number of enterprises in and around the city.

For the auditors the improvement of the certification system is of major importance. Main shortcomings are named as a need for simplification and a more transparent approach. For networking reasons auditors see ÖGNI as a vital instrument. 80% of the auditors from the sample are linked with other auditors in the green building market. This network plays an important role for the continuous improvement of the certification system, since auditors can share their experience directly if they are members as well. The practice of application and their exchange is an important factor regulating ÖGNI who sees the continual improvement of the system as one of the overarching goals. The auditors also see a great potential for sustainable construction in Austria, which occurs mainly due to increased market demand, but also the positive attitude of all the actors involved.

Next to the networking possibilities, public events are also important to the respondents. Moreover, events can also be seen as an instrument for networking, which is actually used relatively often. In

the opinion of the respondents, ÖGNI has a social responsibility, which can be summarized into two areas. On the one hand the awareness of the general public, in which the issue of sustainable construction becomes more acquainted and on the other hand in the awareness of the members that should partly implement this awareness into sustainable outcomes.

The general opinion in relation to the work of the ÖGNI has been very positive. Two major areas were considered separately - the organization and the certification. The assessment of the organization clearly shows that the ÖGNI has a clear focus on Austria and there especially on Vienna. In Vienna, most DGNB certified buildings are located and the city is also seen of having great potential to improving the quantity of DGNB certified buildings. Vienna will establish a leading role in the sustainable office sector in the near future leading to a headquarters function in Austria and drive the market towards sustainability. This is a beneficial effect due to the institutionalization of ÖGNI as stated by respondents. The certification system is clearly perceived as market appreciation, the type of certification has not provided any disadvantages due to lack of experience over longer periods. There is wide consensus that deciding whether a building certificate is sought or not, will be decided solely by the project participants and will thus be a market-driven decision, which is not controlled by any political action (policy push '). Since ÖGNI in its capacity as third party institution awards and promotes the development of sustainable construction, one can speak of an existing non-state market-driven governance regime, which in his actions and engagements supports the overall policy framework without being a political decision maker.

Short Summary

True measurements and evaluation of the sustainability level of products and systems must encompass social and economic aspects. Observed throughout entire life cycles, these factors are the incentives and the inhibitors of potential environmental improvement. However, LCA has traditionally focused on environmental aspects, and even ISO 14040:2006 limits the analysis to environmental effects. This paper aims at using the set of socioeconomic subcategories, proposed by UNEP's guidelines for social LCA, as logical attributes to assist design decision-making processes regarding choices of construction materials. The validity of the attributes in the Brazilian construction sector is evaluated, considering information availability. These attributes are expected to complement and enlighten ranking of alternatives beyond environmental evaluation or when it is not enough to establish a clear ranking between them. Targeted materials and systems will be those associated to the highest life cycle environmentally impacts based upon previous studies of a sample of typical practice Brazilian buildings. Considering the current embryonic stage of Brazilian LCA studies and of consideration of social and economic aspects worldwide, this paper expects to enhance the discussion on integrated life cycle accounting of multidimensional sustainability aspects, and to add practicality to data that are usually perceived as too specific to be properly used by designers and contractors.

Keywords: Life Cycle Assessment (LCA); social; economic; building materials; life cycle indicators; life cycle attributes.

1. Introduction

Aiming at diminishing the negative side effects of human action in the natural environment, sustainability has become the guiding paradigm for humanity's further development [1]. Worldwide, there is a broad consensus that true measurements and evaluation of the sustainability level of products and systems must encompass social and economic aspects.

Companies are increasingly confronted with questions from different stakeholders regarding their social performance; and society's expectations for them to enhance corporate social responsibility is a challenge that has been accepted by those corporations who wish to conduct business in a more responsible way [2]. In that matter, the Global Reporting Initiative (GRI) stands out as an organization that aids companies' communication regarding sustainability, providing a framework for reporting economic, environmental and social aspects.

Observed throughout entire life cycles, socioeconomic factors are the incentives and the inhibitors of potential environmental improvement. However, Life Cycle Assessment (LCA) has traditionally focused on environmental aspects, and even ISO 14040:2006 limits the analysis to environmental effects. In the LCA community, the idea of broadening the analysis to include socioeconomic aspects is taken up by combining the environmental life cycle assessment (ELCA) with life cycle costing and social life cycle assessment (SLCA) to life cycle sustainability assessment [3]. While

ISO 14040 and 14044 serve as international standards for Environmental LCA, there is still little experience with the use and implementation of SLCA as a tool [1]. Recommendations based on LCA do not address possible trade-offs between environmental protection and socioeconomic concerns [2], which raises questions about LCA's ability to support actual decision-making in companies aiming for sustainability. In an effort to take a step towards SLCA standardization, UNEP/SETAC Life Cycle Initiative published the Guidelines for Social Life Cycle Assessment of Products [4], aiming to provide a framework to assess social impacts across product life cycles.

1.1 The Brazilian construction sector

The construction sector plays an increasingly important role on regional and global economies, contributing to jobs generation, to the development of new technologies and infrastructures and to quality of life enhancement. However, the environmental liabilities that arise from construction activities are quite large: approximately 25% of all raw materials extracted from the lithosphere are consumed for building construction [5]; about 23% of the energy produced in Brazil is consumed by the residential sector [6]; and a great part of anthropogenic carbon emissions come from building activities. Because of those significant figures, great attention has been paid to the construction sector's initiatives and measures towards more sustainable practices, usually focusing, however, on the environmental side of sustainable development.

The insertion of socioeconomic aspects on building activities can be common when aiming to assess financial viability of different project choices. However, when considering construction performance in a life cycle perspective, companies usually fail to take into consideration the performance of all of their supply chain contributors. Life cycle studies in Brazil still struggle with the lack of inventory data, which diminishes researchers and designers ability to produce and use, respectively, reliable life cycle results. With SLCA and LCC the main obstacles remain the same.

Aiming at providing more complete and thorough results to aid designers' decision making processes, the present article (i) proposes a set of socioeconomic attributes, based on UNEP/SETAC published guidelines [4] and (ii) evaluates the viability of such attributes through a survey of sustainability reports of different Brazilian companies that produce building materials with highest contribution to a building's environmental load.

Previous studies ([7]; [8]) used four Brazilian case studies to show that, for a certain typology, a core database of about 12 materials and components provides a very accurate description of a building's embodied energy and carbon profile, which streamlines indicator's monitoring scope. The same set of materials and components was used here, to which the socioeconomic attributes were applied.

2. Methodological approach

2.1 Selection of attributes

Life Cycle Initiative's published guidelines [4] state that the bases for Social LCA are the subcategories, which are socially significant themes or attributes, categorized into stakeholders and impacts. The main categories comprise "workers", "consumers", "local community", "society", and "value chain (non-consumers) actors".

Subcategories are defined for each of these stakeholder categories. In this paper the abovementioned subcategories were used as logical attributes to assess the possibility of performing socioeconomic life cycle studies of the Brazilian construction sector, following UNEP/SETAC's guidelines. Chart 1 presented below indicates all the subcategories listed by the published guidelines, and which will be used here.

Stakeholder categories	Subcategories
Stakeholder “worker”	Freedom of association and collective bargaining Child labor Fair salary Working hours Forced labor Equal opportunities/discrimination Health and safety Social benefits/social security
Stakeholder “consumer”	Health and safety Feedback mechanism Consumer privacy Transparency End of life responsibility
Stakeholder “local community”	Access to material resources Access to immaterial resources Delocalization and migration Cultural heritage Safe &healthy living conditions Respect of indigenous rights Community engagement Local employment Secure living conditions
Stakeholder “society”	Public commitments to sustainability issues Contribution to economic development Prevention & mitigation of armed conflicts Technology development Corruption
Stakeholder “value chain actors”	Fair competition Promoting social responsibility Supplier relationships Respect of intellectual property rights

Chart 1: Stakeholder categories and their respective subcategories [4].

2.2 Verification of feasibility

In order to assess the feasibility of using the mentioned subcategories as attributes, to characterize an initial consideration of social and economic aspects in building material selection in Brazil, main production companies' sustainability reports have been analyzed. In theory, all information regarding the listed attributes should be public and available. In the country, however, there is a historic deficiency of such information, and of government policies and inspection demanding its disclosure.

The attributes were evaluated within companies that produce 12 materials/components, which were listed by [7] and [8] as top contributors to embodied energy and carbon in selected Brazilian case studies. The studied typology was basically low-rise (up to 3 floors), low window-to-wall ratio, reinforced concrete-framed, masonry façade and partitions, and ceramic or metallic roofing buildings. Results obtained showed that the ranking was composed by: Portland cement and ready mixed concrete, ceramic brick, steel rebar, PVC tubes and conduits, sawn timber (planks), sawn roundwood, roof steel structure, ceramic tile, plywood, hydrated lime and adhesive mortar.

Wherever possible, materials contained in the ranking were clustered into sectors of production, to facilitate data gathering and interpretation, *e.g.* steel rebar and roof steel structure were grouped and jointly assessed as “steel”. The respective sectorial associations disclosed the reports analyzed. Manufacturing companies that were geographically close to the cases studied by [7] and [8] were prioritized. When such companies have not published reports nor displayed the needed information in their websites or other information vehicles, reports of other companies, typically larger, were evaluated instead.

Results are presented for each material/component or production sector, indicating to which extent the information regarding the selected attributes is available. The scope is later on enlarged to assess information availability related to each stakeholder category, considering all top 12

materials/components.

3. Results presentation and discussion

3.1 Portland cement and concrete

To evaluate information availability regarding the production of cement and concrete in Brazil, the sustainability reports of *Holcim*, one of the largest manufacturer in the country, was analysed. *Holcim* has a unit in the municipality where studies performed by [7] and [8] took place. Chart 2 shows which of the attributes were contemplated by the mentioned report.

Stakeholder categories – cement and concrete	Attributes – cement and concrete
Stakeholder “worker”	Freedom of association and collective bargaining; Child labor; Fair salary; Forced labor; Equal opportunities/discrimination; Health and safety; Social benefits/social security.
Stakeholder “consumer”	Health and safety; Feedback mechanism; Consumer privacy; Transparency; End of life responsibility.
Stakeholder “local community”	Access to material resources; Access to immaterial resources; Cultural heritage; Safe & healthy living conditions; Respect of indigenous rights; Community engagement;;Local employment; Secure living conditions.
Stakeholder “society”	Public commitments to sustainability issues; Contribution to economic development; Technology development; Corruption.
Stakeholder “value chain actors”	Fair competition; Promoting social responsibility; Supplier relationships.

Chart 2: Attributes contemplated by Holcim’s report.

3.2 Steel

Brazil has a significant number of steelmaking companies, with most of them complying with a national institute, *Instituto Aço Brasil*. The sustainability report evaluated here was, therefore, the document published by that Institute, because of its relevant and larger coverage of the national steelmaking sector. Chart 3 indicates the attributes that were contemplated by the referred report.

3.3 PVC tubes and conduits

The socioeconomic information availability of PVC materials was evaluated through *Braskem*’s published sustainability report, since it is one of the major manufacturers in Brazil. Though not located in the region of study, it does, however, supply materials to that area. Chart 4 summarizes the attributes found in the report.

Stakeholder categories – steel	Attributes – steel
Stakeholder “worker”	Freedom of association and collective bargaining; Child labor; Fair salary; Working hours; Forced labor; Equal opportunities/discrimination; Health and safety; Social benefits/social security.
Stakeholder “consumer”	Health and safety; Feedback mechanism; Consumer privacy; Transparency; End of life responsibility.
Stakeholder “local community”	Access to material resources; Access to immaterial resources; Cultural heritage; Safe & healthy living conditions; Respect of indigenous rights; Community engagement; Local employment; Secure living conditions.
Stakeholder “society”	Public commitments to sustainability issues; Contribution to economic development; Technology development; Corruption.
Stakeholder “value chain actors”	Fair competition; Promoting social responsibility; Supplier relationships.

Chart 3: Attributes contemplated by national steel institute’s report.

Stakeholder categories – PVC	Attributes - PVC
Stakeholder “worker”	Freedom of association and collective bargaining; Child labor; Fair salary; Forced labor; Equal opportunities/discrimination; Health and safety; Social benefits/social security.
Stakeholder “consumer”	Health and safety; Feedback mechanism; Transparency; End of life responsibility.
Stakeholder “local community”	Access to material resources; Access to immaterial resources; Cultural heritage; Safe & healthy living conditions; Community engagement; Secure living conditions.
Stakeholder “society”	Public commitments to sustainability issues; Contribution to economic development; Technology development; Corruption.
Stakeholder “value chain actors”	Fair competition; Promoting social responsibility; Supplier relationships.

Chart 4: Attributes contemplated by Braskem’s report.

3.4 Wood

The informal nature of wood extraction and production in Brazil poses considerably challenges to sustainability assessments. The available report found, in this case, was a document prepared by the World Wide Fund for Nature (WWF), adapted to the Brazilian scenario [9]. The so-called “Keep it legal” report lists the main obstacles found in certifying Brazilian wood and fighting corruption, and focuses on providing guidelines to assure supplier’s compliance with regulations. The attributes found in the document are listed in Chart 5.

Stakeholder categories - wood	Attributes - wood
Stakeholder “worker”	-
Stakeholder “consumer”	Transparency
Stakeholder “local community”	Community engagement
Stakeholder “society”	Public commitments to sustainability issues; Prevention & mitigation of armed conflicts; Corruption.
Stakeholder “value chain actors”	Fair competition; Promoting social responsibility; Supplier relationships.

Chart 5: Attributes contemplated by WWF’s national report on certified wood.

3.5 Ceramic bricks and tiles

As observed with wood, production of ceramic materials in Brazil also has an informal character. The national association of the ceramic industry, ANICER, provides a certain level of information regarding national manufacturing. ANICER has already invested in LCA and disclosed comparative studies between ceramic and concrete blocks. The Association, however, does not publish a sustainability report, summarizing social, economic and environmental data of its member companies. A survey of all information available in their website was performed. Information regarding the proposed attributes, however, was not found.

3.6 Adhesive mortar

There is a considerable number of companies that manufacture adhesive mortar in the study area. They do not, however, publish sustainability reports, which might be explained by their local and limited market. The report evaluated in this case was published by *Camargo Corrêa*, an industrial group with high levels of adhesive mortar production and commercialization.

Stakeholder categories – adhesive mortar	Subcategories – adhesive mortar
Stakeholder “worker”	Child labor; Forced labor; Equal opportunities/discrimination; Health and safety; Social benefits/social security.
Stakeholder “consumer”	Health and safety; Transparency; End of life responsibility.
Stakeholder “local community”	Access to material resources; Access to immaterial resources; Cultural heritage; Safe & healthy living conditions; Community engagement; Local employment; Secure living conditions.
Stakeholder “society”	Public commitments to sustainability issues; Contribution to economic development; Technology development; Corruption.
Stakeholder “value chain actors”	Fair competition; Promoting social responsibility; Supplier relationships.

Chart 6: Attributes contemplated by Camargo Corrêa Group’s report.

3.7 Hydrated lime

Analogously to the case of adhesive mortar, the local companies that manufacture hydrated lime do not publish sustainability reports. To assess the socioeconomic information availability of hydrated lime production, *Votorantim*’s report was analysed, since it supplies its products in a national scale.

Stakeholder categories – hydrated lime	Subcategories – hydrated lime
Stakeholder “worker”	Freedom of association and collective bargaining; Child labor; Forced labor; Equal opportunities/discrimination; Health and safety; Social benefits/social security.
Stakeholder “consumer”	Health and safety; Feedback mechanism; Transparency; End of life responsibility.
Stakeholder “local community”	Access to material resources; Access to immaterial resources; Cultural heritage; Safe & healthy living conditions; Respect of indigenous rights; Community engagement; Local employment; Secure living conditions.
Stakeholder “society”	Public commitments to sustainability issues; Contribution to economic development; Technology development; Corruption
Stakeholder “value chain actors”	Fair competition; Promoting social responsibility; Supplier relationships.

Chart 7: Attributes contemplated by Votorantim’s report.

3.8 Information availability per stakeholder category

In order to identify the levels of information availability within the different stakeholder categories, Fig. 1 indicates how each sector complied with the disclosure of the proposed attributes, dividing results by stakeholder group. Steel and cement/concrete stood out as the materials/components with most information publicly available.

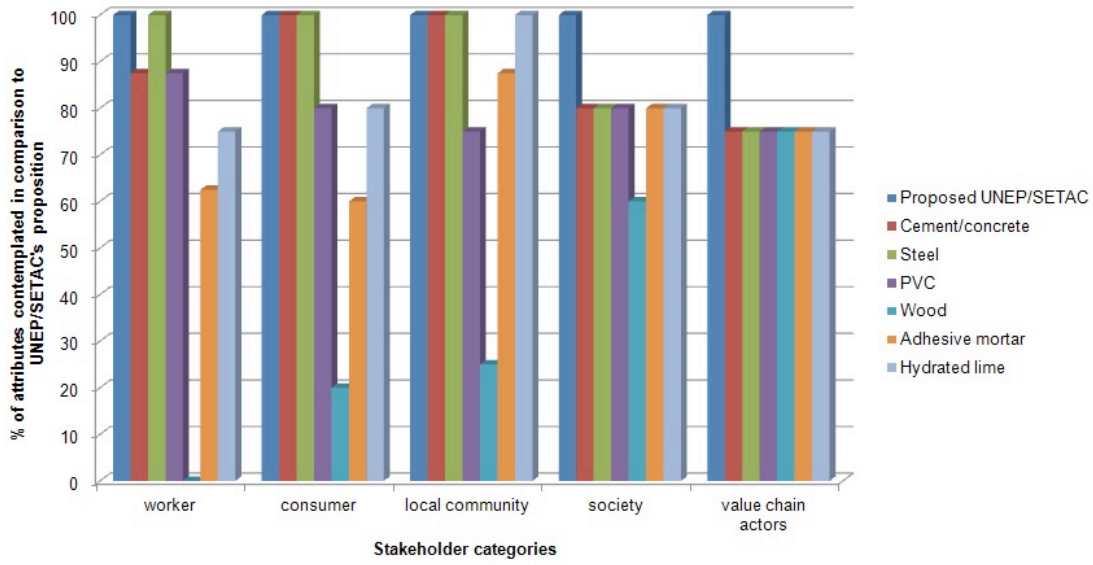

Fig. 1: Attributes information availability, divided by stakeholder, for each material/set of materials.

4. Final considerations

Observed throughout entire life cycles, socioeconomic factors are the incentives and the inhibitors of potential environmental improvement. Still most national life cycle studies fail to consider those aspects in their evaluation, which diminishes the results’ potential to substantially aid decision makers in regards to sustainability. Brazilian historical deficiency in data availability creates many obstacles to LCA experts to provide reliable and thorough results. Within the national building sector, specifically, many academic efforts have been observed to create databases and aid designers’ in project choices, but showing wide methodological variation. However, the current policy adopted by many national companies to protect their internal processes data many times

prevent delivery of trustworthy and strong life cycle results. Considering the mentioned situation, performing a complete Social Life Cycle Assessment consists in a great challenge for the Brazilian construction sector.

In an attempt to begin the insertion of social and economic aspects in daily designer's practice, and to follow the international trend of truly assessing sustainability, considering the "triple bottom line" nature of its concept, this paper evaluated the possibility of using UNEP/SETAC proposed socioeconomic impact subcategories as logical attributes, to be used when environmental evaluation is not enough to establish a clear ranking between different alternatives. Results showed that companies with higher market breadth and, consequently, with higher industrialization level, disclose more complete sustainability reports, usually in compliance with GRI's guidelines. Smaller companies, in almost all cases, did not publish any sort of reports. In the case of wood and ceramics, the informal nature of their production in Brazil implies in a significant lack of information. In such cases, suppliers' ratification projects can assure social and economic responsibility, as recommended by [9].

Steel stood out as the material with most information availability, probably due to the aggregation of different large manufacturers in a national association, which impels companies to disclose results, and even to improve their production processes, as a propeller to increase competitiveness. Finally, results highlighted that, in the current data availability status, the use of impact subcategories exclusively as logical attributes could aid in the process of inserting social and economic evaluations in the construction sector. Some product categories, however, would be harmed in the decision-making procedures due to failure in reporting adequacy of their supply chain contributors and of their own production process.

Short Summary

Given the difficulty to insert life-cycle assessment (LCA) and life cycle costing (LCC) in daily routine of structural design practices, this paper presents a set of LCA-and-LCC-based indicators that integrates functional, environmental and economic performance requirements. The goal is to allow proper design decision-making support and a broader, life-cycle, sustainability evaluation of concrete structural frames. Using a case study approach, it focuses on different residential concrete building flooring systems to show the application feasibility at typical floor and whole superstructure levels. To calculate environmental and economic indicators, Life-365 software was used to predict service life and estimate LCC for the flooring systems, while cradle-to-gate LCAs were performed for the structural materials employed. For the conditions studied, *(i)* prestressed flat slabs showed better functional and economic results than reinforced concrete waffle slabs, which, however, presented the best environmental performance. Results also *(ii)* confirmed the validity to analyse a typical storey in lieu of the whole superstructure; *(iii)* revealed that designing by the Brazilian concrete structural design code, for a marine environment, does not ensure compliance with the recent national performance standard, ABNT NBR 15575:2013, requiring strategies to increase concrete structures' service life, and that *(iv)* design life associated to unit of structural area are convenient functional unit descriptors for superstructure as well as floors, ensuring proper comparison among structural components performing same structural function over a given lifespan.

Keywords: sustainability; indicators; LCA; LCC; structural frame; concrete flooring system; performance requirement.

1. Introduction

Research initiatives for new generations of sustainable buildings assessments state that buildings sustainability level should always be described using indicators. The selection and justification of indicators should be based on clear understanding about the issues of concern and the relevance of building sector to these issues [1][2][3]. Defined as a parameter or value derived from parameters, an indicator should be relevant, measurable and adequate to the analysis [4], whilst remaining objective and providing traceable results. Since indicators main functions are quantification, simplification and communication, they can be used for assessment, diagnosis, comparison and monitoring [5].

Worth mentioning, the work carried out in the past decade within the European thematic network "Construction and City Related Sustainability Indicators"- CRISP provided a database of circa 500 indicators. Later, this network carried out studies concerning the application of these indicators to performance-based buildings. It was concluded that considerable additional work was still required to achieve European indicator systems that could be widely used to support and encourage successful adoption of the performance approach to buildings design and construction [2].

The existing sustainable buildings assessment systems offer a number of indicators to be used in different contexts and building life cycle phases [2]. Research projects like SUPERBUILDINGS (Sustainability Performance Assessment and Benchmarking of Buildings) and currently OPENHOUSE aim to develop a logical structure for them, among other goals. While the first focused on research and development of indicators, their reliability, comparability and validity, the latter develops and tests assessment methodologies through case studies [1].

European Standards developed by CEN TC 350 - "Sustainability of construction works" - acknowledge that environmental, economic and social performances are all important dimensions to make a good sustainability assessment at the building level. Indicators can thus be developed and used separately or together to indicate various sustainability aspects of buildings [6]. However, advancement in all three dimensions of the sustainability tripod is not equally balanced. Literature review [7] has pointed out many unsolved difficulties regarding integration of social aspects to environmental life-cycle assessment, mainly because the former methodologies are still embryonic and lack consensus on crucial impact integration and calculation steps.

Life cycle-based studies have shown the structural frame and envelope as major contributors to material environmental loads of a building [8][9][10][11][12]. However, service life, durability, and role played by structural frames have not gained enough attention in sustainable buildings assessment systems, except perhaps for AQUA [13] and CASBEE [14], which include measures to minimize structural materials resources and service life extension of the structural frame among their encouraged sustainability strategies [15].

Considering *(i)* that service life of the structural system ultimately defines the lifespan of a building, *(ii)* the role of structural systems in environmental terms, mentioned by studies in other contexts, and *(iii)* the complete absence of data in this regard in Brazil, this work is dedicated to the study of structural systems typically used in Brazilian residential concrete buildings typology. For that, this paper aims at proposing a set of LCA- and LCC-based indicators to evaluate sustainability aspects of concrete structural frames from a life cycle perspective. A case study approach was adopted to investigate its feasibility to compare sustainability performance of different concrete building flooring systems. Other relevant building systems as well as the relation with the other parts of the building and the impacts on the technological system as a whole are being targeted by parallel research and are therefore beyond the scope of the present paper.

2. Methodological approach

The present study comprised the following steps: *i)* literature review, covering the concept and methodology for developing sustainability indicators for the building sector, and the building performance requirements recommended by the Brazilian performance standard [16] as well as ISO 6240 [17] and ISO 6241 [18]; *ii)* proposition of a set of indicators for concrete structural frames, based on functional, environmental and economic performance requirements; *iii)* application of these indicators for election from a choice of structural flooring systems at the design stage. The final sessions of the paper are dedicated to results, discussion and final remarks.

2.1 Selected set of indicators for structural frames selection

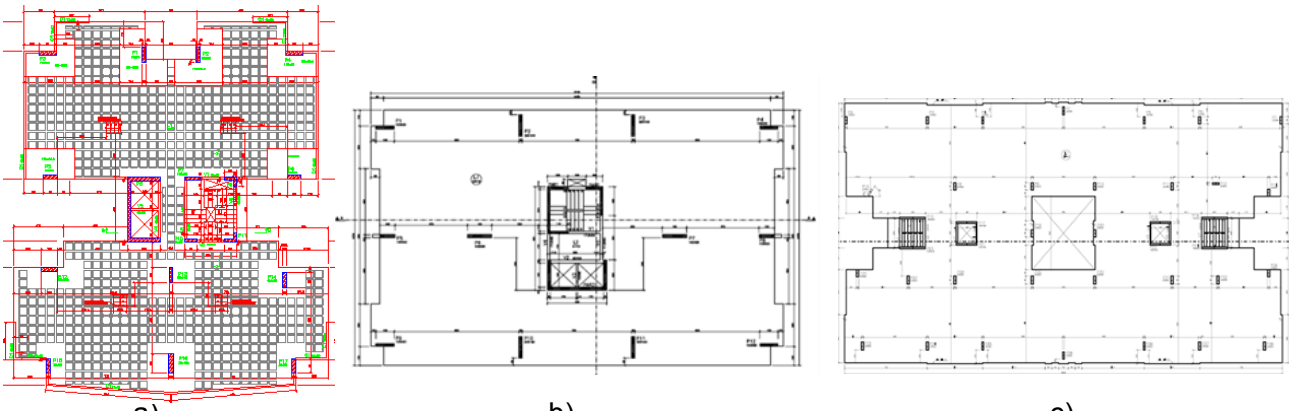
The functional indicators proposed in this paper refer to structural safety, adaptability and durability requirements [16][17][18]. The environmental performance indicators are based on ISO/TS 21929-1 [5] and mainly associated to resource management. They measure environmental performance of structural frames in accordance with ISO 21931-1 [19] methodological guidelines. Economic indicators describe monetary flows connected to the building. The indicators suggested in this

study were life cycle costs and local economy support. Table 1 shows the proposed set of indicators, filtered by predefined criteria [15][20].

Table 1 - Set of functional, environmental and economic indicators filtered based on specific criteria [19][20] and proposed for buildings structural frames selection

Indicators for structural frames / elements	
Functional (associated to performance requirements)	***Span over height ratio* (ℓ/h)** between the structural element span and its dimension in the corresponding direction, [m/m]
	***Column density**:* structural floor area over number of columns (m^2/nr), [m^2]
	Beam over slab height ratio, [m/m]
	Reuse potential (% prefabricated with connections for disassembly), [% volume]
Environmental (associated to resource management)	***Embodied CO_{2e}* (ECO_{2e})** [$kgCO_{2eq}$/fu]; (obtained through CML 2001 v.2.05 environmental impact assessment, regarding the global warming impact category).
	***Embodied Energy* (EE)** [MJ/fu];
	***Blue Water Footprint* (bWF)** [m^3/fu]; (surface and groundwater used, except water for turbine use)
	***Materials resource consumption* (Mc)** [kg/fu]:(steel + concrete+ plywood formwork).
	***Non renewable Content* (NRc)** [$kg_{\text{tot abiotic mat}} - kg_{\text{recycled}} - kg_{\text{reused}}$] [kg/fu]
Economic (associated to life cycle costs)	***Life cycle costs* (LCC)** [$/fu];
	Local economy support (**LES)** local materials over total materials cost (percentage of material and products extracted or fabricated locally, within a 300 km radius), [% cost].

2.2 Case studies description



Three case studies on structural flooring systems, used in different residential concrete building typologies in the Brazilian coastal area are presented. They comprise low-and medium-rise concrete-framed residential buildings. Case study (CS) 1 has a total built area of 5,829.19 m2, in 6 floors (24 apartments), with a 27.5cm-thick reinforced concrete waffle (RCW) slabs flooring system. CS 2 (8,841.37m2 in 15 floors; 48 apartments) and CS 3 (4,943.31m2 in 6 floors; 32 apartments) have 18cm-thick prestressed concrete flat (PCF) slabs flooring systems (Figure 1). The structural materials' usage was quantified for all three buildings from structural design drawings provided by the local construction company, including labour calculated from reference costs tables (February 2013) from the Federal University of Espírito Santo's construction costs estimates laboratory [21]. For each case study, environmental indicators were calculated for two situations: one typical floor and the total superstructure. Foundations were disregarded to isolate the effects of soil's carrying capacity on sizing, and consequently on material consumption.

2.3 Calculation of multidimensional indicators

Data for computing the functional indicators was extracted from structural design shop drawings and calculation sheets provided by the responsible structural design practices.

Cradle to gate LCA studies for calculation of the environmental indicators were supported by software SimaPro 7.3 and performed following ISO 14040 [22] methodological guidelines. Thus, transportation and building construction, use and end of life stages were disregarded. Modelling of CP III-32 blended cement production has not considered any impact allocation criterion between steel and ground granulated blast furnace slag (ggbs). This assumption reflects the current practice of considering ggbs as a waste, with no environmental load, and is also aligned with ISO 14040 [22] recommendation to avoid allocation whenever unessential. Allocation is a widely recognized and challenging methodological problem in LCA for its potential significant impact on the results, but was not imperative for this study's purpose. Data for materials production cycle modelling were taken from national literature [23] or adapted from processes within SimaPro built-in Ecoinvent and ELCD databases [24] upon switching into the Brazilian energy mix. Data from Worldsteel database [25] however, could not be edited. Table 2 shows the functional unit adopted

and data sources used for modelling the studied production processes.

a) b) c)

Figure 1 – Case studies' typical floor plans: a) CS 1 RCW slab: b_{rib} = 15cm, h_{flange} = 5cm, distance between rib axis = 90cm; b) CS 2 PCF slab; c) CS 3 PCF slab.

Table 1 - Functional unit and inventory data source for the materials studied.

Construction materials	Functional unit	Data source
Concrete (fck 30MPa) [a]	1 m^3	Silva, 2006 [23]
Portland cement (CPIII-32) [a]	1 ton	Silva, 2006 [23]
Steel rebar (reinforcing steel)	1 ton	ELCD (European life cycle database) [24]
Plywood formwork, Sand, Gravel	1 m^3	Ecoinvent [24]
Wire Rods (prestressing steel)	1 ton	Worldsteel Association [25]

[a] Concrete mix with cement type CPIII-32 (66% of ggbs as clinker replacement in cement)

Service life is defined as the period between construction and the time to the first repair (tr), which may be determined using quantitative service life models for a particular element in a given environment. In this study, software Life-365 v.2.1.1 supported the prediction of service life and life-cycle costs of reinforced concrete structures exposed to chlorides [26]. Parameters considered are structure type and dimensions; temperature, chloride exposure conditions; concrete mix characteristics, such as water to cementitious materials ratio (w/cm), and replacement of cement (%) by slag, Class F fly ash, or silica fume (SCMs); steel type, and steel over concrete cross sectional area ratio (%).

To enable comparison and level the life span to reach 50-years design life, which is the minimum required design life (DL) of Brazilian residential buildings [16], LCA-based indicators considered the necessary repair schedules: 10 % extra volume of material was therefore added to the overall material consumption of the respective floor for each predicted flooring system repair event.

50 years was then considered as the reference period for the LCC studies, being 2013 set as the reference year. LCC indicators have also considered the same repair schedule. Life-cycle cost was calculated as the sum of the initial construction costs and the discounted future repair costs including labour, over the design life of the flooring system. The Inflation rate (%) is the annual rate at which the prices of goods and services will increase over the future; the Real discount rate (%) is the annual rate at which future costs are discounted to base-year dollars, net of the rate of inflation (that is, it is the real discount rate, which does not include the effects of changes in the prices of goods and services). Future material and labour costs are calculated on a present worth basis using the inflation rate, *i*, and the real discount rate, *r*. The present worth, *PW*, of a future cost *c* in year *t* is given by Eq.1.

$$PW = c \left(\frac{1+i}{1+r}\right)^t \qquad \text{Eq.1}$$

Annual inflation rate of 6.59% and real discount rate of 7.5% were adopted. These figures respectively represented (in April 2013) the Price index to consumer rate (IPCA), defined by the Brazilian Institute of Applied Economic Research (IPEA), and the special system of liquidation and custody rate (SELIC) established by the Brazilian Monetary Policy Committee. A 10-year interval between repairs was adopted, being the date of the first repair based on the service life predicted for each case study.

The local economy support (LES) indicator, on its turn, was calculated considering a 300 km radius threshold, established to better reflect the conditions in the region of study, for which there are plenty of known material suppliers available within a smaller radius than the usual 800-km limit suggested by some rating systems.

3. Results and discussion

Concerning the functional performance, CS2 (PCF slab) presented the best performance for span over height ratio and column density indicators. As to the reuse potential indicator, all three slabs were cast in situ and not designed for disassembly. CS1 (RCW slab) has better end-of-life performance, due to smaller spans which make demolition easier and safer, resulting in lower demolition costs than the PCF slabs used in CS2 and CS3. Furthermore, reinforcing steel has higher recycling market value than prestressing steel. Notwithstanding, the flooring system with no beams and longer spans (CS2) provides increased adaptability. Table 3 shows functional indicators' results. The highlighted values are the best among alternatives.

Table 2 – Functional indicators results for the three case studies

Functional Requirements	Indicators	Typical floor		
		CS 1	CS 2	CS 3
Structural safety	*Span over height ratio (ℓ/h)* [m/m]	24.7	**40.3**	33.3
Maintenance and constructability	*Reuse Potential* (% volume prefabricated with connections for disassembly) [% volume]	0	0	0
Flexibility/ adaptability	*Column density:* gross floor area over number of columns (m^2/ n^o), [m^2]	17.8	**30.6**	19.8
	Beam over slab height ratio, [m/m]	1	1	1
Durability	*Estimated Service life* [yrs] = time to first repair	**11.7**	11.2	11.2

The results of service life prediction for the studied conditions (Table 4) confirm the need of a repair schedule for each alternative to ensure service lives of 50 years, which means that, under those conditions, designing by the Brazilian standard NBR 6118 [27] does not assure compliance to NBR 15575 [15]. The environmental indicators per functional unit were multiplied by consumption of each material in mass or volume, including the material added by predicted repair events, and then divided by m^2 of structural area, in order to obtain each indicator per m^2. At typical floor scale, the PCF slabs of CS 2 (15-storey building) and CS 3 (6-storey building) presented the best results for EE and ECO_{2e}, respectively, while CS 1 (6-storey building with RCW slabs) showed best results for bWF, NRc and Mc. Results for the whole superstructure showed a similar trend, except for EE, whose best result pointed to CS 1 (Figure 2).

Service life estimated by software Life-365 v.2.1.1 for all case studies was similar because they had identical characteristic strength (30 MPa), mix composition and minimum concrete cover (c_{min}=2.0cm). LCC estimation by the software considers only concrete and rebar data. Thus, an input data adaptation was required to include plywood formwork and prestressing steel costs and labour concerning construction and maintenance. Therefore, for one typical floor, the total cost of plywood formwork including labour was divided by the concrete volume, and then added to the concrete cost with labour per cubic meter. Similarly, cost of steel input represents the weighted average between reinforcing and prestressing steel costs per kg, including anchors and labour. LCC for CS1 was 14% greater than for CS3, while the differences between CS2 and CS3 (~4%)

were negligible. Table 4 presents values of LCC indicators for the three typical floors, showing the best results for CS 3.

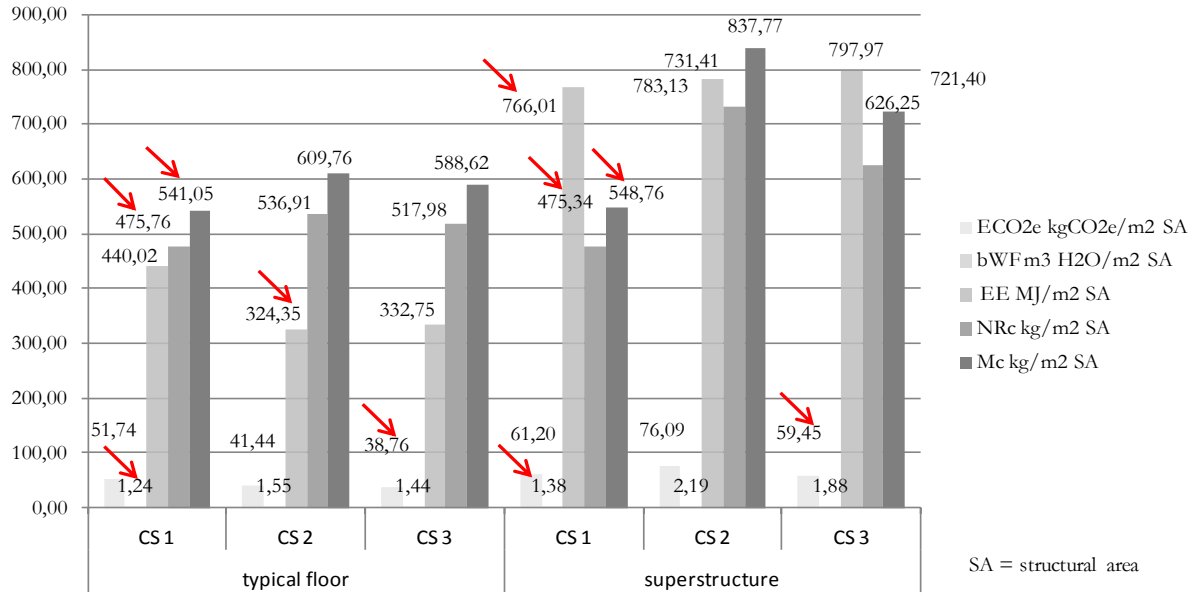


Figure 2 - Environmental indicators (ECO2e, bWF, EE, NRc and Mc) normalized per unit of structural area, calculated for a typical floor and whole superstructure of the case studies, assuming implementation of measures to achieve a 50-year DL, in accordance with Life-365 v.2.1.1 software

Table 3 - Service life and life cycle costs estimated for the three case studies using Life-365 v2.1.1.

Case study (CS)	Typical floor slab	Estimated Service life [years]	Life cycle costs (LCC) US $ /m^2 structural floor area						
			Initial costs					Repair costs[b]	Total life cycle cost
			Plywood formwork[a]	Concrete	Rebar	Prestressing steel	Total initial costs		
1	RCW	11.7	13.34	28.24	45.90	0.00	87.48	254,03	341,55
2	PCF	11.2	10.71	32.30	21.58	11.10	75.61	236,24	311,89
3	PCF	11.2	12.96	31.22	19.52	8.83	72.53	227,94	300,35

[a] considering plywood formwork reuse of five times maximum.
[b] values corresponding to four repair events discounted to present value.

Savings may result from the initial or maintenance costs of the structural frame itself, or given by optimization of other building systems. An LCC indicator calculation encompassing both the envelope and structural systems, for instance, should address the savings provided by *(i)* the lowest column density of CS 2 (Table 2) concerning parking spaces and typical floors adaptability, *(ii)* the reduction from a 27.5cm-thick waffle slab (CS 1) to 18cm-thick PCF slabs of case studies 2 and 3 on envelope plaster and coating consumption and costs, and *(iii)* the smallest dead weight of CS 1 RCW slabs (equivalent to a 14.7cm-thick flat slab) contribution to whole superstructure sizing and foundations. Savings resulting from design for disassembly-oriented options are more difficult to estimate, but could also be captured by the LCC calculation. As the envelope system was out of the scope of this paper and monetary figures and flows related to such additional data are usually not readily available at the structural design offices, they were not provided for the studied cases. Implementation of continuous value engineering techniques during an integrated design process would enable reasonably accurate estimation and allow the recommended approach.

For local economy support indicator (LES), the PCF slabs' systems of the typical floors in Case studies 3 and 2 presented the best results, with local materials responding respectively for 43% and 42% of total material costs, followed by the RCW slabs' system of Case Study 1 (32%).

4. Final remarks

The use of different databases for production cycles modeling, due to discrepancies or deficiency of national and international reference data for insertion in LCA platforms, may compromise accuracy of LCA-based indicators results, but still provides some reference. Also regarding these indicators results, the study showed that design life associated to unit of structural area are convenient functional unit descriptors for superstructure as well as floors, ensuring proper comparison among structural components performing same structural function over a given lifespan.

At whole superstructure scale, Non Renewable content (NRc), Material content (Mc), blue Water Footprint (bWF) and Embodied Energy (EE) indicators pointed to CS 1 (RCW slabs) as the best solution concerning the environmental dimension, while the Embodied CO_{2eq} indicator (ECO_{2e}) pointed to CS 3 (PCF slabs) as best performing flooring system. Concerning the indicators of the economic and functional dimensions, PCF slabs performed best. Therefore, next research steps include application of analytic hierarchy process to define relative importance of indicators in each dimension structuring them in a decision matrix assembling different weighting scenarios, to streamline choice of a single solution, whenever indicators show contrasting trends.

For vertical typologies, to proceed with the analysis of a typical structural floor in lieu of the whole building superstructure - analogously to structural design common practice - seems to be potentially valid. Amongst the five environmental indicators, four of them showed similar trends at both typical floor and whole superstructure scales. Embodied Energy indicator shifted trend when zooming into typical floor scale. The local economy support indicator provided useful information when applied to a typical floor. Due to the limited number of case studies, these findings are promising but still exploratory. Twenty-eight case studies are currently under analysis. If the observed tendencies are also confirmed for this larger sample, it might provide a significant reduction of time and effort for data collection. Also, enlargement of the case study library will provide robustness to analysis and allow in-depth statistical treatment and more assertive conclusions.

Exploring the most cost-and environmentally-effective strategies for increasing concrete structures service life exposed to a marine environment is also of interest. It is expected that this set evolve to a framework of functional, environmental and economic indicators as a tool to support design decision-making regarding important sustainability aspects in concrete structural frames selection.

Short Summary

Domed roofs have been adopted by architects and engineers throughout the North Africa and other hot dry areas. However, the solar performance of such forms has rarely been quantitatively studied. In this study, variation of the direct solar radiation (DSR) over domed roofs was estimated and compared with standard horizontal flat roofing used in the typical houses.
A number of investigations have been carried out on domed shapes with varying cross section ratio (height/width) and orientations to study their solar performances. The geographical latitude (30 N) has been chosen to represent the hot region areas. The comparison showed that the use of the domed roofs leads to a significant improvement of indoor space in summer. The height-to-width ratio (Cross Sectional Ratio) has a significant impact on the solar performance

Keywords:Circular Dome, Roofs, Solar Performance, Curved Surface, Direct Solar Radiation.

1. Introduction

Economic buildings can be built in such a way that the structural elements are designed and oriented to take maximum advantage of the local climate (Sanjay et al, 2008). Olgyay [2] and Fathy [3] indicated that the curved roofs can reduce local radiant flux on a rounded surface. As a result, the heat flowing into buildings will be reduced. Bahadori [4] mentioned that domed geometrical structures with vents in their crowns increase natural ventilation through buildings. As a result, the indoor air will not become humid and the mean radiant temperature can be reduced. Gadi [5] reported that about 40% of domed roofs would be reduced from direct solar radiation. According to Vector [6], at noontime, the dome's performance is always better than that of a horizontal surface.

2. The Geometrical Resemblance

Wang [7] mentioned that the continuous curved surfaces could be approximated using a finite number of small flat planes. Elseragy [8] also explained that it is possible with an acceptable result to undertake calculation of radiation incidence on a large number of infinitesimal tilted planers that resembled the curved forms
In this study, the curved exposed surface has been divided into a number of small flat planers called "elements", The element can be a horizontal, vertical, or tilted surface; the slope angle for each element is different from the others, depending on the surface curvature of the exposed surface. The solar irradiation on each element depends on its specific orientation and tilt angle, and upon the other common parameters such as the time, latitude, atmospheric conditions and ground reflectivity. The total solar radiation received by the entire exposed surface can be estimated as the sum of the irradiation on the surfaces of all elements.

3. Geometrical Descriptors

If the geometrical characteristics (curvature parameters) of a domed form are well defined, the tilt

and azimuth angles for all elements can be determined. In this paper the geometrical characteristics are the height(H), depth(D), and width(W) of the dome form. As shown in Figure 1. The dome geometry was split into a number of segments (M-1) and rings (N-1).

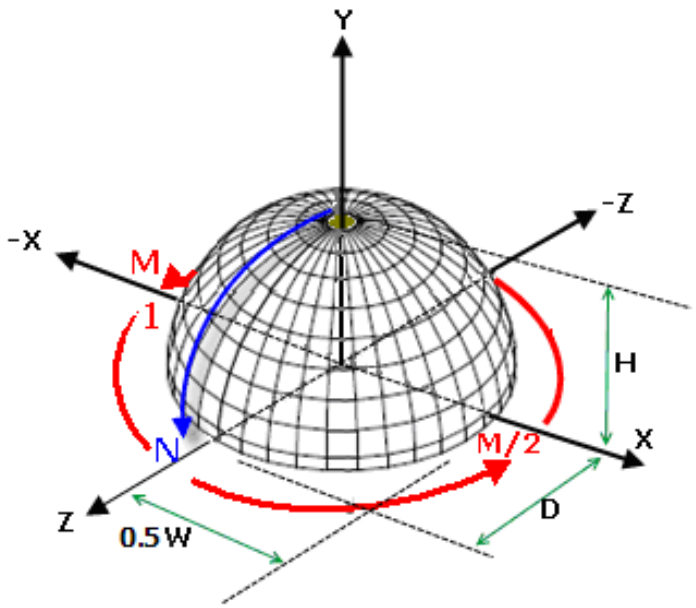

Fig. 1: A 3D-view of dome configuration

result is a grid consisting of a number of planar trapeziums (N-2)x(M-1), and a set of planar triangles (M-1) at the top of the dome. Each trapezium element has a node at each corner and each triangle has three nodes. M is the number of points (nodes) that are distributed on the perimeter line of the dome base, N is the number of nodes distributed along the curved line of the cross section. It is important to point out that the more resembling planar elements, the more accurate the result will be. The planar elements that have the same tilt angles constitute one horizon ring around the vertical axis (y-axis). Moreover, each group of planar elements has the same azimuth angles (same orientation) constitutes one segment.
The generated elements are mainly trapeziums and only one ring at the top of the dome consisted of triangular elements (due to that all the top nodes share the same location). The curved exposed surface of the circular dome CD can be defined as a (N-1)x(M-1) grid mesh. The mesh includes MXN nodes. The x, y, and z coordinates for all nodes can be changed by altering the dimension of the cross-section form.
The dome model is represented as shown in Figure 2. by a flat-bottom semi elliptical configuration (circular in CD). It is possible to define the exact position (x, y, z) of the node P on the dome surface by using the concentric circle method and through the following three steps:

Step 1 The elevation of the node on the dome surface can be determined by using the following equations.

$$TT=180//N-1 \quad (1)$$

$$y=H \text{ Sin } TT \quad (2)$$

Step 2 Consider the cross-section-shaped elliptic (circular in CD) at a certain height (y) above the horizontal base and determine its semi-major and semi-minor axes (radius=R).

$$R=NW=W/2 \text{ Cos } TT \quad (3)$$

R=ND=D SinTT (4)

Step 3 The position of a node at the new circular with the coordinates *x* and *z* can be located from the following formulas

x=RCos T (5)

z=RSin T (6)

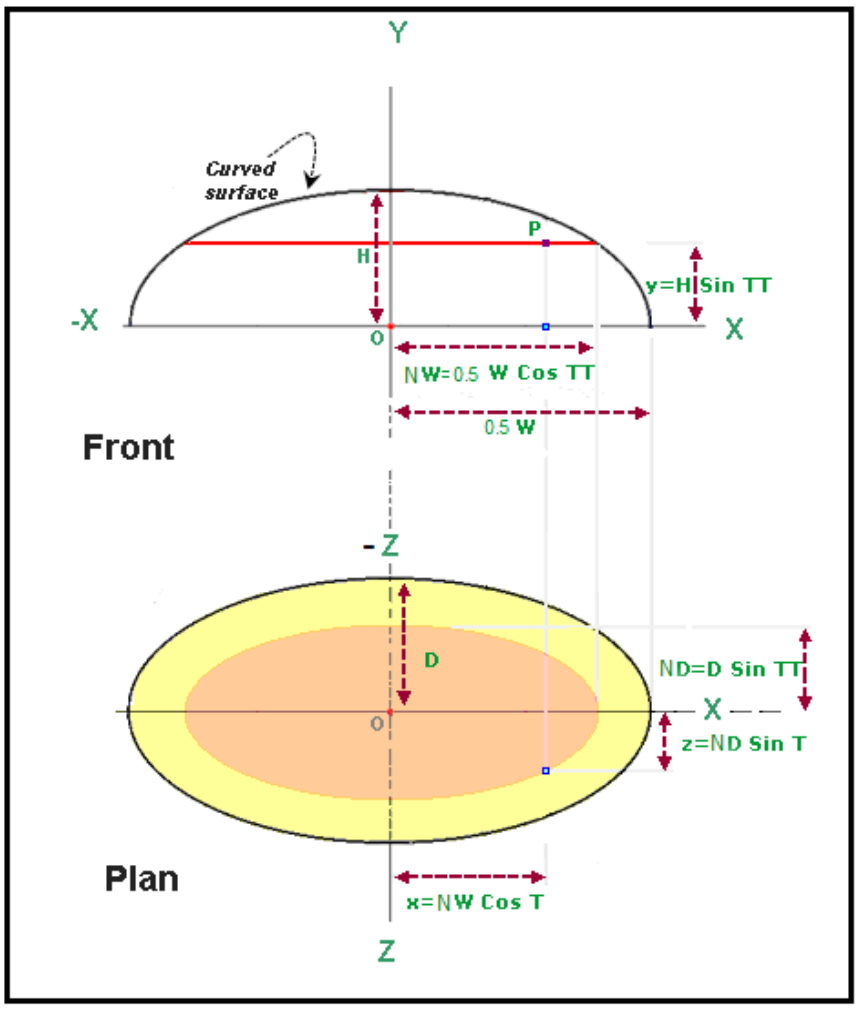

Fig. 2: A plan and cross-sectional view of dome form

4. Calculation of direct solar radiation

Several geometric calculations are needed to compute the DSR received by the dome surface: the slope, the area, and the azimuth angle for each grid cell. For area calculation, a simple algorithm was developed to calculate the area of trapezium and triangular elements. The tilt angle for each element on the dome surface is the angle between the element surface and the horizontal plane. the element's azimuth angle(ξ) for each element depends on the element angle (ψ) and that element's deviation (de) from the x-axis. The element angle can be measured on the horizontal plane, from the positive z-axis to the surface normal of the element. The surface azimuth angle (sh) for the domed form can be defined with respect to the z-axis, which is perpendicular on the cross section form.

In the Southeast and Northeast quadrants, the sign convention used for the element's azimuth angle is negative. In contrast to this, the element's azimuth angles in the Northwest and Southwest quadrants are positive.

The azimuth angle for each element in the Southeast quarter equals the surface azimuth of the dome (the angle between the south and the z- axis) minus the element angle. In this quarter, the element angle equals the deviation angle.

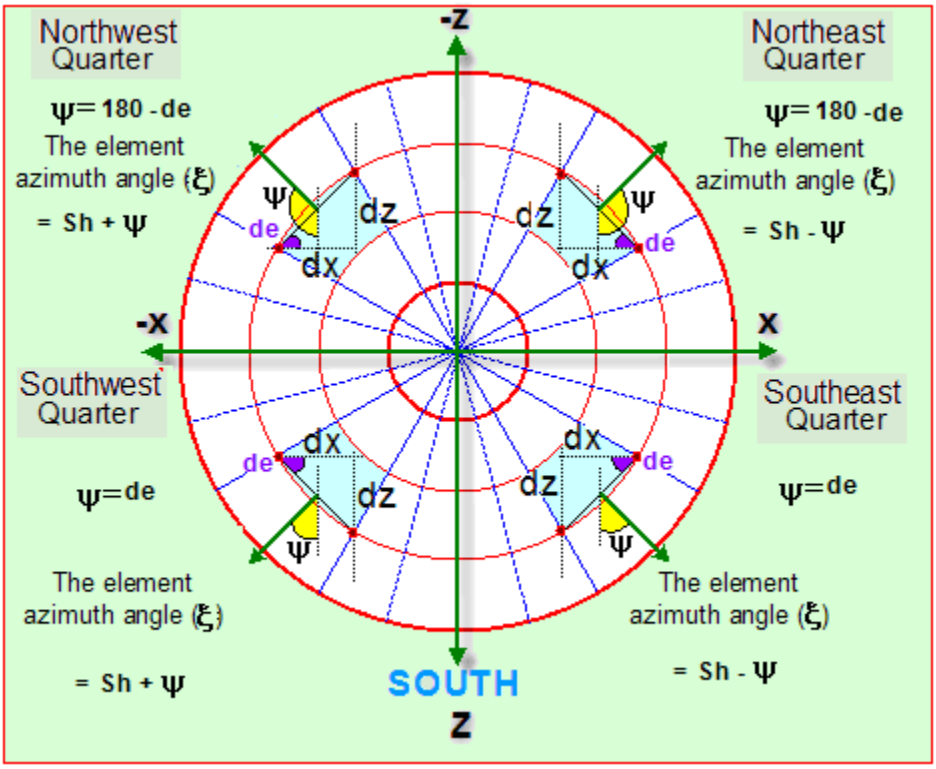

Fig. 3: The element azimuth angle for different elements with respect to the x and z axes

$$\psi = de = \tan^{-1}\left|\frac{dz}{dx}\right| \tag{7}$$

$$\text{The element's azimuth angle} = \xi = sh - \psi = sh - \tan^{-1}\left|\frac{dz}{dx}\right| \tag{8}$$

The following simple relation gives the element's surface-azimuth angle in the Northeast quarter:

$$\psi = \pi - de = \pi - \tan^{-1}\left|\frac{dz}{dx}\right| \tag{9}$$

$$\xi = sh - \psi = sh - \pi + \tan^{-1}\left|\frac{dz}{dx}\right| \tag{10}$$

In this quarter the sign convention used for the element's azimuth angle is also negative. For the surface-azimuth the following simple relation gives angles of elements in the Northwest quarter:

$$\psi = \pi - de = \pi - \tan^{-1}\left|\frac{dz}{dx}\right| \quad (11)$$

$$\xi = sh + \psi = sh + \pi - \tan^{-1}\left|\frac{dz}{dx}\right| \quad (12)$$

The sign convention used in this quarter for the element's azimuth angle is positive. The azimuth angle of each element in the Southwest quarter equals:

$$\psi = de = \tan^{-1}\left|\frac{dz}{dx}\right| \quad (13)$$

$$\xi = sh + \psi = sh + \tan^{-1}\left|\frac{dz}{dx}\right| \quad (14)$$

The sign convention used for ξ, is positive.

5. Validation of the Developed Program

The performance of the developed simulation program has been validated through comparing its results with the results of three different proven available models, namely ESRA, SRSM and RadOnCol. Three statistical indicators were used: root mean square error, RMSE, mean absolute error, MAE, discrepancy percentage, DP.
Comparison results (Table 1) for DSR intensity have illustrated a good agreement in the summer and excellent agreement during the winter months.

Table 1: Comparison results for DSR intensity in terms of MAE, RMSE, and DP

	MAE			RMSE			DP		
	Rad	ERSA	SRSM	Rad	ERSA	SRSM	Rad	ERSA	SRSM
Summer	1.56	-0.28	0.21	1.67	0.04	0.376	3.1	-4.2	-3.9
Winter	0.65	1.02	0.8	0.66	1.06	0.846	9.4	-0.93	1.86

6. Solar Performance of a Circular Dome.

This section examines the solar performance of seven CDs (CD is a dome having a circular base) surfaces with different curvatures, and compares the received solar radiation on their exposed surfaces to the solar radiation received on the horizontal surface. The cross section ratio (*CSR1*) between the vertical (the height of dome) and the radius of the dome base is used to define the curvature of the dome surface. Due to geometry of a CD, which is fully symmetrical, it does not have a particular orientation as in the case of elliptical dome. In other words, a CD shape faces all directions equally at the same time. For this reason, there is no impact of dome orientation on the

amount of solar radiation received by the exposed surface, since the DSR received by the CD surface is independent of the azimuth angle. Therefore, the changes of the solar performance of a dome are solely a consequence of the solar elevation angle.
In order to evaluate the effect of curvature (*CSR1*=0.5, 0.8, 1.0, 1.25, and 2) on the solar performance on CD surfaces, the insolation values of DSR received by the exposed surface of the CDs have been shown at latitude 30° north of the Equator (North Africa and other hot dry areas.), under different climate conditions (summer- winter), the form distribution of DSR on all of these shapes have an identical trend performance. However, worth to mention that there is a small distinguishing difference in the magnitude between the values of both seasons. It can be seen from figures 4 and 5 that the direct solar radiation per unit area received by the flat horizontal roof is higher than the domed roofs of various geometries in the midday. However, when considered on the total direct solar radiation of the roof itself, then the domed roof receives the highest value compared with the flat roof of the same base area.

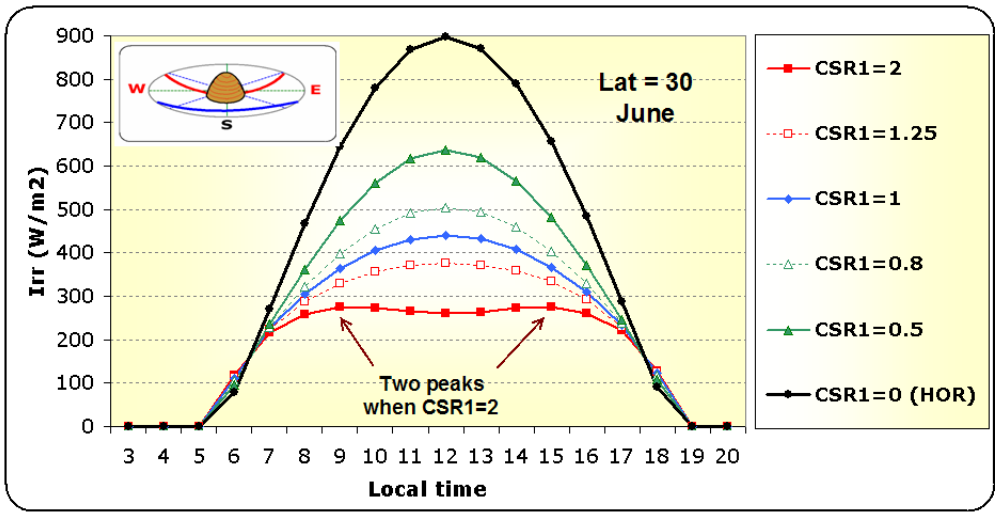

Fig. 4: DSR on CD surface during summer at 30°N

It is clearly recognized that all DSR curves have similar characteristics. At the Summer Solstice, each curve increases gradually from the intersection point at 6:30 am until it reaches the highest value at 12 noon when it drops gradually till it interacts with the other curves at 5:30 pm. All curves are symmetrical at about the noon axis. The distribution forms with *CSR1* equals two remains constant most of midday. The horizontal surface receives a maximum DSR. Curves in Figure (4) also indicate that all domes receive approximately the same values of DSR at either the early morning or the late afternoon. As can be seen from the same figure, as the *CSR1* increases the DSR incident on the dome surface decreases. Receiving less DSR during summer may add some credits for employing a domed surface with a higher cross-section ratio. However, it is necessary to keep the loss in the intensity as small as possible in the winter.
Figure (4) shows that throughout the day there is only one time-period *(6:30-5:30)* in which horizontal roof receives more DSR than that received by curved roofs. This scenario has not existed in winter time, as seen in figure (5), which created two desirable times during the early-morning and the late-afternoon. Both two periods are similar in that the horizontal surface receives less DSR than the curved surface.
In winter months, the daily DSR variation profile, as shown in the figure, can be divided into three periods. The first period is at the early morning from sunrise to 9 am, when all curves ascend individually from the sunrise point at 7 am, reaching approximately 300 W/m^2 at 9 am.
The second period (midday period) is from 9 am to 3 pm, all distribution forms soared independently from the intersection point at 9 am to the highest values at midday when each curve decreased sharply till intersecting again at 3 pm (third period). Results in Figure (5) suggest that the received DSR on curved surfaces decreases with the increase of the cross-section ratio.

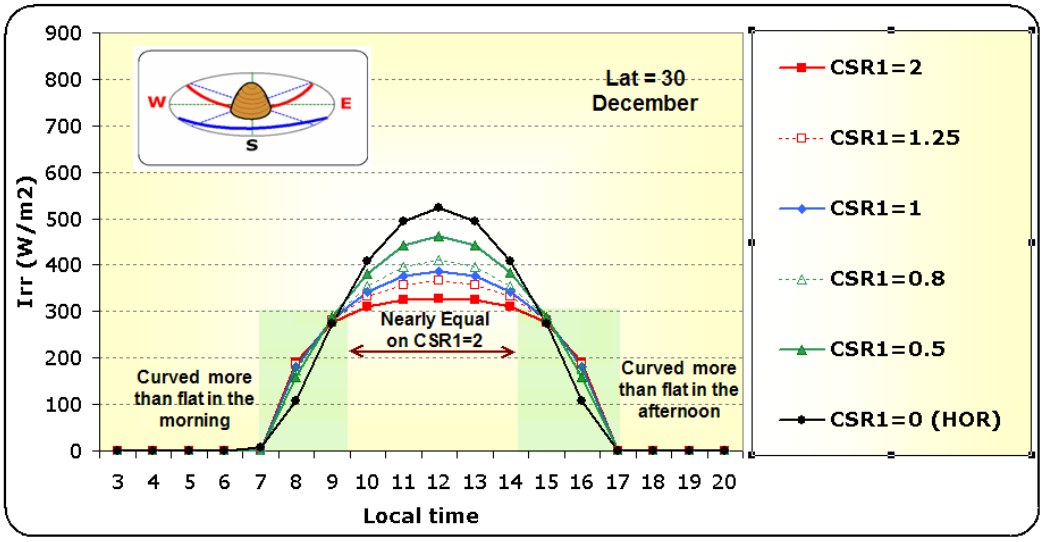

Fig. 5: DSR on CD surface during winter at 30°N

The result showed that the solar performance of circular dome is affected by its curvature in a following way: In summer, the circular dome with the highest ratio performs better than with low ratio at any orientation. In winter, the circular dome with the low cross section ratio is more preferable (receives maximum solar gain) than the circular dome with the highest ratio. In general, the circular dome is desirable in summer. However, the flat surface more efficient in the winter.

Summary

This study quantifies the embodied energy and embodied CO2 associated with building construction by using energy intensities and CO2 intensities obtained by process analysis and I/O analysis, and compare with each others in Japan.

The energy intensity and CO2 intensity table is calculated, which is based on 2005 I/O tables in Japan. In the intensity table, intensities of energy consumption and CO2 emission are shown as values of MJ and kg-CO2/million Yen, and each values are shown as based on producer's and purchaser's prices. It can be possible to calculate embodied energy and CO2 emissions due to constructions of various buildings.

The process-based data were referred to existing databases in Japan.

In this study, following comparisons are implemented;

・Comparison on energy intensity and CO2 intensity of building materials of the different databases: Cement, concrete, steel, glass, glass wool and lumber.

・Comparison on embodied energy and embodied CO2 of building by using different databases: a reinforced concrete office building and a steel frame structure office building.

The energy and CO2 emissions associated construction buildings were calculated by using energy intensity and CO2 intensity obtained by the I/O based analysis and the process based analysis. The results showed that many of intensities by obtained I/O analysis are larger than the intensities by obtained process analysis. The embodied energy and CO2 of office buildings by using I/O analysis are approximately 13% larger as the results of process based analysis.

Keywords: Embodied energy; Process based database; I/O based database

1. Introduction

Environmental and energy saving initiatives are becoming important strategies in the building sector today. Most of cases focus on operating stage of buildings. Building sector consume a lot of materials and components. When we look at energy and CO2 emission associated with building construction, embodied energy and CO2 occupy about 11% roughly in Japan, and it suggest that we should consider embodied energy and CO2.

If the energy saving strategies effect and reduce operating energy in near future, importance of embodied energy and embodied CO2 will increase.

Life cycle assessment is the one of the popular tools to assess building environmental loadings.

There are several issues among the life cycle assessment, different data collection measures, various or unclear data boundary condition settings and so on.

This study tries to make clear how different inventory databases influence on embodied energy

and CO2 emissions of buildings by comparing exiting databases.

This study selected three databases, JLCA-LCA Database, EE/EC database based on 2005 IO Table in Japan and Ecoinvent, and compared energy intensities and CO2 intensities of building materials and components. Furthermore, the study conduct analysis of embodied energy and embodied CO2 of a reinforced concrete building and the steel framed building.

2. LCI databases

2.1 Trend of databases

This study reviews LCA tools and LCI databases around the world. Fig.1 shows that LCI databases around the world and clarifies based on the methods of process-based analysis, I/O based analysis or hybrid analysis. This study could find 42 databases and most of the databases are created based on the process based methods.

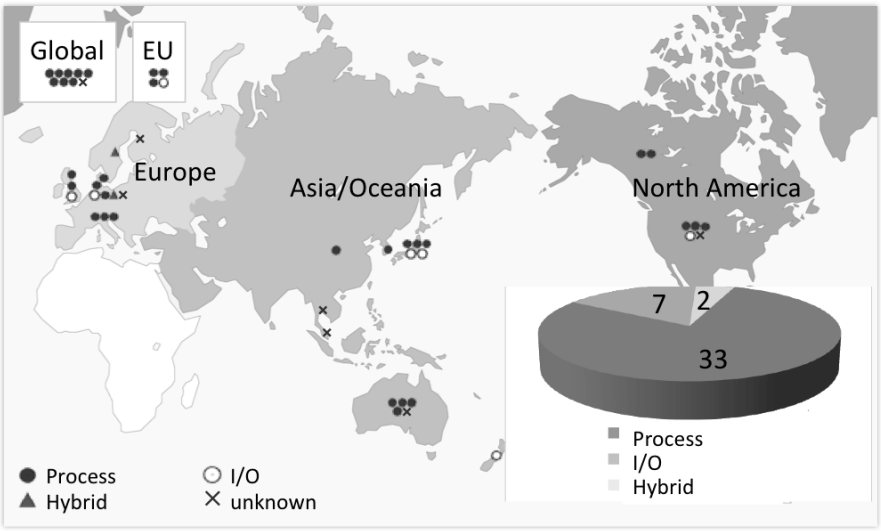

Fig.1 LCI databases in the world

3. Analysis of energy intensity and CO2 intensity of building materials and buildings

3.1 Summary and methods

This study selected three databases, JLCA database, IO database in Japan and Ecoinvent v2.2 compared these databases each other, and the energy intensities and the CO2 intensities of main building materials and components. Furthermore, the study conduct analysis of the embodied energy and the embodied CO2 associated with building construction.

This study conducted two case studies;

- Comparison on energy intensity and CO2 intensity of building materials
- Comparison on embodied energy and embodied CO2 of a steel frame building and a reinforced concrete building.

3.2 Selected databases for the case study

There are several databases in Japan and three database were selected considering characteristics of the process based database and the I/O based database, and the difference by the region.

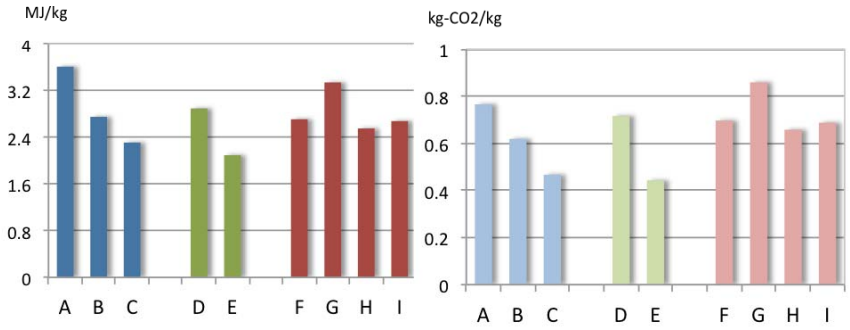
- JLCA database in Japan
- Ecoinvent in Swiss
- EE/EC Database based on 2005 I/O Table in Japan

Table 1 Selected databases

		Total number of data	Number of data relating buildings	Data creation method
DB-1	JLCA	550	71	Process
DB-2	Ecoinvent	4000	39	Process
DB-3	EE/EC database 2005 I/O	401	57	I/O

3.3 Analysis

JLCA-LCA Database and Ecoinvent v2.2 provide energy and other environmental loading data for each items with explanation boundary conditions and the remarks by the data providers. JLCA-LCA 's energy data provide as consumption of electricity, crude oil, kerosene, coal and so on. It needs to convert these data into primary energy by using the primary energy factor.



EE/EC database based on 2005 IO Table provides the energy intensity and CO2 intensity data. The unit of energy intensity and CO2 intensity of the I/O based database express MJ per 1million Yen and kg-CO2 per 1million Yen. This study converted these intensities into the unit uses MJ per kg or MJ per m3 and kg-CO2 per kg or kg-CO2 per m3 by using purchasers' price and quantity data of cost estimation information.

4. Results

4.1 Comparison on the energy intensity and the CO2 intensity of building materials

Fig.2, Fig.3 and Fig.4 show that the energy intensity and the CO2 intensity of cement, reinforced steel bar and sheet glass.

4.2 Comparison on embodied energy and embodied CO2 of buildings

(1) Summary of buildings

A reinforced concrete building and a steel framed building are compared. Table 2 shows summary of these buildings, and Table 3 shows material quantities of the buildings. This study covers only seven building materials, concrete, reinforced bar, steel frame, timber, plaster board, glass wool and sheet glass.

Table2 Summary of case study buildings

	Bldg.A	Bldg.B
Structure	RC	S
Total floor area	9,097m2	9,097m2
Number of floors	10F, 1BF	10F, 1BF
Building type	Office	Office

Table 3 Material quantity of case study buildings

Main materials	(unit)	Structure	
		RC	S
Concrete	m3	0.919	0.426
Reinforced bar	t	0.122	0.036
Steel frame	t	0.009	0.103
Timber	m3	0.016	0.006
Plaster board t12.5	m2	0.777	1.012
Glass wool t50	m2	0.202	0.154
Sheet glass t12	m2	0.186	0.400

(2) Reinforced Concrete structure Building

Fig.5 shows the embodied energy and the embodied CO2 of the reinforced concrete building by using DB-1, DB2 and DB3. The result of embodied energy of DB-3 is 6.3 % larger as the result of DB-1, and the results of embodied CO2 of DB-3 is about 18% larger as the result of DB-1. Concrete and the reinforced bar occupy about 80% of embodied energy and embodied CO2.

(3) Steel structure buildings

Fig.6 shows the embodied energy and the embodied CO2 of the steel frame building by using DB-1, DB2 and DB3. The result of embodied energy of DB-3 is about 16 % larger as the result

of DB-1, and the results of embodied CO2 of DB-3 is about 28% larger as the result of DB-1. Steel frame occupies about 60% of embodied energy and embodied CO2.

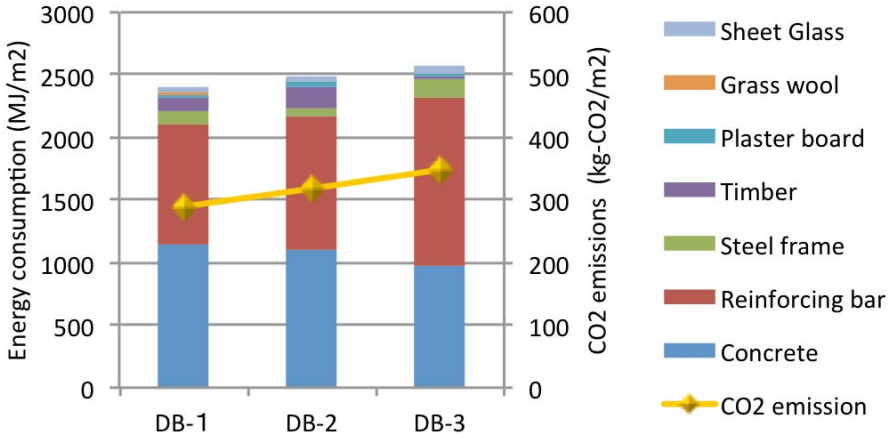

Fig. 5 Embodied energy and Embodied CO2 of Reinforced Concrete Building

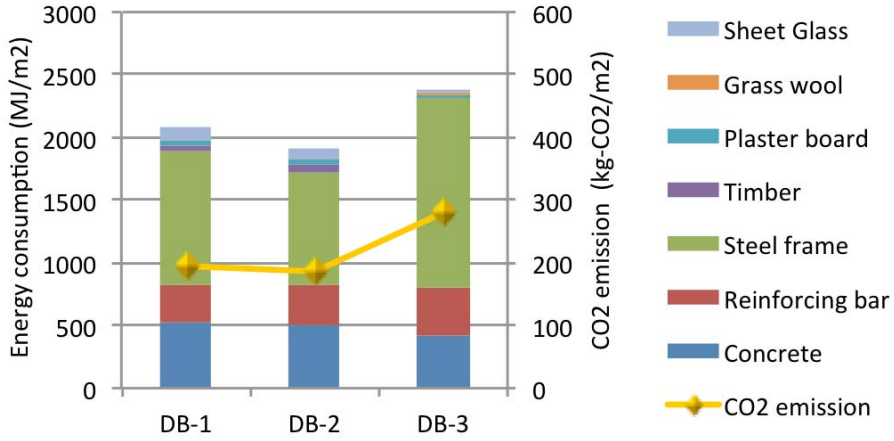

Fig. 6 Embodied energy and Embodied CO2 of Steel frame Building

5. Conclusions

This study conducted reviewing existing LCI databases and comparative case study on energy intensity and CO2 intensity by using different databases. The results show that different databases bring different results of embodied energy and embodied CO2 of buildings, and suggest that it is needed to prepare more accurate databases. This study compared only three databases and the number of building materials was limited to use as comparative study.

Short Summary

For the economic and environmental optimization of new construction projects as well as renovations, it is essential to estimate the resource consumption, e.g. of different design alternatives, at a very early stage of planning.

This paper presents an integrative environmental-economical model built on the life cycle costs model LEKOS [1], developed by Danube University Krems, and the environmental assessment software ECOSOFT by IBO. Purpose of the system integration is a combined economic and ecological life cycle model for buildings, realised in an easy-to-use tool for the evaluation of life span resource consumptions at different stages of the service life of the building.

The particular challenge is to link the various levels of detail and different system logics of real estate, construction ecology and energy optimization.

Acknowledgments:
The paper is based on the research project „LEKOECOS - A combined economic-ecological life cycle assessment model“ which is implemented through the research programme Haus der Zukunft Plus and financed by the Austrian Federal Ministry for Transport, Innovation and Technology.

Keywords: Life cycle costs; life cycle assessment; economic and environmental building optimisation; life cycle design tools

1. Motivation

Sustainable construction and refurbishment of buildings requires to know the economic and ecological resources consumed during building life cycle at an early stage of planning, in order to choose the optimized alternative.
The presented model LEKOECOS shows a combined life cycle model for buildings, developed on the basis of LEKOS, representing the life cycle costs model of the Danube University, and ECOSOFT, the ecological assessment tool of IBO. The model combines an economically and ecologically relevant catalogue of basic elements with the criteria of klima:aktiv and uses an implementation in an excel-tool. Validation of the model is done using practical examples of buildings. The great challenge in this project is the combination of details and systems as used by the real estate industry, the ecological assessment of construction and the energy optimization business.

2. Idea of the project LEKOECOS

It is the aim of the development plan of LEKOECOS (project duration March 1st 2012 until 31st January 2014, project supported by FFG) to create a simple tool that allows to determine the expected resource consumption over the life cycle of a building. The new tool represents a new model for the life cycle of buildings and is based on the life cycle costs model LEKOS of the Danube University, with main emphasis on costs, and on the ecological assessment tool ECOSOFT of the Austrian Institute for construction and ecology (IBO), with main emphasis on the ecological assessment of construction elements.

The first step is the establishment of a catalogue of economic and ecological basic elements. It is intended that the life cycle model for buildings LEKOECOS allows the combined economic and ecological optimization already at an early stage of the planning process, at a stage with various possibilities for planning variants. The calculation of life cycle costs is relevant for users, facility managers and owners of buildings as they have to judge on the long-term affordability of a property or estate. As opposed to that, benchmarks like CO_2-equivalents or the Global Warming Potential (GWP) are mainly of relevance for the public sector, e.g. with respect to meeting the target requested in the frame of the Art.15a B-VG agreement for the reduction of greenhouse gas emissions in the building sector or in the frame of the Kyoto-protocol.

Until now the corresponding analysis for costs or the ecological assessment of construction elements was carried out by a separate analysis using different tools. The combined tool allows for the integrated examination of economic and resource related performance. The tool supports the combined efficient use of financial means and natural resources and thus contributes to the protection of the environment and to the strengthening of the economic competitiveness.

Up from January 2014 the tool will be available for free download with a technical description and a user manual.

3. Life cycle costs programme LEKOS and eco software ECOSOFT

ECOSOFT was developed by IBO - Österreichisches Institut für Bauen und Ökologie on the basis of Microsoft Excel and is a software for the ecological assessment of building constructions and building equipment (HVACR). ECOSOFT may be applied to new buildings as well as to refurbished buildings.

The basis for the calculation in ECOSOFT is given by the table of reference values by IBO including more than 500 materials. The table is by default provided as part of the software and other data records can also be incorporated. With ECOSOFT is possible to determine the ecological effects of new buildings, refurbishments and waste management processes.

Moreover the following ecological benchmarks may be calculated: global warming potential (GWP),

acidity potential (AP), primary content of of renewable and non-renewable energy (PEI e, PEI ne), POCP, EP, OI3-Index (benchmark based on GWP, AP, PEI), indicator for waste disposal (EI). The results of the calculation are presented as an “environmental certificate for buildings”. Evaluation of these ecological parameters is based on the standardised method of LCA (Life Cycle Assessment), systematically determining the environmental impact of products, services or processes during certain stages of their service lives or throughout their entire life cycles.

LEKOS refers to the model for the expectation of life cycle costs for buildings and was developed by the Danube University Krems. It was one of the results of the basic research project “life cycle costs of building” that was funded by the “Klima- und Energiefonds” within the programme „Energie der Zukunft“ (Energy of the Future). The model also provided the basis for the standardised structure of life cycle costs which became the fundament of the new Austrian Standard B1801-2 [2].

Since 2009, comprehensive analyses and parameter studies according to Austrian Standard B1801-2 were carried out with LEKOS on various newly constructed and refurbished residential buildings, office buildings, and business centres, determining life-cycle costs values to generate planning recommendations for optimised follow-up costs. The current version of LEKOS has been available since 2012 as a product of the construction software ABK by the company ib-data. The LEKOS model is clearly structured according to the current standards of ÖNORM B1801-1 [3] and ÖNORM B1801-2. It contains no database, but is, however, equipped with various default settings and values.

4. Stages and boundaries of life cycle approach

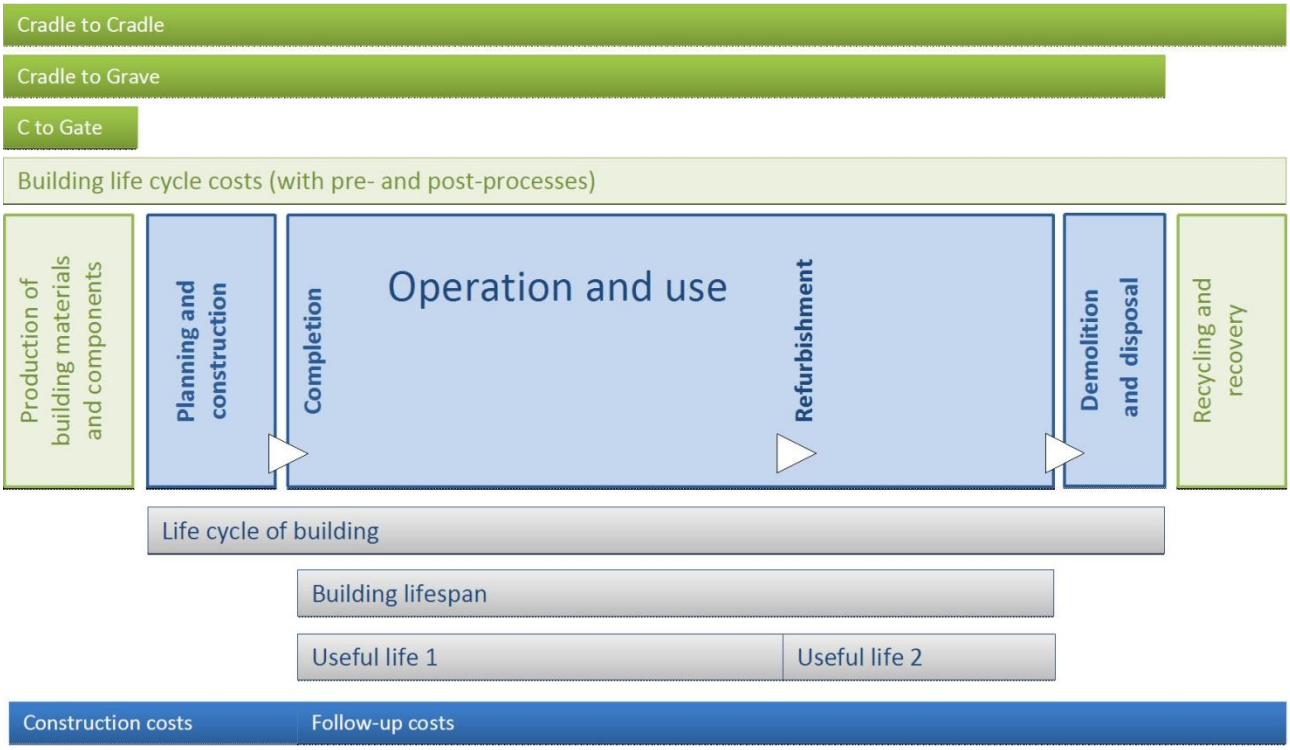

Figure 1. Building life-cycle costs and resources

One major challenge of the project LEKOECOS is the consistent combination of different approaches. Figure 1 shows the slightly different approaches of the economical and environmental definition of a building’s life cycle. The life cycle costs are the total costs of a building amounting throughout its life cycle. It is divided into construction and follow-up costs according to Austrian standards. Construction costs are those occurring during the planning and construction stage, whereas follow-up costs comprise of usage costs during the period of utilisation, and costs of demolition and disposal of the building. Life cycle costs can be seen as a parameter for a building’s economical sustainability.

The stage before planning and construction, in which the construction materials and components of the building are produced, is often taken into account for the evaluation of environmental sustainability of buildings. From an ecological point of view, the processes taking place after demolition and disposal of the building, such as recycling, recovering, or re-usage of materials and components, are of additional interest. Taking into account merely the production of building materials and components from raw material extraction to dispatching at the factory gates is called a “Cradle-to-Gate” view. Incorporating the stages of planning, construction, and usage as well as demolition is called a “Cradle-to-Grave” view. Closing the ecological cycle i.e. recycling, recovering, or re-using construction waste material is called “Cradle-to-Cradle”.

5. The concept of economical/environmental life cycle model LE-KOECOS

The tools LEKOS and ECOSOFT start each from a different degree of detail. The life cycle costs analysis of LEKOS is carried out on an aggregated level whereas ECOSOFT is working on a more detailed level of elements (construction elements and building equipment). In order to combine the two tools it is necessary to define a level of detail that allows to establish a working interface between the two tools. In this way several elements of ECOSOFT were combined in order to represent typical construction elements or building equipment for a defined type of building. At the same time it was necessary to install and maintain the compatibility with the structure of LEKOS. This approach induced for LEKOS the integration of additional data into the system in order to be able to produce the necessary ecological benchmarks.

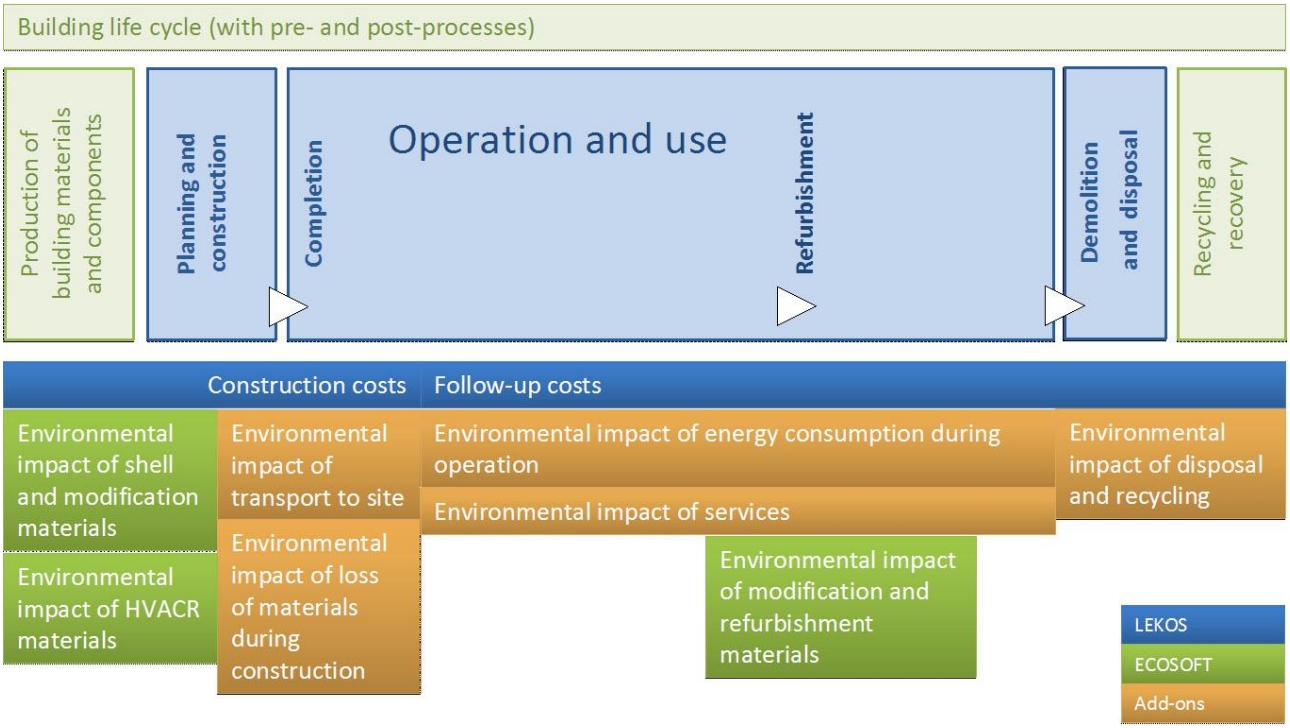

Figure 2. Costs and environmental impacts in a building’s life cycle

In a first step it was necessary to analyse both tools in order to decide on a degree of detail that is applicable for both tools. The analysis of the basic models revealed that the life cycle costs programme LEKOS has not only a much more complex structure than the ecological evaluation tool ECOSOFT, but also offers a comprehensive analysis of the building’s entire life cycle. Therefore, the decision was made to use LEKOS as the basic model and to adopt and expand the ECOSOFT model according to the structure of LEKOS.

Figure 2 schematically shows costs and environmental impacts evaluated by the LEKOECOS

model throughout the entire life cycle. The colour coding indicates which of the existing components of the base models can be adapted and used, and which model extensions are required. The life cycle costs model LEKOS (blue) covers the building's entire life cycle fairly well, whereas the ECOSOFT tool (green) is particularly suitable for the environmental assessment of building materials and components contained in shell construction and extension, as well as in HVAC. As a result, model components are added (brown) allowing environmental assessment of the life cycle stages planning and construction, operation and utilisation, as well as demolition and disposal or recycling.

Environmental impacts due to transport of materials and components to the building site and due to loss of material during construction are mapped with the LEKOECOS model. The energy consumption during construction is only partially taken into account since is negligible in comparison to the life cycle energy consumption. The environmental impacts during the stages of operation and utilisation mainly result from the energy consumption during building operation. The LEKOECOS model, however, maps also the environmental impacts resulting from services that are directly related to the operation of the building, such as buildings management or maintenance and cleaning services.

6. Basic elements catalogue and energy consumption during operation

Based on the process as described in part 2 a catalogue of basic elements is in development. It comprises typical elements of construction and building equipment (HVAC) for pre-defined types of buildings - that is office buildings, schools and residential buildings - and the corresponding eco-indicators for the construction and the operating phase.

At an early stage of planning only rough data on the quality of the building are available. However, data for energy consumption and the choice of energy carriers are a prerequisite for the determination of environmental performance indicators of the construction phase and the operating phase. Environmental performance indicators together with cost indicators for construction and operation are necessary for an integrated optimisation of the system.

In order to allow for the application of benchmarking tools in real estate without knowledge of details of the building, a classification of “low”, “medium” and “high” quality is widely used. The qualities “high”, “medium” and “low” are assigned to different concepts of buildings and related costs that are activated when choosing one of the qualities.

This approach of classification in the benchmarking of real estate is used to determine energy related eco-indicators in LEKOECOS. For example, for the input parameter “energy consumption” the user of the LEKOECOS tool may choose between “low”, “medium”, “high”. With that choice a scenario with all necessary parameters for energy consumption is activated in the background.

7. Results of the economical/environmental evaluation

The results of the LEKOS life cycle costs model are organised according to ÖNORM B 1801 part 1 (construction costs - Baugliederung) and ÖNORM B 1801 part 2 (follow-up costs). An analysis of the results' structures from an environmental point of view has shown that they are also suitable, with a few minor modifications, for presenting the ecological result of the LEKOECOS model. Not only the costs themselves, but also environmental indicators are displayed per cost position in the combined economical and environmental life cycle costs model. Some cost positions were, however, further subdivided to meet ecological demands. On the other hand, relevant environmental impacts are not associated with each individual cost position, nor is it possible to scientifically represent these with the data and methods currently available.
Therefore a structure of the LEKOECOS model with a clear allocation of economical and environmental results is given.

For the first version of the model the Global Warming Potential (GWP) was selected as a suitable indicator. It is comparatively easy to let the LEKOECOS model calculate further environmental indicators (AP, PEI, etc.) by extending the stored database.

Figure 3 presents the economical and environmental model's result showing costs and Global Warming Potential (GWP) as an example for individual cost positions, such as construction costs (floor construction) as well as annual (auxiliary power) and perennial (façade repair) follow-up costs.

Position in accordance with B 1801-1 and 2 Examples		Costs	GWP
E2.C.04	Floor construction	€	kg CO_2 eq.
F3.1.b	Auxiliary power	€/year	kg CO_2 eq./year
F7.1-4.C	Repair of façade	€/repair	kg CO_2 eq./repair

Figure 3. Presentation of economical and ecological model's result

8. Environmental impacts in the building life cycle

To define system boundaries, an evaluation of the ecological relevance of the individual products, processes and services of the building life cycle was therefore performed. In essence, each cost position was examined for relevant environmental impacts of various pre-products and sub-processes. The following environmental impacts were taken into account: production of materials and building components, freight and passenger transport, usage of cleaning agents, energy consumption during construction and building operation, waste disposal processes. Figure 4 depicts the simplified results of this environmental impacts analysis, and thus the system boundaries of the LEKOECOS model.

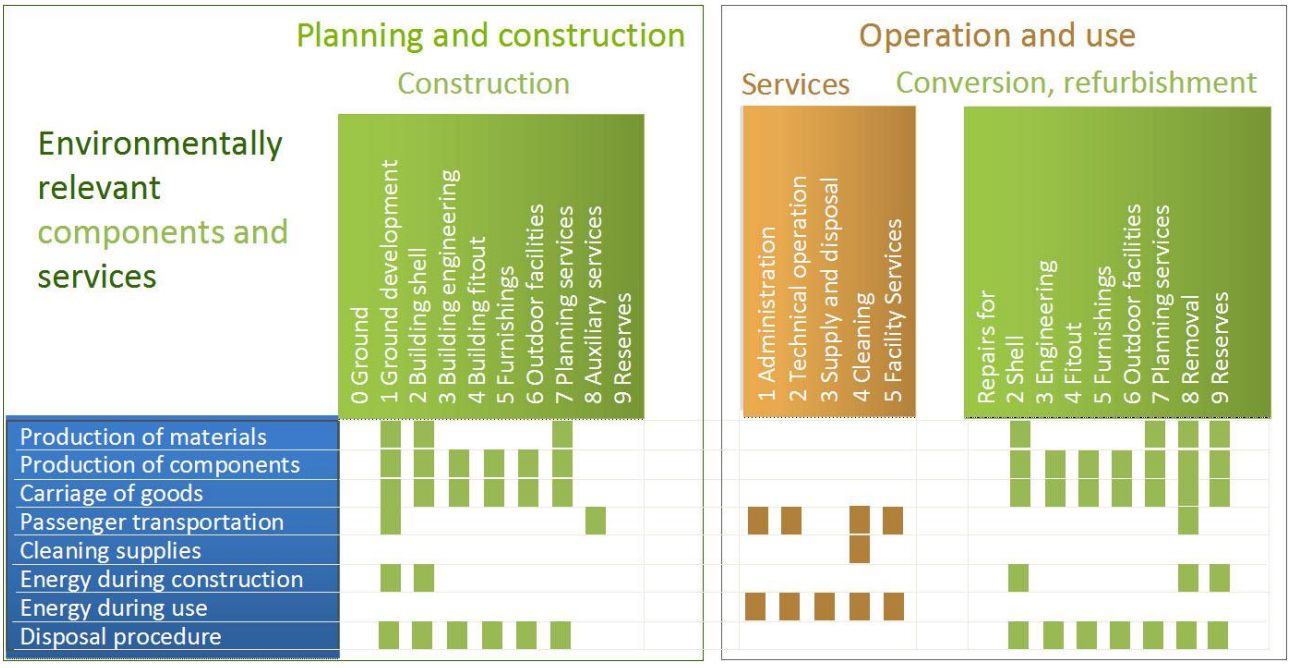

Figure 4. Environmental impacts of products, processes, and services of the building life cycle

9. Benefits of an integrated life cycle approach

The LEKOECOS project shows very clearly that the ambitions and requirements of ecology and economy do not differ greatly when considering the entire building life cycle. In both cases, the

focus is on optimising life cycle resource consumption. The individual resources may also be viewed financially, such as raw materials or energy. By combining the ecological and economical life cycle analysis, the user can simultaneously optimise all resources pertaining to the building life cycle. The LEKOECOS model allows the determination of important parameters for which, at present, calculations using two or more different tools are needed, causing partial overlapping of the respective input data and not guaranteeing complete consistency of parameters. The model's development also demonstrated that input data for cost determination can be, to some extent, gathered from the intermediate results of the life cycle analysis and vice versa. Apart from the simplified comparability of ecological and economical parameters, another major advantage of LEKOECOS is the reduced time and effort concerning data input.
The model's development also shows that methods and tools for economical evaluation have provided valuable input for the scope and system boundaries of the evaluation of ecological resource consumption. Thus, portions of the life cycle costs tool LEKOS have been adapted accordingly and used for the determination of ecological parameters. An inverse approach is also conceivable.

The LEKOECOS model will allow us to obtain new insights into the ecological-economical optimisation of a building during its entire life cycle. We will be able to identify potential ecological and economical conflicts of goals at the planning stages of buildings and solve them by optimising planning.

Short Summary

The claim, that form can be derived from a desired performance, is quite popular among practitioners of architecture. Nowadays a lot of projects apply computational optimization methods to achieve this goal. The paper deals with the question in how far building geometry can be derived from the demands placed on it using such methods. It is highlighted that the process of defining the computational model always precedes a performance-based generation of a design. Thereby a model is defined, which can generate possible solutions to a given problem. These variants can be searched for optimal solutions (solutions which correspond to the performance criteria).
By using a simple case study, the automatic reproduction of the Socrates house, it is shown which factors must be considered when modelling for design optimization and how these factors actually influence the extent a form can be derived from certain performance criteria. It is argued that to be able to purely derive form from performance the generative model of the optimization model must be able to systematically vary topological as well as metrical properties of the building geometry.

Keywords: performance based design, optimization, design methodology, modelling

1. Introduction

Performance-based design (PBD) is one of the guiding principles of recent developments in architectural design methods. The idea of PBD is to derive architectural solutions (such as a building form) on the basis of the demands placed on them (performance criteria). Among others, one performance criteria is the energy demand of a building, also referred to as energy performance [1]. The energy performance is influenced by several factors: firstly produced by the geometry of the building, secondly by the materials of which the building is made and thirdly, by technical equipment used in the building. In the following we only refer to the first factor, the geometry of the building. This is particularly due to the fact, as the geometry of a building creates the conditions for the potentially possible energy gains and losses of a building. Of course thanks to the use of materials and technology on the one hand one can minimize deficits that are due to the geometry of the building (avoidance of thermal bridges by adding insulation, increasing the efficiency of the system technology) or use it's potentials (such as photovoltaic and solar thermal systems on sunny surfaces or the placement of thermal mass in sunny places in the interior of the building). However, the definition of the geometry of the building usually stands in front of such interventions and therefore can be regarded as the essential step in the design process.
Using computational methods, the search for an optimal geometry can be supported because they enable to generate and evaluate a large number of designs in a relatively short time. Criteria that are hard or slow to evaluate by humans, thus can be effectively integrated into the design process [2]. Optimization methods play an essential role for this. They also provide the key tool for PBD [3].
In the following we will examine in how far a form can be derived purely from the performance by an optimizing process, as it is propagated by the slogan "form follows performance" [4]. Therefore we will illustrate the basic functioning and the potential of optimization methods using a simple

case study. Based on this case study we will furthermore highlight critical factors which limit the extent to which form can purely follow performance.

2. Case study – The Socrates House

The Socrates House represents a very early example of a building form optimized in terms of passive use of solar energy [5]. This follows a simple principle. The walls and roof of the house were aligned in a way that the interior of the building gets as much sunlight as possible in winter and as little as possible in summer. As can be seen in Fig. 1, the roof of the house first is slightly inclined, so that the rays of the low winter sun reach far into the interior. Second, it forms a canopy to keep the rays of the high-standing summer sun from the interior. Third the two side walls are not parallel but form a trapezoidal ground plan to widen the opening so that the morning and evening sun gets into the building.

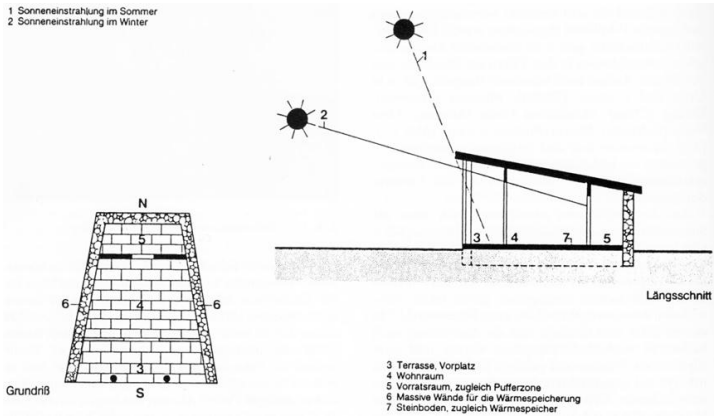

Fig. 1: Socrates House (Image taken from [5]*).*

In our case study we want to test whether solutions can be generated by means of a computer-based optimization strategy, which are similar to the "original" shown in Fig. 1. This study firstly serves the purpose of demonstrating the performance of such a strategy and second we want to draw attention to critical factors in computational modelling of such optimization or design problems. As an optimization method, we use an evolutionary strategy. This is very well suited for our purposes because for optimization, a priori, very few details are given about how a solution should be improved [6]. This is particularly important because we want to investigate the influence of the performance criteria on the geometry of the building.

2.1 Modelling

Modelling is an essential step in the application of optimization methods. This step always preceded the actual optimization and is needed to represent the optimization problem in a mathematical model readable by the computer [7]. Stachowiak [8] distinguishes three essential attributes of models: transformation, abbreviation and pragmatism. The former means that a model is always an image of something, a representation of natural or artificial originals that can itself be models. With second is meant that not all attributes of the original must be mapped in a model, but only those that are relevant for the particular problem. For this, the third feature of pragmatism is especially taken into account, which means that the model must be based on practicality. A model is not associated with an original by itself. A model is used by the model-makers within a certain period of time and for a specific purpose for an original. In our case, it should be noted that the original is not referring to a real existing building, but merely a building design whose attributes are not known at the time of modelling.

For the problem at hand, the optimization of building geometry using evolutionary algorithms, a model is needed for the representation of geometric variations, and for the performance evaluation of these variations. Models to generate geometric variants comprise algorithms that describe the properties of and the relationship between geometrical elements. These models are also referred to as Generative Models (GM). They can be controlled by parameters, whereby a change of one or more parameters results in a new geometric variant. To arrive at an optimal solution, these parameters are varied until a variant fulfils the performance criteria best as possible. The

parameters can be distinguished into those that change the metric and those that change the topological properties of the geometric model. Metric properties define the size and position of elements (e.g. a wall has a start coordinate P1 and an end coordinate P2 and a height h). Topological properties describe the relationships among the elements (ceiling X lies on wall Y and wall Y touches wall Z with their starting coordinates).
The Socrates House can be described by a simple generative model. The essential elements of the house are the three outer walls, the floor and the roof. The three walls include the rear wall of the building connected with the two side walls. The definition of the parameters for the generation of variants can be implemented in different ways. In the following two variants are presented to show different ways to create generative models and on the other hand to check whether the results differ depending on the model used. The two models are shown in Fig. 2. In model A only three parameters for the generation of variants are used: the height and the displacement of the front roof edge and the width of the opening of the house. The height of the back wall, or the depth of the interior are fixed. In model B all vertices of the house can be varied within a certain range.

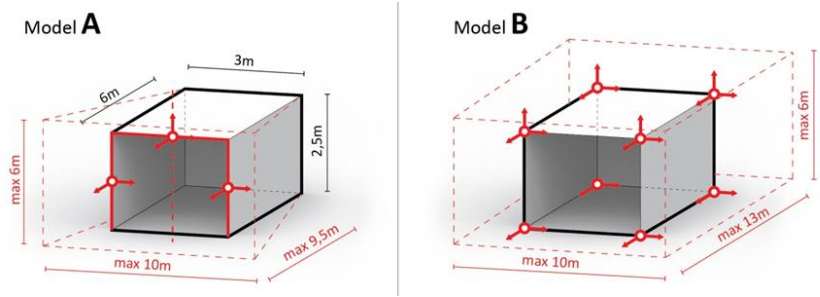

Fig. 2: Schematic of the two models.

For the evaluation of the variants generated by one the two GM the direct solar gains on the interior surfaces of the building are calculated. The performance criteria are to maximize solar gains (*Sg*) in winter and minimize them in summer. The result is a multi-criteria optimization problem with two conflicting criteria. Since the tool used for optimization (Galapagos, a plugin for Grasshopper for Rhino), does not allow systematic multi-objective optimization, the two performance criteria were combined into a single objective criterion as follows:

$$f(x) = Sg_{Winter} - Sg_{Summer} \qquad f(x) \rightarrow max$$

Sg_{Winter} and Sg_{Summer} are calculated from the amount of direct sunlight on all interior surfaces of the building on a winter day (21.12.) resp. on a summer day (21.06.). For this purpose, the corresponding areas were divided evenly and checked whether and at what angle the sun's rays for different time levels meet the respective grid cells. Fig. 3 shows the result of such an analysis on an exemplary model. The amount of solar gain is colour coded. Red cells indicate high, blue cells very low values.

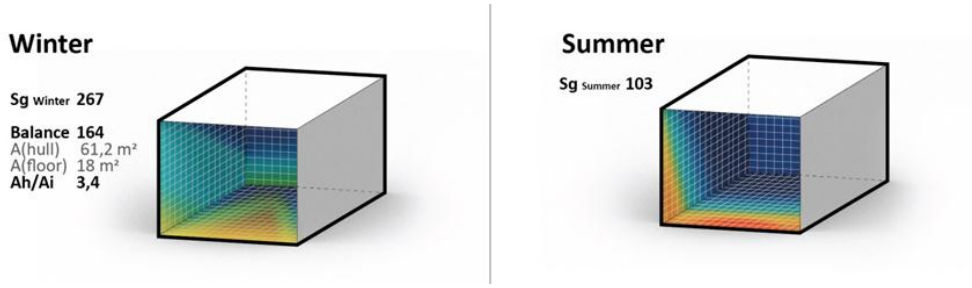

Fig. 3: Performance analysis (left: Solar Gains on a winter day, right: Solar Gains on a summer day).

2.2 Discussion of Results

For each of the two GM described above multiple optimization runs were made. A representative selection of the results is shown in Fig. 4. In the left column optimized solutions based on the model A, in the right column optimized solutions based on the model B are shown.

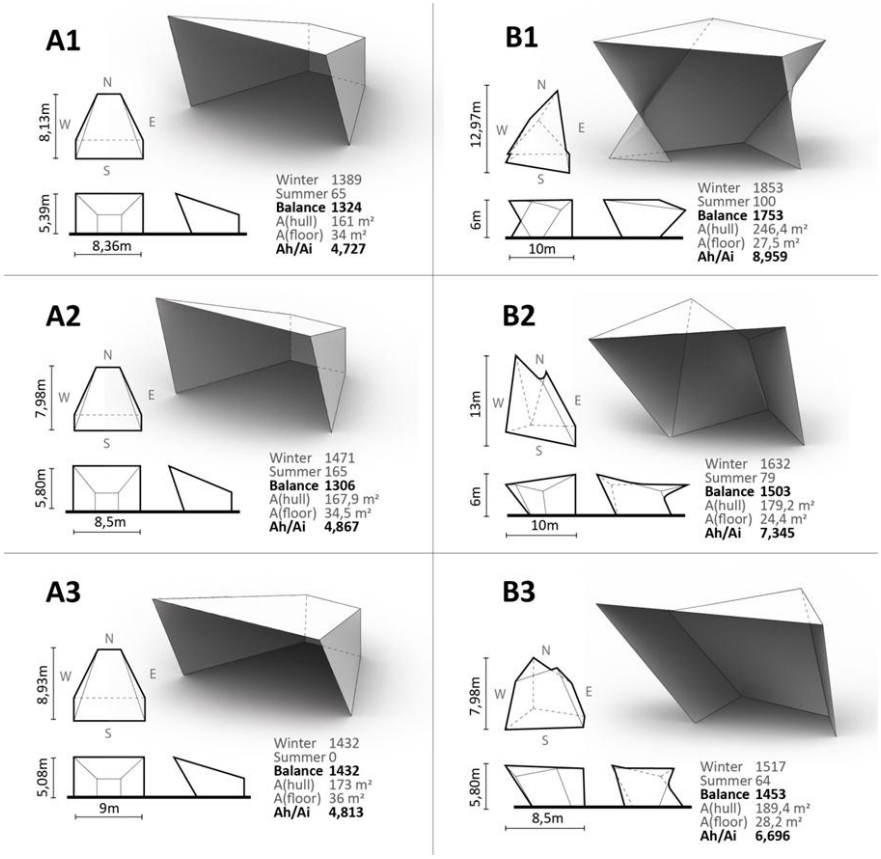

Fig. 4: Different optimal solutions resulting from the two different GM (left: Model A, right: Model B).

The results arising from the optimization using both GM show the essential characteristics of the solar house. Thus the sloping roof and the trapezoidal floor plan can be found in all solutions. It can also be noted that all the variants achieve the performance criteria. Compared with the not-optimized variant shown in Fig. 3, the balance (the difference between winter and summer) is up to 10 times higher. Large differences between the solutions derived from the two GM can be observed in the exact shape of the building, and in the ratio between floor and envelope. Using GM A, the forms are very similar to the original shown in Fig. 1. However, the results of GM B have a highly asymmetric and skewed shape. In addition, they have a much worse ratio of floor area to envelope (A_H / A_F). This is due to the fact that in models with a large envelope and the solar gains are higher since there is a larger surface to be shone on. Accordingly, such variants were favoured in the selection process of the optimization. A bad A_H / A_F ratio has a negative effect on the energy balance of the building, thus although the results of GM B have a slightly better winter-summer-balance compared to the ones of GM A their energy performance is significantly worse.

The similarities of the optimal solutions generated (high performance, essential shape features of the Socrates house) show that optimization methods in the design of buildings are effective in principle. However, the differences between the results of the two GM shows that creating a GM is an essential step in the application of optimization strategies: Depending on how the model is designed not only the range of variants, but also the solutions resulting from the optimization process changes. In the following two critical factors for creating a GM are discussed and implications for the use of optimization techniques in the design process are drawn.

3. Knowledge mapping in generative models

When creating generative models always a certain amount of knowledge about the problem and about possible solutions flows in. By knowledge all information is meant used for the description of

the model. This includes e.g. the information that a wall Y is connected to wall Z or that a certain minimum ceiling height should not be undercut. The amount of knowledge used is a useful criterion for distinguishing between generative models. If much knowledge is used to build in a model, one can speak of well structured models, if little knowledge is used, one can speak of weakly structured models.
The advantage of well structured models is that by a large number of constraints (restrictions), the generation of many unusable variants (e.g. buildings with a floor area of 5m², a triangular ground plan or a ceiling height of 1m) is avoided a priori. To search for an optimal solution in such a case only a few criteria are needed, since it is assumed that many other criteria are met by the introduction of restrictions. In weakly structured models, however, only a few constraints are defined, thus a greater range of variants can be generated. The advantage of such models is that they are able to generate solutions that have not already been covered by the foreknowledge of a model maker (designer). However, numerous useless variants are possible, which conflict with criteria, which were not defined as performance criteria. To find reasonable solutions in this extended range of variants, additional evaluation criteria are required.
The GM described in 2.1 fall into the above two categories: Model A (Fig. 2, left) can be regarded as a well structured model since many constraints were used for the description of variants (only the shape and size of the opening can be changed with three parameters). The solutions generated by optimization of the model only show few differences compared to each other and are similar to the original Socrates House. Model B (Fig. 2, right) can be described as a weak structured model. All points in the model can be moved. There are no dependencies between the points. The solutions obtained have large differences compared to each other and are only partially similar to the original. They also reveal a bad energy performance due to their high A_H/A_F ratio.
Considering the fact that due to the extended variant spectrum in weakly structured models the many unusable solutions need to be sorted out by additional evaluation criteria, the poor results of the second model are reasonable. In the following the weakly structured Model B is extended for one further evaluation criterion, the ratio of floor area to envelope area. The aim is to check whether it is possible if by this Model C solutions can be generated which have an improved energetic performance. The three performance criteria can be summarized as follows:

$$f(x) = Sg_{Winter} - Sg_{Summer} - (\mathrm{A_H}/\mathrm{A_F})\mathrm{w} \qquad f(x) \rightarrow max$$

A_H/A_F is the ratio of base to the envelope surface and a factor *w* is introduced to compensate the size differences of the values of *Sg*. Again several optimization runs were performed for this extended model. A representative selection of the results is shown in Fig. 5.

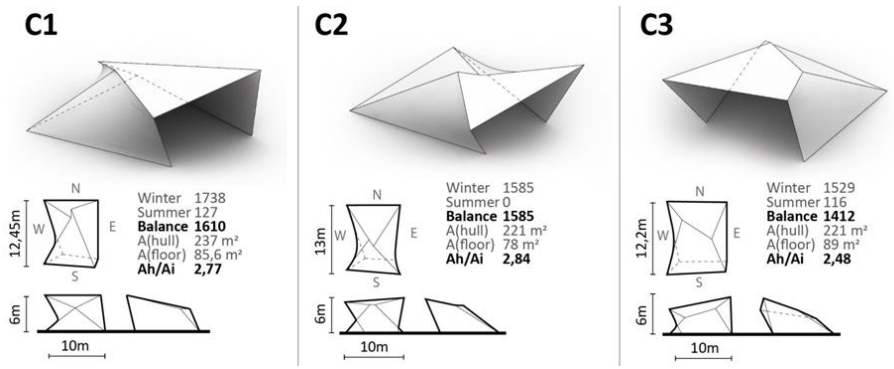

Fig. 5: Different optimized variants of the Socrates House resulting from an extended weakly structured model (Model C).

As can be seen in Fig. 5, all solutions show very good values in both the winter-summer balance, as well as in A_H/A_F ratio. The energy performance of these solutions is thus even significantly higher than those of Model A. This was achieved by not only inclining the side walls forward (to keep the summer sun from the interior), but also slightly outwards, thus in winter more sun rays meet the wall surface at right angles. Is noted as negative, that all variants have, compared to Model A, a large floor area, which due to the steeply sloping walls can not be used completely. This

problem could be avoided in principle by extending the model to other performance criteria.
If all evaluation criteria are known weakly structured models offer one main advantages. First, because the solution space is less restricted than in well structured models, the chance is higher to find innovative solutions. Thus for design problems in principle weakly structured models are preferable to well structured models. For a better understanding of this thesis a distinction of design problems into well-defined (tame) and ill-defined (wicked) problems [9] is helpful. Well-defined problems are problems that can be completely described and thus be easily converted into a problem-solving mechanism (in our case an optimization method). In ill-defined (or wicked) problems, the solution method, the elements, and the design goals are only incompletely known. These are defined through numerous iterations in the design process, where the objectives and the elements are changed frequently. This makes well structured models only partially suitable for such problems, since for any changes, the generative model must be adapted, which is both time consuming and knowledge-intensive. However mapping too much fore-knowledge about possible solutions in optimization models for solving ill-defined problems is unavailing, since the *"lack of knowledge is precisely what makes a problem a problem"* [5, p. 218].

4. Metric and topological properties of geometric models

Another critical factor for using optimization approaches for design problems are the parameters for describing the geometric variations in a GM. As described in Section 2.1 one can distinguish between metric and topological parameters. In the case study on the reproduction of the Socrates house, the topological properties were set fixed (side walls touching the rear wall, the roof lies on walls, etc.) and the metric properties were set variable (position of the start and end points of the walls, length of the roof, etc.). Thus the spectrum of variants include buildings with three connected walls and a roof, wherein the position of the walls, as well as the inclination and length of the roof is variable. Only within this spectrum (also called search space), an optimal solution can be found. Solutions which have, for example, a window in one of the two side walls are excluded a priori. However, making such decisions (e.g. whether and how many windows are placed in a building envelope) is an important step in the design of buildings. These decisions are made by defining the topological properties of the geometric model.
Limiting GM on the variation of metric properties is typical for many projects on optimizing the building form (e.g. [10–12]). Exemplarily for such an approach the work of Caldas [10] is briefly described: Caldas developed a system called GENE_ARCH, which allows to optimize building designs with respect to heating/cooling demand and the available amount of daylight in the interior. The performance of the variants was calculated using a special framework for energy and lighting simulation (DOE2.1E). The optimization algorithm tries to find solutions lying on the so-called Pareto front, which represent the best compromise between the different criteria. The system was in a case study, shown in Fig. 6. It shows very clearly the changes in the shape of the building, depending on whether the minimization of heat loss or maximizing the light entry has priority in the optimization: The best solution for minimal heat losses is a compact building form, while the best solutions for light interior result in buildings with a large envelope surface.

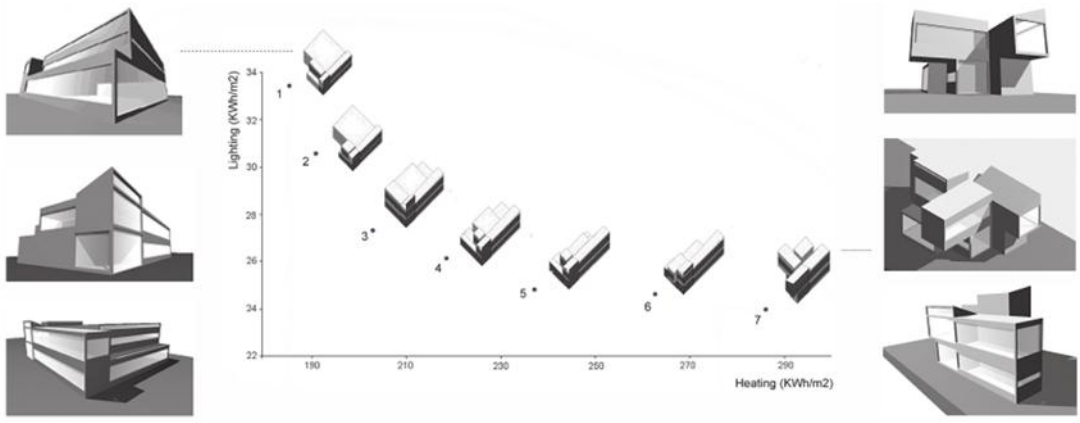

Fig. 6: Variations of building form, optimized for light entry and heating (image taken from [10]*).*

Regarding the modelling of the problem, it is easy to see in this example that the variation spectrum of the GM is highly restricted. The model describes eight cubes, each four are distributed on two floors. The cubes are joined in one point and can be varied in length, width and height. Variants, for example, which have a central courtyard, are not included in the model. The windows are located on two sides of each cube and can only be changed in their height. The width of the window is determined by the length of the respective wall. Placing multiple smaller windows is therefore excluded a priori. Similar to the case study presented in section 2 it can be noted that in models in which topological properties are fixed, and only metric properties can be varied, the search space is highly restricted. More generally one can also say that although numerous variations of a concept can be tested and optimized the creation of new concepts (which have the potential to be more optimal) is not possible. Assuming that important decisions of a building design are defined by its topological properties, then GMs are need to allow the variation of topological properties.
In the works of Watanabe [13] and Dillenburger et al [14] an interesting approach can be found in which only the topological properties of the building geometry are varied. Therefore a GM is used based on a three-dimensional grid. The points of this grid (also called voxels) represent spatial units (e.g. rooms or apartments). The GM generates variants by switching these units in the grid active (available) or inactive (not available). Dillenburger et al [14] showed that different building types can be generated through optimization of different performance criteria (Fig. 7). For example, minimizing the facade area and maximizing the light entry results is a compact building structure with numerous courtyards (Fig. 7, left). If only the amount of daylight in the interior shall be maximized solutions with several tall buildings occur (Fig. 7, middle). Between these two extremes numerous mixed solutions can be generated (Fig. 7, right).

Fig. 7: Different variants of an office building resulting from optimization (image taken from [14]*).*

With respect to the model used it can be considered as advantageous that a priori no information on the relations between the elements is needed. Thus solutions can arise, which consist of many individual buildings or even with connected volume. However, the voxel-model is based on elements with fixed positions and dimensions, thus only the existence of elements is variable. A precise tuning of e.g. distance between elements is not possible.
To summarize it can be stated that by defining the rules for generating variants also the range of optimal solutions is set. This issue was brought to the point by Gero & Radford [15] who compared the use of optimization methods for design with George Bernard Shaw's short story of a man who *"having lost his keys one night, searches under the lamp post, not necessarily because that was where he lost his keys but because that is where the light is"*. To find innovative solutions for a variety of performance criteria with the help of a computational optimization method the GM needs to cover the widest possible variant spectrum and thus must be able to change both topological metric properties. Such models are not yet known to the authors.

5. Form follows the computational model

Performance based architectural design is an interesting approach to meet the diverse needs of the building. Using computer-based methods, this approach can be supported usefully. The case study on the reproducibility of the Socrates House demonstrated on the one hand the potential of optimization methods in designing. On the other hand, it made clear that the extent a form can actually be derived from a desired performance depends on the model used to represent the optimization problem. This model consists of a generative model (GM) for the generation of geometric variants and an evaluation model (EM) in which the evaluation criteria and their weighting is determined.

Setting the GM is a crucial step, because a building can only be optimized within the spectrum of variants which can be generated with this model. When describing this model, a differentiation between metric and topological properties is necessary. It can be noted that, although important information for variation of the building geometry is defined by the topological properties, most models for performance-based form-optimization only vary the metric properties. In these models, the variation-spectrum is severely limited. Such models are only suitable for solving problems in which many decisions have already been made.
Defining the EM depends on the amount of knowledge used for defining the GM. Here, a distinction was made between weakly and well structured models. Generalizing, we can conclude that in well structured models, the solution of a problem is mostly included in the specifications and in weakly structured models, the solution of a problem is defined by the evaluation criteria. Although weakly structured models require many criteria, they are regarded as more suitable for solving design problems, because the variant-spectrum is not too narrowed in advance.
Concluding one can say that how to build a computational model for performance-based design optimization needs to be decided anew in each particular case, but on thorough considerations of the critical factors described in the article. To what extent a general model for design optimization can be built needs to be investigated in further research.

Short Summary

This paper aims to examine the energy performance of multi- story buildings by changing the settings on available building façade keeping other parameters constant at standardized values (such as orientation, illumination load, type of HVAC system etc.) in Saudi Arabia. Simulations were carried out for different types of facades. The DesignBuilder 3.0 software was used as a simulation tool for calculating energy consumption of the analyzed building. This paper shows the annual energy performance of the building for typical Saudi Arabian climate. Six different economically available building façade are compared. It is shown that there is a significant effect on energy consumption and cooling load on the change of façade as a result of which utility operational costs are reduced. The result of the paper enables to select the optimum alternative of façade configuration; to help decision makers reduce the energy consumption of commercial buildings.

Keywords: Energy performance, Building facades, operating costs, Energy consumption,

Simulation, optimum alternatives

1. Introduction

Façades not only shape the appearance of building, they also determined the indoor climate, energy consumption and operating costs of a building. They directly influence the heating and cooling loads, and also indirectly influence on lighting loads when day lighting is considered. In addition to being a major determinant of annual energy use, they can have significant impacts on the cooling system and electrical demand. However, they are prominent architectural and design elements and they responsible of occupant's performance, satisfaction and comfort.

Air conditioning systems is buildings in Saudi Arabia are responsible for about 70% of their energy consumption [1]. Whereas the electric consumption for air-conditioning in United Kingdom and United States is 22% and 21% respectively as the analysis provided by Saudi Electric Company. Also, according to the same analysis the average electricity consumption of an apartment in Dammam is 20,000 kWh/year, while the average consumption of areas of similar climates in the United States is 8000-10,000 kWh/yr. From this we conclude that buildings are large consumers of energy in Saudi Arabia and therefore prime candidates for energy conservation activities. Since they are replaced very slowly and most of the existing buildings do not meet energy efficient standards, retrofitting would be essential to minimize energy usage. At least cost energy strategy conservation should be supported in the energy future. For every unit of energy saved by a given

measure of technology, resources will be saved, and the annual maintenance costs of producing the unit of energy will be eliminated [1-3]. Therefore, considerable attention is currently been paid on reducing the energy demand for cooling purposes in buildings. Ways to monitor energy consumption of buildings and the prospects of energy saving in residential space cooling have been widely discussed [4–8]. Methods for predicting the annual building cooling energy demand have also been presented in a variety of studies [9, 10]. The demand for energy efficient buildings has made the application of building simulation a must, rather than a need.

Because of the increasing amount of new residential and commercial construction using building facade technologies, it is very important to examine the energy consumption for the building by selecting the effective façade system considering the availability of material in Saudi Arabia. This study aims to examine design factors that could contribute to greater reductions of energy consumption and CO_2 emissions. In comparing several facade with the different U-value, it can be observed that some facade configurations are more thermally effective than others (Table 2).

2. Methodology

The test building analyzed in this paper is constructed in a moderately exposed parking area within the compound of University of Dammam and are constructed in such a way that they shield another building from the outdoor winds.

DesignBuilder 3.0 was used to fully integrate the various aforementioned factors (see considerations on the program [11]), to determine hourly building energy loads and specific loads for end users, such as external lights and others. This made it possible to simulate many architectural designs with the aim of obtaining better solutions for the project within the analyzed context. DesignBuilder 3.0 is a computer simulation program used to explore the electrical energy consumption pattern of a typical building, simulating its dynamic thermal performance.

At first, several technical visits, followed by surveys were carried out to collect information about the existing building. The following items were taken into consideration:

- Built volume with internal partitions and outside openings, described in terms of materials as well as its thermal characteristics, use (office, toilet, etc.) and dimensions.
- Existing façade configuration of the building
- Geographic orientation of the construction
- Timetable of working hours, usage intensity of equipment and air conditioning system data.
- Hourly meteorological data for Dammam.

Through the use of simulation software, a building model was created; based on this model, architectonical modifications were simulated. This building energy-use simulation software uses its own climate data file. Building description for the the simulation of program is mentioned in Table1.

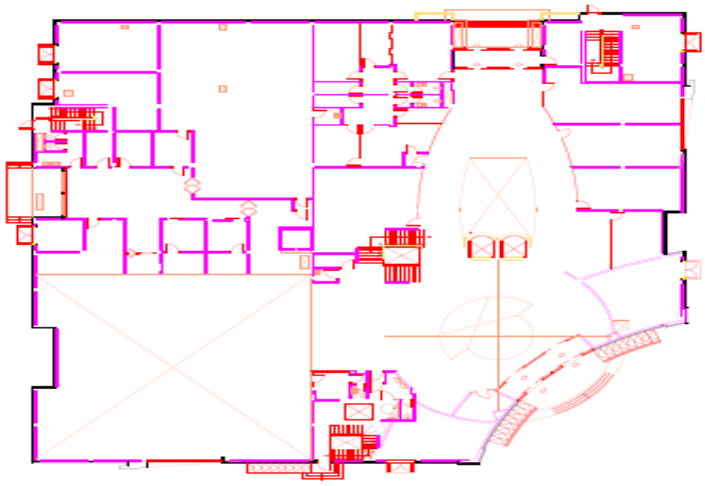
Table 1: Building description for the simulation program

Parameter	Value
No. of floor	3
Total area	4394 m^2
Floor height	3.7 m
Orientation	North to South
Infiltration rate	5.0 m^3/h/ m^2
Ventilation rat	7.5 L/s/person
Thermal zones	Multi-zones
Equipment	20 W/m^2
Lighting	18 W/m^2
HVAC	Central System
Occupancy	4.5 m^2/person
Set point	(22–24 ◦ C) summer, (20–22 ◦ C) winter

The methodology used to study the building consisted in checking the existing façade configuration and comparing it with other alternatives based on locally available economical façade materials.

Six scenarios were developed by façade alteration in the existing building which effect in reducing cooling loads and hence energy. The results of these alterations were shown in Table 3 that provided input for a critical analysis of these parameters.

3. Data description



The analysis focus on an institutional building, located in a North Zone of the city of Dammam, Kingdom of Saudi Arabia at latitude 26˚23´N and longitude 50˚11´E, and temperatures varying from 15.3℃ to 45 ℃ on average. The building is in an urban area, with medium density occupation. The orientation of its frontal facade is 58˚ east of North. Construction of the building ended in 2012. The plans of a typical floor of the building under consideration and its elevations and location of Dammam city on Saudi Arabia map are shown in Figs. 1 and 2 respectively.

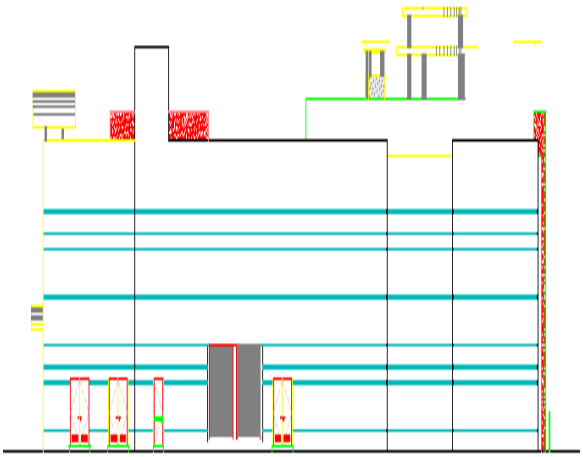


Fig. 1: Location of Dammam city on KSA map

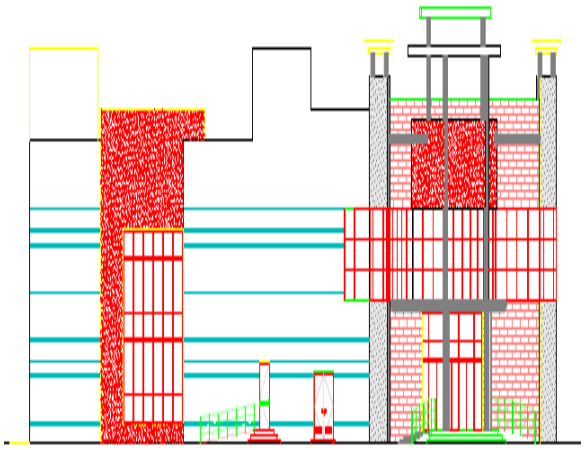
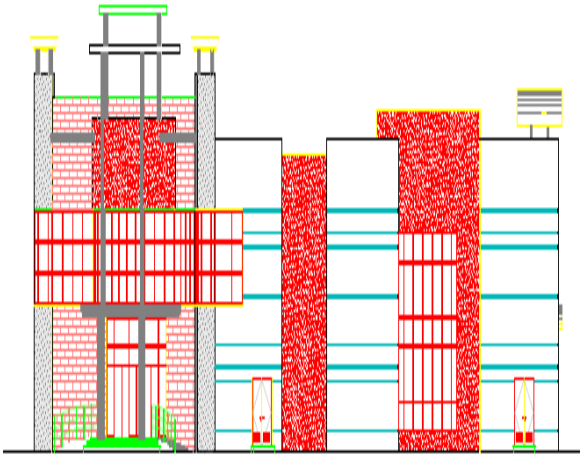
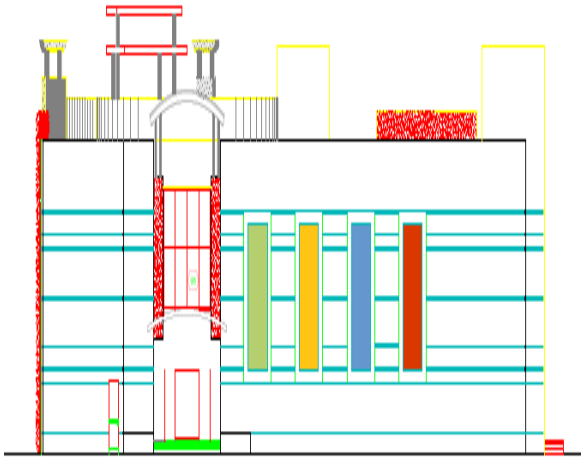
4. Simulation data



A total of six façade configurations have been analyzed including the base case i.e. Façade-I. Wall conductance and resistance values have been computed for all the six cases as shown in Table 2. The values obtained are then used for the simulation of program.



Floor Plan



North Elevation

West Elevation

East Elevation

South Elevation

5. Results and discussions

The properties of the material are inserted into the programme such as specific heat, conductivity, density, thermal absorptance values etc. software which computed the cooling loads and total energy consumption for all six cases of facades. The results are shown in Fig. 3 and 4. It is clear from the results that Façade-II configuration has minimum values of annual energy consumption and cooling load.

Based on these values the cost of annual energy consumption and annual cooling load has also been evaluated. The results are shown in Fig. 5 and 6.

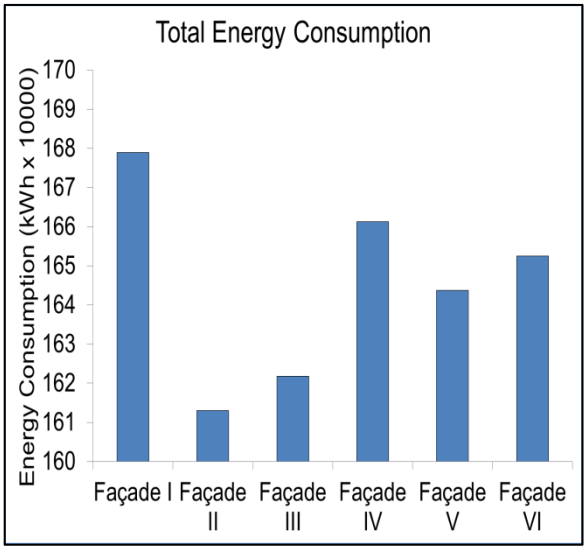

Fig. 3: Annual total energy consumption

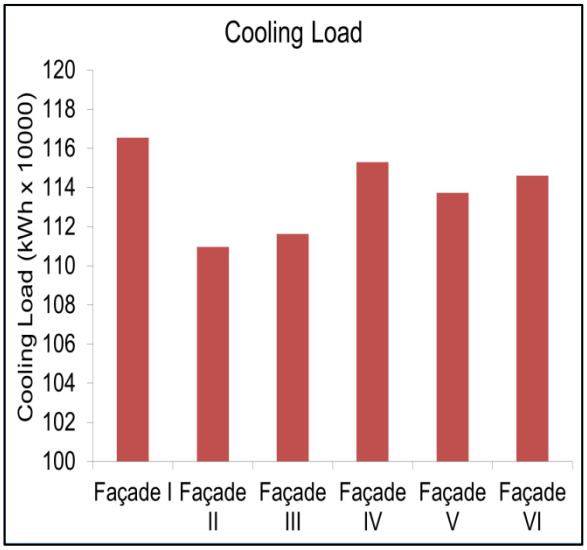

Fig. 4: Annual cooling load

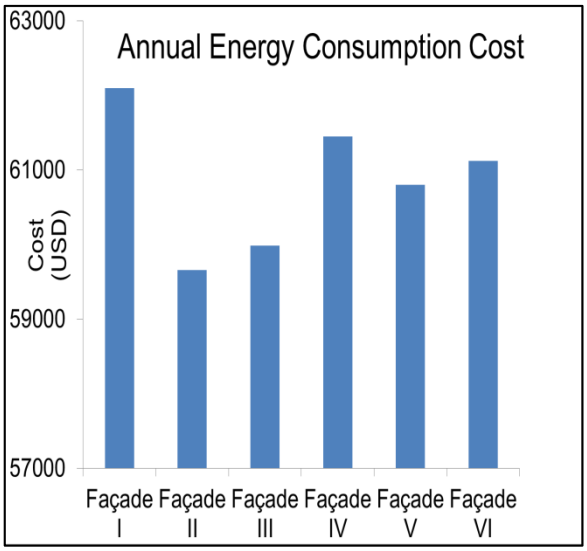

Fig. 5: Annual energy consumption cost

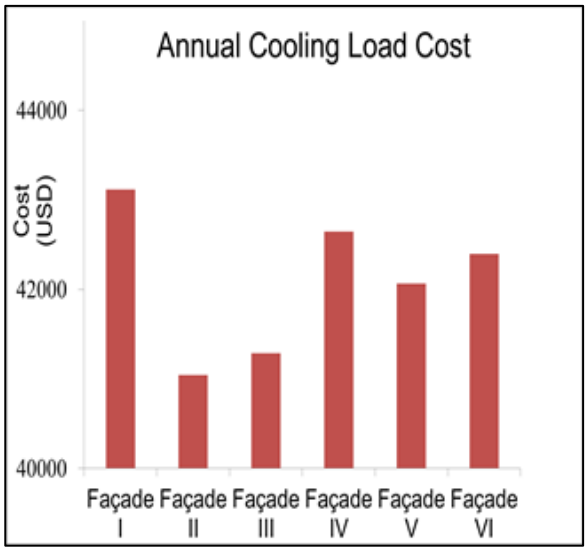

Fig. 6: Annual cooling load cost

Table 2: Structures and thermal characteristics of facades used mostly in Saudi Arabia building

Façade Type	Composition	Thickness of wall components (m)	Thermal conductivity of wall components (W/mK)	Wall Conductance U (W/m^2K)	Wall Resistance (m^2K/W)
Façade-I	Plaster	0.02	1.5	**2.33**	**0.43**
	Concrete Block	0.25	0.62		
	Plaster	0.03	1.5		
Façade-II	Plaster	0.02	1.5	**1.47**	**0.68**
	Concrete Block	0.1	0.51		
	Polystyrene	0.05	0.04		
	Concrete Block	0.1	0.51		
	Plaster	0.03	1.5		
Façade-III	Limestone	0.02	1.8	**1.64**	**0.61**
	Concrete	0.1	0.51		
	Polystyrene	0.05	0.04		
	Concrete	0.1	0.51		
	Plaster	0.03	1.5		
Façade-IV	Limestone	0.02	1.1	**2.13**	**0.47**
	Precast concrete	0.15	1.13		
	Air gap	0.05	0.28		
	Precast concrete	0.1	0.75		
	Plaster	0.03	1.5		
Façade-V	Aluminum	0.01	160	**1.82**	**0.55**
	Air gap	0.015	0.28		
	Concrete block	0.25	0.62		
	Plaster	0.025	1.5		
Façade-VI	Terracotta tile	0.02	1	**1.92**	**0.52**
	Air gap	0.02	0.28		
	Concrete block	0.25	0.62		
	Plaster	0.03	1.5		

Now, it is clear from the results that the façade configuration-II consumes the minimum energy and has minimum cost impact while the existing one consumes the maximum energy and has maximum energy costs. Annual energy consumption per square meter of the area for all the cases has also been simulated and the results are shown in Fig. 7.

The air-conditioning system is responsible for a significant share of total energy consumption of the building, approximately 69% (concluded from Fig. 3 and 4). Fig. 3 and 4 shows the office building total annual electric energy and cooling load consumption. For the purpose of discussion the electric energy and cooling load variation is due to the reason of different U values.

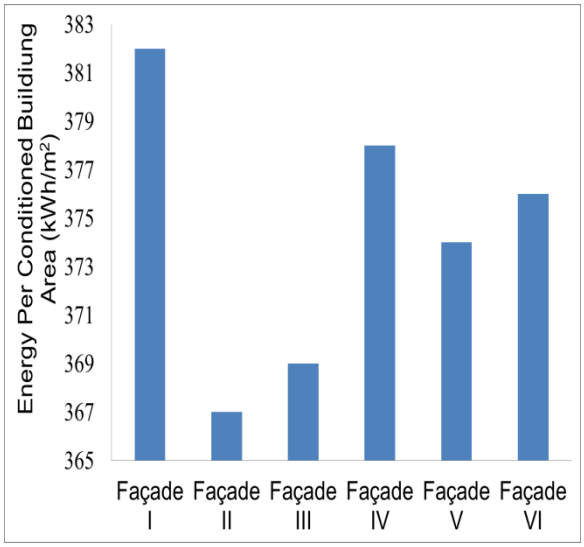

Fig. 7: Energy per conditioned building area

From the Table 2, it is clear that the Façade-I has highest value of thermal wall conductance (U) and hence solar energy transfer rate is maximum or in other words the thermal resistance is lowest among the discussed cases. While Façade-II has the lowest value of U which results in highest thermal resistance and hence the lower energy consumption and cooling load.

It is depicted from Fig. 3 and 4 that by opting Façade-II instead of base case the annual electric energy consumption and cooling load are reduced by 3.92% and 4.80% respectively. Fig. 5 and 6 shows the cost of annual energy consumption and cooling load for different façade configuration. The difference between the annual cost of energy consumption is also significant between the base case (Façade-I) and the best case Façade-II and comes out to be USD 2,439 and USD 2,072 for annual energy and cooling load usage.

6. Final comments and Conclusions

It was confirmed that solar radiation is main source of heat gain in the building. The result shows the importance of façade in preventing solar radiation reaching into the building. Therefore different configuration of facades was developed among the existing economically provided material to minimize the effect. Among them we can cite the use of thermal efficient material with low U factor. The study shows that there is the significant drop of 3.92% and 4.80% in total energy and cooling load consumption respectively by opting the façade-II instead of Façade-I.

Energy conservation and sustainable design in building would make the façade II being the most attractive one among the existing building envelop in Saudi Arabia and should be implemented as it will provide higher rates of comfort accompanied by lower air conditioning energy cost.

Short Summary

The effectiveness of insulation in reducing heat loss depends to an important extent on the quality of its installation. For new buildings, it is advantageous if the performance of insulation can be checked before construction work is complete. This enables problems to be rectified before the building is occupied. The research presented in this paper is investigating how thermal imaging techniques (thermography) can be used during the construction of new domestic buildings to assess construction quality and the energy efficiency of the building fabric. Thermal imaging surveys are usually conducted post-construction and so this approach to testing constitutes a novel area of practice. Further insights into the results of a thermal imaging survey can be gained from computational models of heat transfer through the building envelope. The particular focus of the paper is how these virtual models and thermography can be used in a complementary way to diagnose and assess the severity of insulation defects in construction work. This idea is explored through three case studies, which illustrate some practical considerations for the application of thermography during the construction process. The research topic will be of interest to built environment professionals, thermographers and researchers interested in methods of investigating the thermal performance of new housing.

Keywords: infrared thermography; construction quality; workmanship defects; low carbon housing; building fabric performance; residential buildings; energy efficiency; thermal bridges

1. Introduction

Thermal imaging (thermography) is held to be “the most powerful technique for determining position and to some extent magnitude of thermal bridges in existing buildings” [1]. In this research project, a testing approach is being developed for conducting thermographic inspections at different stages during the construction of new domestic buildings [2]. The purpose of these inspections is to investigate the quality of workmanship and energy efficiency of low carbon homes as they are being built, and thus increase confidence that design targets for thermal performance will be achieved in practice. This type of testing is motivated by evidence of a “performance gap” in UK housing construction between the energy performance predicted at the design stage and that achieved in completed buildings [3]. Identifying problems at an early stage of construction could help to close this gap, and enables remedial work to be completed before the building is occupied (post occupancy remedies are often much more disruptive and expensive). This could bring significant energy and carbon savings, since heat loss from thermal bridges can be responsible for a large proportion of total fabric heat loss. For example, modelling undertaken by Comiskey [4] found that thermal bridging from poorly designed junctions could account for 31% of the total fabric heat loss in a dwelling. Furthermore, the performance of an energy efficient design detail can still

be compromised by poor execution on site.

If an anomaly is identified in the building fabric using thermography then two questions arise: the cause of the defect and its severity. Two-dimensional (2D) and three-dimensional (3D) heat transfer models can be used to help gain insight into both of these problems. In the paper, three case studies considering the complementary use of heat transfer modelling and thermal imaging are discussed:

- An example of a defect in masonry cavity wall construction (Case Study A);
- A thermography survey of an eaves junction in a timber frame building during the construction process (Case Study B); and
- Tests on a full-scale model of an external wall with deliberate defects (Case Study C).

Together, these case studies explore some practical considerations for the application of thermography during the construction process, including:

- Testing procedures to establish suitable environmental conditions for thermography;
- Assessing the severity of thermal bridges in terms of the effect on building energy performance and also risk of condensation and mould growth; and
- Limitations to the types of defect that can be identified using thermography.

The THERM [5] and HEAT3 [6] software is used for the diagnosis and evaluation of defects in the paper for 2D and 3D modelling respectively. 2D models are generally quicker to define (the geometry) and run and are suitable for assessing linear thermal bridges. However, more complicated geometries may require the use of 3D models, which also have the advantage of being able to generate projections of the temperature field over a surface so that variations in temperature across a structure can be more clearly visualised.

2. Case Study A

2.1 Introduction

An overview of common construction problems observed in UK housing is reported in [7]. An example given is the case of rigid insulation boards in partial-fill masonry cavity construction being cut short of the cavity closer around an opening. This type of defect was documented in a research project carried out by Leeds Metropolitan University which surveyed a number of construction sites in England during 2004 [8]. The problem was observed in 5 out of the 12 sites that used masonry cavity construction, and in one case a 50mm gap was observed between the rigid insulation fitted to the inner leaf and the cavity closer. For this case study, the THERM software has been used to calculate the surface temperatures in the proximity of this type of defect (for a specfic wall construction and under assumed steady-state heat transfer conditions). The additional heat loss resulting from this linear thermal bridge (psi-value) is also calculated using the software.

2.2 Model Description

Three separate models were constructed in THERM:

- A plan section through a partial-fill masonry cavity wall construction (Model A.1)
- A window jamb section, including a cavity closer and window frame (Model A.2)
- A window jamb section as Model A.2, but with a 50mm gap between the cavity insulation and cavity closer (Model A.3)

Model A.1 was used to calculate the modelling U-value of the wall (U'_w). Note this is not a conventional U-value (since it excludes the effect of mortar joints and wall ties on the actual thermal transmittance of the wall) but is used as reference data in Model A.2 and Model A.3 to calculate the installation psi-value for the interface of the window and wall. The external wall construction used in all models is described in Table 1 and Fig. 1.

Table 1: Specification of materials used in THERM model of masonry cavity external wall

Component	Description	Thickness (mm)	Thermal conductivity (W/m.K)	Reference
1	Plasterboard	12.5	0.21	[9]
2	Plaster dabs	15	0.43	[9]
3	15mm airspace	15	0.088	[9]
4	Lightweight blockwork	100	0.11	Manufacturer data
5	PIR insulation	50	0.022	Manufacturer data
6	Unventilated air cavity	50	0.273	[9]
7	Brickwork	103	0.77	[9]

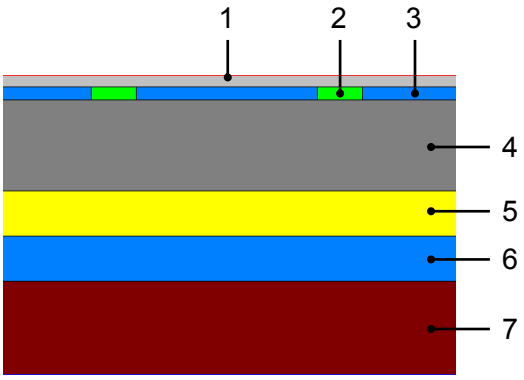

Fig. 1 Masonry cavity wall construction used in THERM model for Case Study A (Model A.1)

Model A.2 and Model A.3 include a 100mm wide cavity closer with the same thermal conductivity as the cavity insulation (based upon manufacturer data) and a window frame. Data for the window frame is based upon THERM modelling reported in [10]. For the purpose of the present work, the modelling of the window frame is simplified by using an equivalent rectangle with the same width and thickness as the actual window frame and with the same heat flow. The two models and boundary conditions used in the THERM model are described in Table 2 and Fig. 2.

Table 2: Components included in non-defective and defective window jamb model

Component	Description	Notes
1	Internal boundary condition (20°C)	Surface resistance = 0.13 m^2K/W
2	External boundary condition (0°C)	Surface resistance = 0.04 m^2K/W
3	Continuous line of dabs at reveal	
4	Cavity closer	Thermal conductivity = 0.022 W/m.K
5	Window frame	Based on Rationel Aldus window frame [10] U_f = 1.162 W/m^2K, frame dimensions: 57mm wide and 115mm thick (in the direction of heat flow), thermal conductivity = 0.1665 W/m.K
6	50mm gap in insulation	Thermal conductivity = 0.405 W/m.K

2.3 Results

The thermal transmittance of the external wall (Model A.1) calculated using THERM is U'_w = 0.259 W/m^2K. The different pattern of heat flow through the non-defective (Model A.2) and defective (Model A.3) wall-window junction is shown in Fig. 3. As would be expected, higher levels of heat flow occur through the break in the insulation layer adjacent to the cavity closer in the defective junction. The temperature profile across the wall-window junction for Model A.2 and Model A.3 (represented by colour isotherms) is shown in Fig. 4. The psi-value for the non-defective wall-window junction calculated using THERM is $\psi_{A.2}$ = 0.013 W/mK and for the defective junction $\psi_{A.3}$ = 0.061 W/mK. This means that the heat loss along the defective junction is almost five times that of

the non-defective junction. Neither of the two junctions would be assessed as being at risk of surface condensation and mould growth according to the calculation procedure defined in [11]. Note that psi-value calculations were performed using a spreadsheet developed by WARM: Low Energy Building Practice [12].

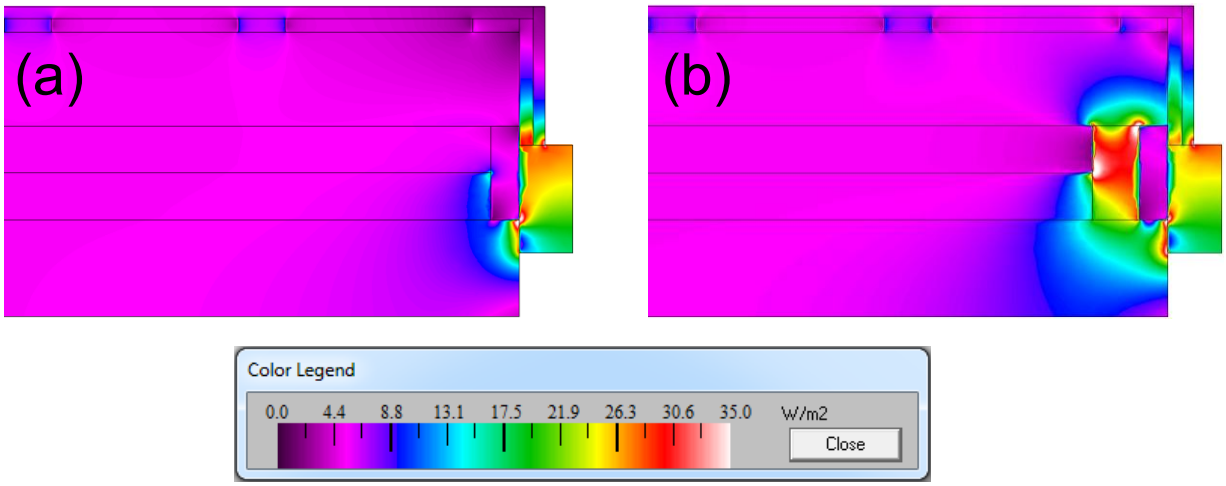

Fig. 3 Heat flux diagram for (a) non-defective and (b) defective junction

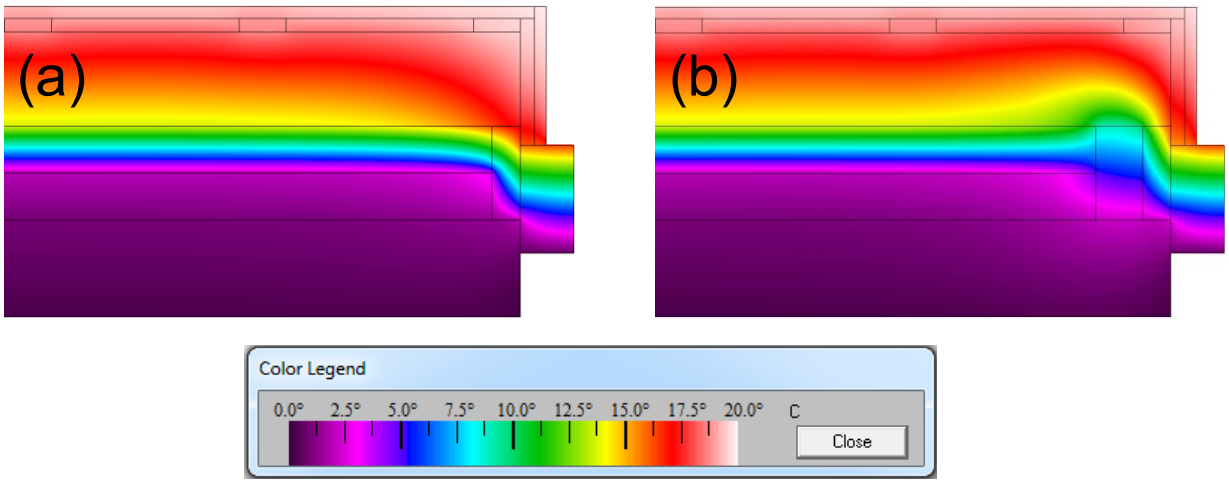

Fig. 4 Temperature profile for (a) non-defective and (b) defective junction

2.4 Discussion

The THERM software has been used to calculate the additional heat loss associated with partial-fill cavity insulation being cut short 50mm from the cavity closer at a window opening (for the particular external wall and window jamb detail modelled above). However, the temperature profile across the junction shown in Fig. 4 suggests that it may not be possible to establish the presence of this defect by a retrospective thermal imaging survey. Although the insulation gap results in a clear discontinuity in the isotherms across the wall, this occurs in the middle of the construction and the effect is diffused through surrounding material. Comparing the non-defective and defective junctions, there is no obvious disruption to the isotherms at the inner or outer surface in Fig. 4(b) that could be clearly related to the presence of a defect below. Although this conclusion is derived from the results of a simplified heat transfer model, it does reinforce a useful caveat to the use of thermography: that the ability to detect a defect depends upon its effect on surface temperatures. In general, this means that the continuity of insulation within a building can be assessed more effectively with thermography when there is less intervening structure between the insulation layer and the internal or external surfaces. This has further implications for the best time to carry out a thermal imaging survey with respect to the sequencing of construction. Modelling may provide a useful predictor of the best stage in the construction sequence at which to survey.

3. Case Study B

3.1 Introduction

In this case study, thermal images obtained from a building survey are compared with THERM modelling data. The case study building comprises a row of terraced houses divided into 12 flats constructed in timber frame. A thermal imaging survey identified lower surface temperatures at the junction between wall and ceiling in the bedroom of one flat, indicating higher levels of heat loss at the eaves. The THERM software is used to predict surface temperatures for the eaves detail as designed and also for poor installation of the loft insulation. Considered together, the thermographic and modelling data provide complementary insights into the performance of the detail.

3.2 Thermography Results

A thermal imaging survey of the building was conducted in April 2013 during the construction phase. Following consultation with the site manager, the main bedroom in the flat at the most advanced stage of completion was selected for testing. The interior finish of the flat had progressed to the stage that the plasterboard had received a skim finish and a base coat of paint. Fig. 5 shows a photograph of the bedroom and a plan layout.

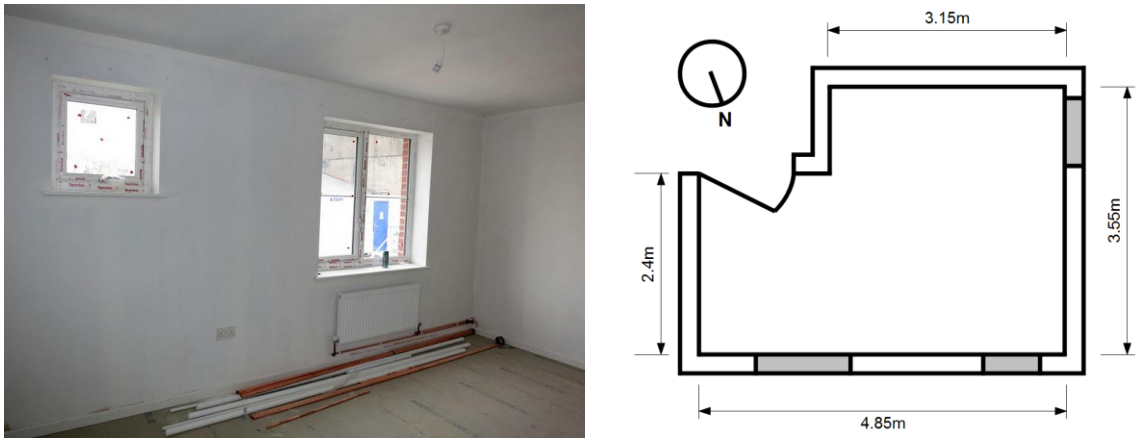

Fig. 5 Photo of north-facing windows and plan layout of test bedroom

A difference of 10°C between internal and external temperatures is often recommended as a “rule

of thumb" for identifying insulation defects using thermography [13]. Establishing these conditions on a construction site can be problematic, particularly since the building heating systems are unlikely to be operational until the building is close to completion. At an intermediate stage of construction, electrical fan heaters can be used to achieve a stable pattern of heat flow through the building envelope (provided that the part of the building under test can be made reasonably airtight). On the morning of the test a 1.5kW electrical fan heater was installed in the bedroom (using a 110V electrical supply compatible with use on a construction site). After a heating period of 4 hours, the air temperature in the bedroom had increased by 9°C resulting in a difference between internal and external air temperatures of 10°C (satisfying the "rule of thumb" criteria). Lower surface temperatures were observed at the junction between the wall and ceiling of the north elevation as shown in Fig. 6.

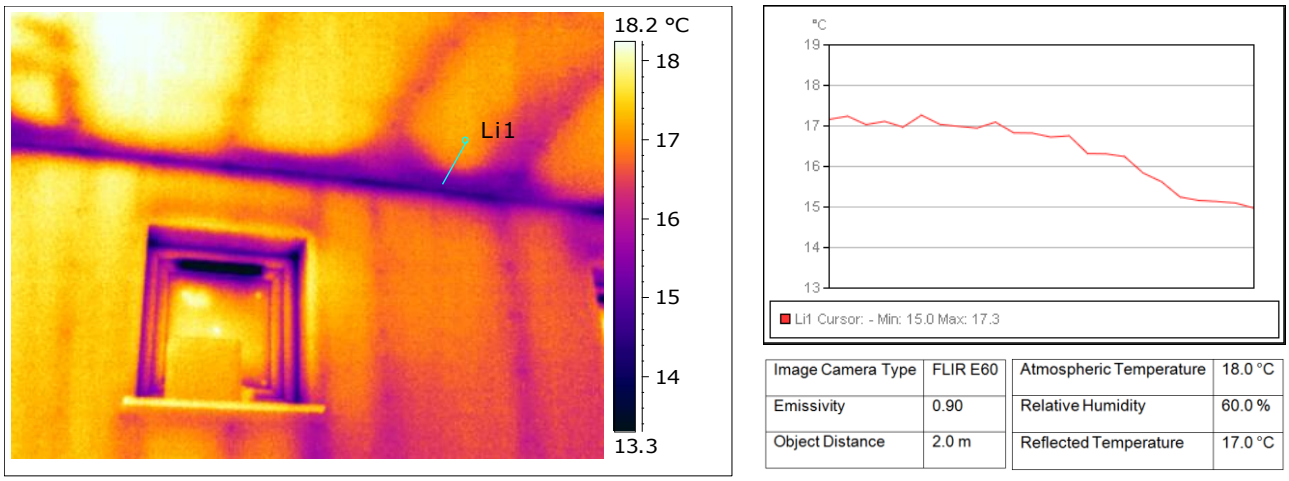

Fig. 6 Thermal image of junction between wall and ceiling at Case Study B

The minimum internal surface temperature (T_{si}) is 15°C. To assess the severity of this defect, the temperature factor (F_{Rsi}) is calculated as follows [11]:

$$F_{Rsi} = \frac{T_{si} - T_e}{T_i - T_e} \quad (1)$$

Where T_i = internal temperature and T_e = external temperature. For this location, F_{Rsi} = 0.7 which is less than the critical temperature factor (F_{CRsi} = 0.75) recommended for dwellings and would therefore be considered at risk of surface condensation and mould growth. Possible causes of lower surface temperatures at this location include: insulation not lapped over top of timber frame wall; insulation not rolled up to eaves; and wind penetration over the brick outer leaf resulting in a thermal bypass [14] over the top of the timber frame wall.

3.3 THERM Modelling Results

To further investigate the issues observed in the thermal imaging survey, two models of the eaves detail were constructed in THERM:

- The "as-designed" detail with insulation installed correctly lapped over the top of the timber frame wall and up to the eaves ventilator (Model B.1)
- A "poor installation" detail with insulation missing above the top of the timber frame wall and not pushed up to the eaves ventilator, and with also higher convective heat loss from the exposed surfaces to approximate the effect of wind penetration (Model B.2)

Drawings of these two models are shown in Fig. 7 and the temperature profiles calculated using the THERM model are shown in Fig. 8. Note the presence of additional timber is included in Fig. 7.b (a ceiling joist and purlin based on site observations) to illustrate where the insulation might stop if poorly installed.

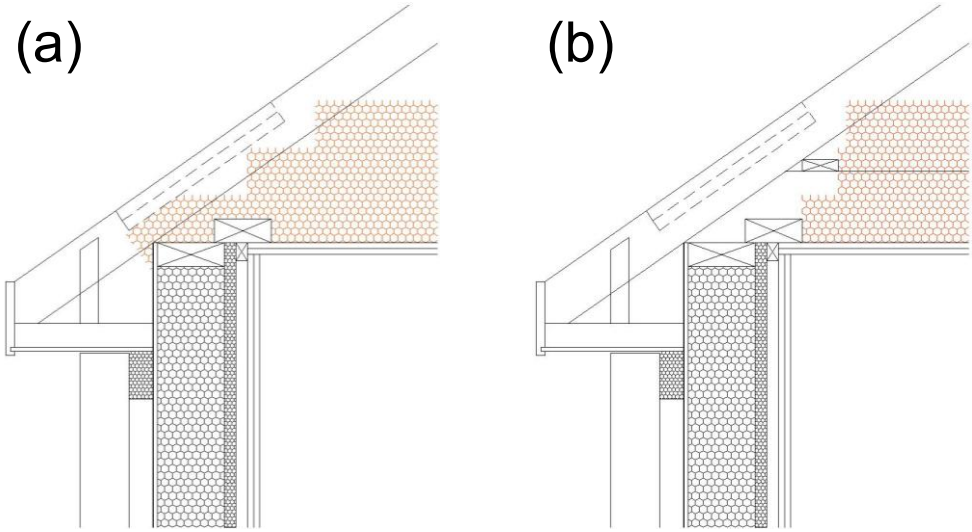

Fig. 7 Eaves detail (a) as-designed and (b) with poor installation of loft insulation

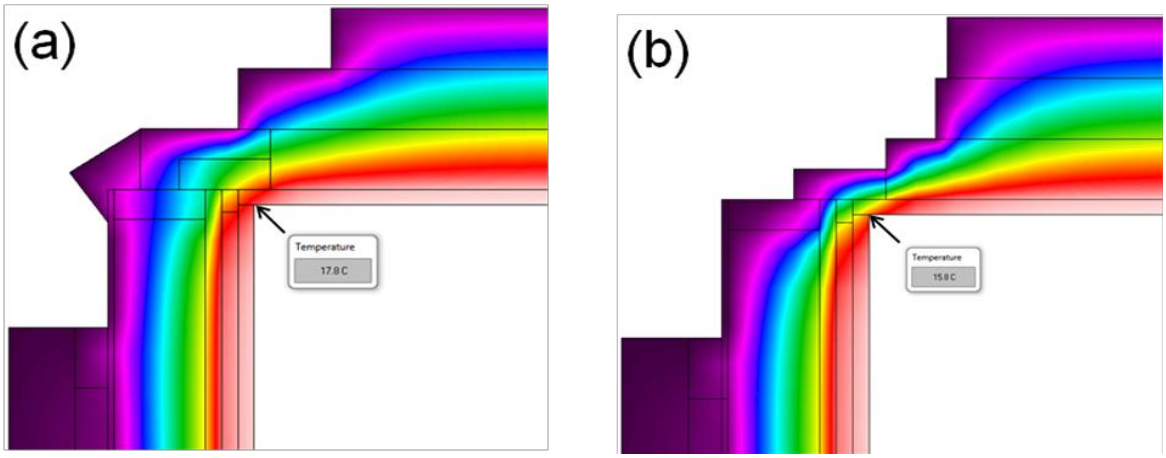

Fig. 8 Temperature profile (a) as-designed and (b) with poor installation of loft insulation

The temperature factor for the as-designed detail (Model B.1) is $F_{Rsi_B.1}$ = 0.89 and for the poor installation detail (Model B.2) is $F_{Rsi_B.2}$ = 0.79. Neither detail would thus be considered at risk of surface condensation and mould growth.

3.4 Discussion

The thermal imaging survey at Case Study B indicated a problem with the loft insulation and possibly also wind penetration at the eaves. This was communicated to the site manager and is to be subject to further investigation. The results of the THERM modelling for the poor installation case (Model B.2) indicates the effect of poorly placed insulation on the surface temperatures at the junction and, to this extent, is consistent with the thermal image data. As a general observation, the comparison between the thermography and THERM modelling is revealing of how the assumptions underlying design calculations of thermal performance (with insulation placed in perfect contact with the surrounding structure) may bear little relationship to the as-built reality encountered on site. This disparity may go some way towards explaining the difference between the modelling results and thermography. An additional advantage of modelling the eaves detail in THERM was that it was possible to calculate the as-designed psi-value for the junction, $\psi_{B.1}$ = 0.077 W/mK. The default psi-value for an “Accredited Construction Detail” [7] at the eaves (with insulation at ceiling

level) is 0.06 W/mK [15]. This suggests the design of the eaves detail could be improved.

4. Case Study C

4.1 Introduction

The previous case study introduced the requirement for a stable pattern of heat flow through the building envelope to obtain reliable results with thermography. Maintaining a sufficient difference between internal and external temperatures can be harder to achieve in buildings at an early stage of construction (e.g. before windows or doors are installed). A solution for early-stage tests being developed in this research project involves the use of electrical radiant heaters to target heat at an area of the building envelope. Since this heating method does not rely on raising the air temperature, suitable conditions for thermography can be established in buildings that are not fully sealed. To investigate the efficacy of the approach, a full-scale physical model of an external wall (referred to here as the *test panel*) has been used to investigate the type of defects that can be identified in timber-frame structures. The results of model testing are compared with predicted surface temperatures calculated using HEAT3.

4.2 Test Panel Results

The design of the test panel comprises 4 layers of construction: a 12.5mm thick plasterboard layer on the “inside” face; a polythene vapour control layer fixed to a 140mm by 38mm timber stud framework filled with mineral wool insulation; and a 9mm OSB “outside” sheathing layer. It aims to represent a section of a timber-frame external wall 2.4m wide (i.e. 5 studs across the width at 600mm centres) prior to the construction of the outer cladding. In preliminary tests a 110V 1.5kW electrical radiant heater has been positioned 3m from the panel. Fig. 9 shows an image of the constructed panel and a plan section.

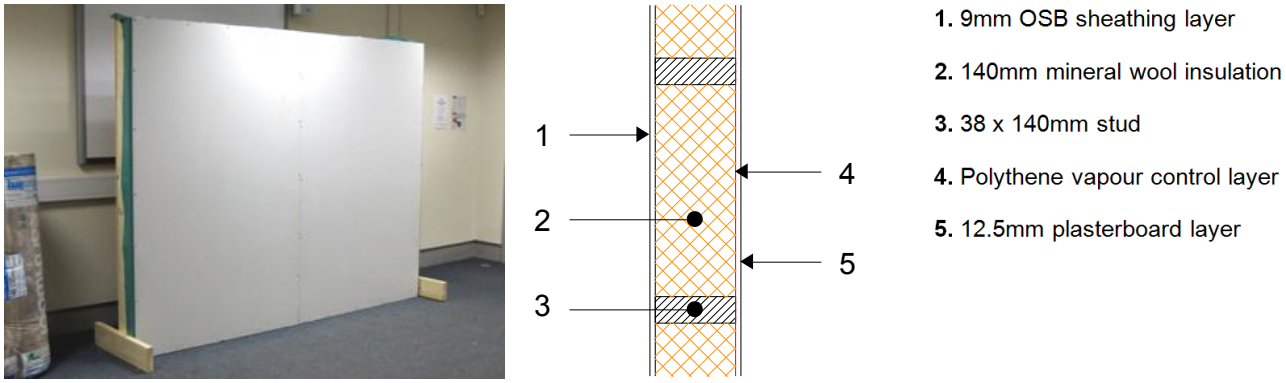

Fig. 9 Test panel design

Preliminary testing has investigated a range of possible workmanship errors in the installation of insulation. This paper considers two specific defect configurations: the replacement of one section of insulation with a section of different thermal performance; and the removal of one section of insulation (i.e. leaving an air void between the studs). The results after 1 hour of heating are shown in Fig. 10.

The difference in surface temperatures between the section of wall missing insulation and the rest of the panel is clearly visible. However, the section with different thermal conductivity is not distinguishable from the adjacent areas of the panel. Note that the two horizontal bands that are warmer in the images are caused by the design of the heater reflector (an uneven heat output).

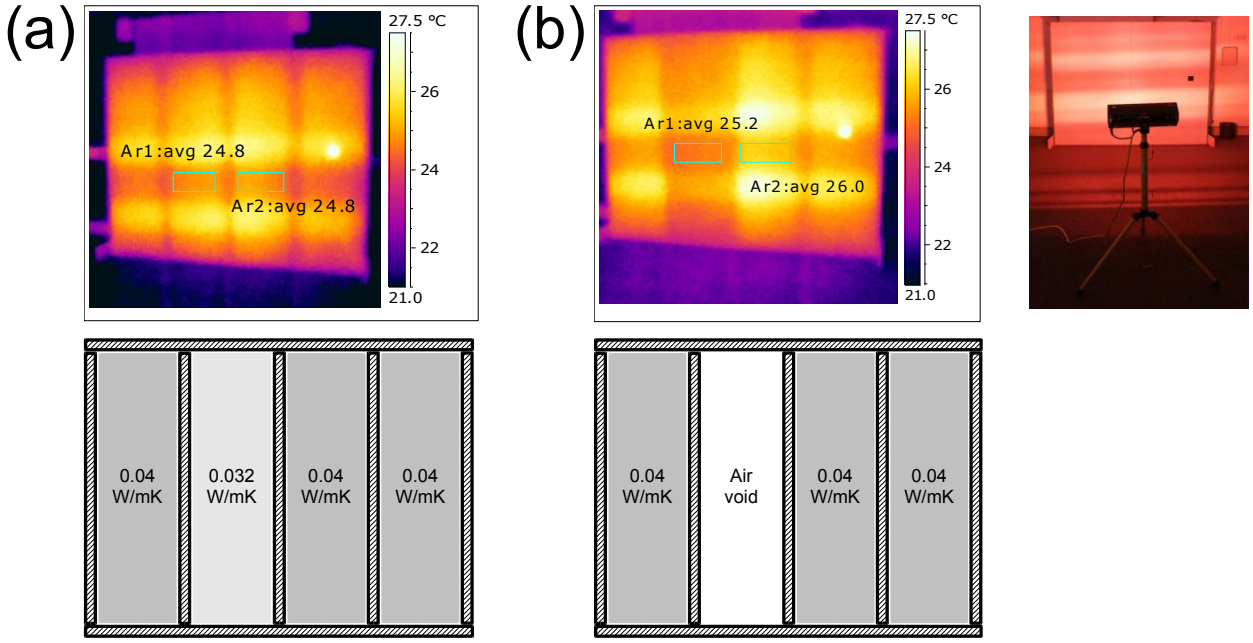

Fig. 10 (a) Section of insulation with different thermal conductivity (b) Section missing insulation

4.3 HEAT3 Modelling Results

For comparison with the results of physical testing, a virtual model of the test panel was created using the HEAT3 software. The use of a 3D model enables a 2D projection of surface temperatures to be generated for the “inside” face. The results for the two defect configurations introduced in the previous section are shown in Fig. 11. This shows the predicted surface temperature distribution under steady-state conditions for constant temperature boundary conditions (inside = 1°C, outside = 0°C). Annex B of ISO 6946:2007 [16] was used to calculate the thermal resistance of the airspace for the missing insulation panel (0.197 m^2K/W).

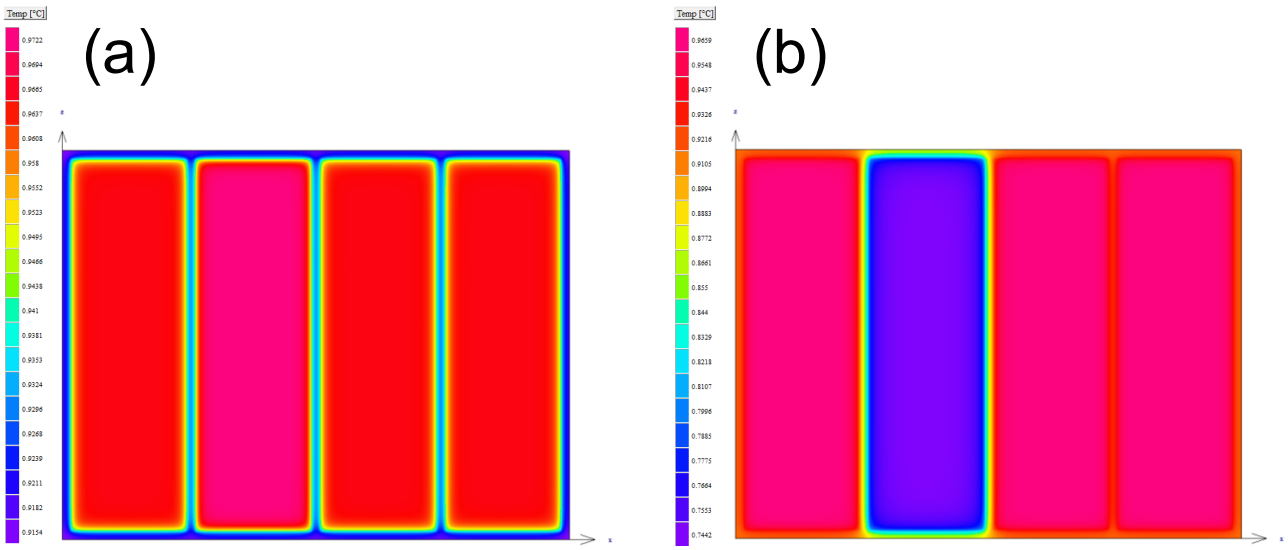

Fig. 11 Surface temperature plots for (a) different thermal conductivity and (b) missing insulation

For the different thermal conductivity case, the difference in surface temperatures between the two standards of insulation is 0.0063°C (for a 1°C difference between boundary temperatures). Whereas the difference between the surface temperature of the area of missing insulation and the insulated area is 0.222°C (or a temperature factor of 0.74 for the missing insulation).

4.4 Discussion

Although the steady-state modelling undertaken in HEAT3 is not directly comparable with the thermal images obtained from model tests, together they support the following two conclusions:

- The use of insulation materials with different thermal conductivity within a wall (i.e. substitution of the specified product by an inferior one) is likely to be difficult to detect using a thermal camera.
- The presence of air voids within a timber frame structure can be determined relatively easily and quickly using a thermal camera and radiant heater.

Thus, the preliminary tests using the radiant heating approach indicate that it can provide useful insights into the quality of installation of insulation in timber-frame construction. Specifically, the approach can identify the presence of air voids within the insulation layer. This could occur if insulation is disturbed by a follow-on trade (e.g. an electrician wiring a power socket) or the insulation is cut short or sags. In addition, it enables the presence of timber to be identified (e.g. studs, noggings etc.).

5. Conclusions

The three case studies presented in the paper provide examples of how thermal imaging and heat transfer modelling software can be used in a complementary way to investigate the thermal performance of buildings. Thermography can be used to obtain feedback from real buildings and improvements in design can be supported by computer modelling, with the lessons from both potentially carried forward to future projects. Some specific ideas explored in the three case studies are summarised below:

- Thermography is a powerful tool for assessing the continuity of insulation in buildings, but there are limitations to the technique related to both the environmental conditions in which a thermal imaging survey is undertaken and the impact of discontinuities in the insulation layer on surface temperatures. The latter point is perhaps not sufficiently acknowledged within existing literature, since it places limitations on the ability to detect certain types of insulation defect.
- The impact of poor design or workmanship on building energy performance can be quantified (e.g. a psi-value for linear thermal bridges) using computational methods provided some basic information about the problem is known. This is a useful complement to thermography, which is primarily a qualitative diagnostic tool.
- Design calculations typically assume perfect placement of insulation to the adjacent structure. This may be an unrealistic assumption, particularly for details that are awkward to build, and may result in actual performance being considerably less than predicted (as may be revealed by thermal imaging).
- 3D heat transfer models can be used to generate 2D projections of surface temperatures. This enables a direct comparison to be made with thermal images, with the potential for a building to be “calibrated” against this expected thermal pattern.

Water and Energy recycling in a Residential Passive House

Dipl.-Ing. Erwin Nolde
Managing Director
Nolde and Partner Innovative Water Concepts
D-10405 Berlin, Germany
Email: Erwin.Nolde@t-online.de

Summary

Before producing new energy, whether fossil or renewable, or pumping freshwater from groundwater resources, one should look first on how to avoid energy and water consumption and how to optimise the total resource efficiency for both the energy as well as the water sector.

Greywater recycling is one effective tool to improve the efficiency of water use in buildings. Advanced greywater systems have been developed and tested which produce high quality non-potable water (service water) for indoor (toilet flushing, laundry) and outdoor use (gardening, cleaning).

In this paper the treatment of greywater from showers and bathtubs in combination with heat recovery from greywater is presented. Greywater undergoes an advanced mechanical-biological treatment and a final UV disinfection without the use of chemicals, at the same time the heat recovered from greywater is used to pre-heat the drinking water for the building's combined heat and power plant (CHP).

Well planned greywater recycling systems can contribute considerably to water and energy savings in buildings and should therefore be marketed in future urban context as sustainable, environmentally friendly and safe technologies.

Keywords
Greywater recycling, water and energy efficiency, heat recovery, passive house, non-potable water, service water.

Introduction

Water and energy are very much closely linked as water is often needed to generate energy, and vice versa. In order to produce 1 kWh of electrical energy from fossil or nuclear fuel, about 2.7 – 3.2 litres of water will be needed for cooling.

On the other hand, the water supply and wastewater disposal sectors are the largest municipal energy consumers. A city like Berlin with 3.5 million inhabitants and modern conventional water technologies requires for its water sector as much electrical energy as the household electrical energy demand for a city with 280,000 inhabitants [1].

Low-energy houses and passive buildings are milestones when it comes down to reducing the heating demand in a building. What remains ignored is that most of the energy released today into the environment is through wastewater rather than through the building's facade.

In contrast to material recycling of household wastes, which had been reinvented 30 years ago und put into praxis, the value of wastewater had been also long recognised but its realisation compared to waste management lags more than 30 years behind.

Although the first large greywater recycling plant for a 400 bed, four-star hotel is successfully in operation since 1996 [2], many investors and home engineering planners have not yet realised that today water costs in many buildings are significantly higher than the costs for space heating or electrical power and that there exists in buildings a high saving potential, not only for water but also for energy.

Therefore, wastewater should be regarded as a resource and segregating wastewater into its different streams, e.g. blackwater and greywater, can contribute towards a holistic water management strategy. Greywater is the wastewater sourced from bathtubs, showers, washbasins, kitchen and laundry. Greywater is different from blackwater in its composition, and constitutes the largest proportion of wastewater by volume produced in an average household.

Although early efforts to recover heat energy from greywater largely failed mainly due to high maintenance expenditure, low energy yield, low energy prices as well as the lack of legal requirements, there are very promising approaches today that are able to considerably improve sustainable energy and water efficiency in buildings through decentralised systems.

1. Greywater recycling

Greywater is generally classified as low load and high load. Low load greywater usually originates from showers, bathtubs and sometimes hand washbasins, while high load greywater also includes greywater from kitchens and washing machines. Figure 1 shows the average partial water flows in private households in Germany. With greywater recycling, the total drinking water demand can be easily reduced to 45 l/p/d [3].

Greywater recycling in buildings is a sustainable water management approach offering several benefits including economical, environmental and social. Once appropriately treated, greywater is considered suitable for non-potable uses such as toilet flushing, irrigation, laundry and cooling.
In general, greywater recycling systems should fulfil four criteria: hygienic safety, no loss of comfort to the users, environmental tolerance and economic feasibility [4]. The choice of a greywater management strategy is highly dependent on the end use of the effluent produced and should therefore be adapted to a specific application such as for outdoor agricultural reuse (gardening, irrigation), indoor reuse (toilet flushing, laundry) or for safe discharge into surface waters.

In an urban context, the potential for greywater recycling is mainly new-build residential developments, where dual piping can be included during the construction phase. However, greywater recycling is also feasible for already existing buildings within the scope of rehabilitation measures.

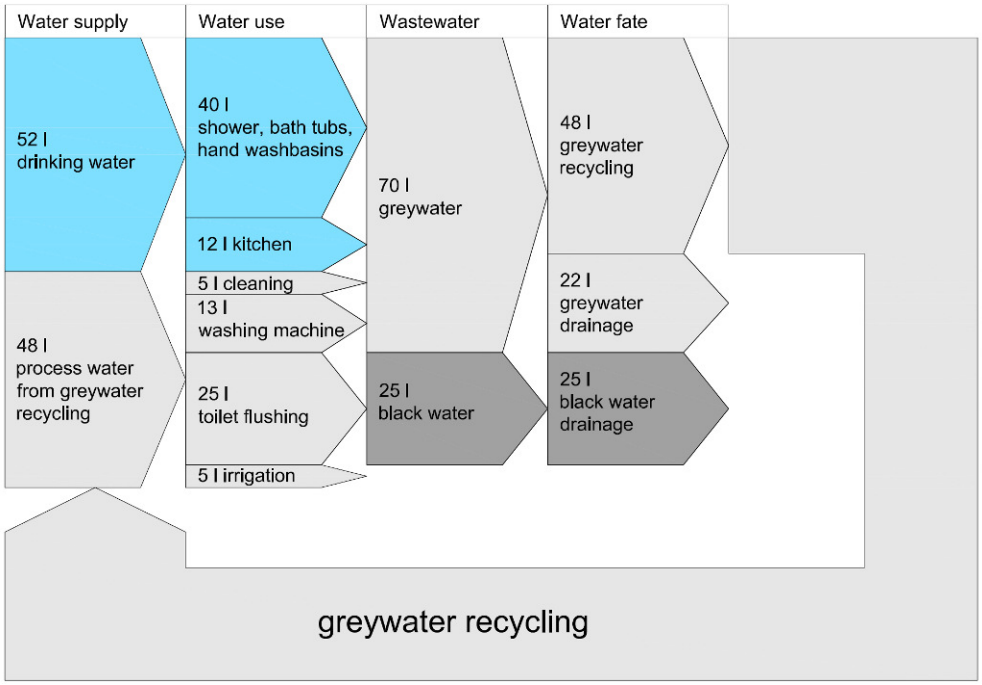

Figure 1: Average partial water flows (litres per inhabitant and day) for private households in new and rehabilitated buildings [Mehlhart, 2001].

Since fresh greywater exhibits relatively high temperatures, the feasibility of energy recovery from greywater is also high, as can be demonstrated in this project. Such an integrated approach would also considerably increase the efficiency of the entire system.

Taking as an example the passive house at Arnimplatz it has been shown that during the winter months heat recovery by means of very low-maintenance heat exchangers can achieve a coefficient of performance (COP) of ≥ 10, producing at the same time high-quality service water (non-potable water). Service water can be used in the building for applications which do not mandatorily require a drinking water quality, whereby further savings can be achieved.

2. Project Arnimplatz

Greywater recycling and heat recovery from greywater can be viewed as an ideal system combination to increase the total efficiency of the system. Fresh greywater has relatively high temperatures (up to 35°C) and therefore a potential for heat recovery already exists in the system.

A greywater recycling plant combined with heat recovery was launched in March 2012 in a multi-storey passive house in Berlin, Germany. For a standard passive house, which has a heat demand for space heating of <15 kWh/m^2/a, about 1.5-fold more energy is needed for hot water generation than for space heating. A total of 41 flats with 123 tenants occupying an area of 4,600 m² and 4 commercial units (600 m²) are connected to the greywater/heat recovery system. About 3,000 litres of low load greywater from showers and bathtubs are treated daily to produce high quality service water which is reused for toilet flushing.

The greywater system including heat recovery is placed in the cellar where the building's heating system is also found, occupying an area of 9 m^2 (ca. 0.1 m^2 per person) (Photo 1).

Photo 1: Greywater recycling combined with heat recovery in a multi-storey passive house in Berlin, Germany (Photos: E. Nolde).

The filtered greywater from showers and bathtubs enters the heat exchanger, where heat is withdrawn by means of a 20-watt circulating pump (Figure 2).

A self-cleaning sieve provides for a very low-maintenance operation of the heat exchanger and the greywater recycling system.

The cooled greywater exiting the heat exchanger enters two aerated buffer tanks acting as a biological pre-treatment stage. Subsequently greywater enters a secondary treatment stage (also a moving bed biofilm reactor (MBBR)) with an integrated particulate removal setup, before it finally passes a UV disinfection unit to enter the service water tank.

The biologically treated greywater (BOD_7 < 3 mg/l; turbidity < 1-2 NTU) is then fed into the service water network by means of a booster pump to serve as non-potable water for toilet flushing. The total electrical demand for heat recovery, greywater treatment and service water distribution is less than 1.5 kWh/m³. Treatment is achieved without the addition of chemicals and at very low maintenance.

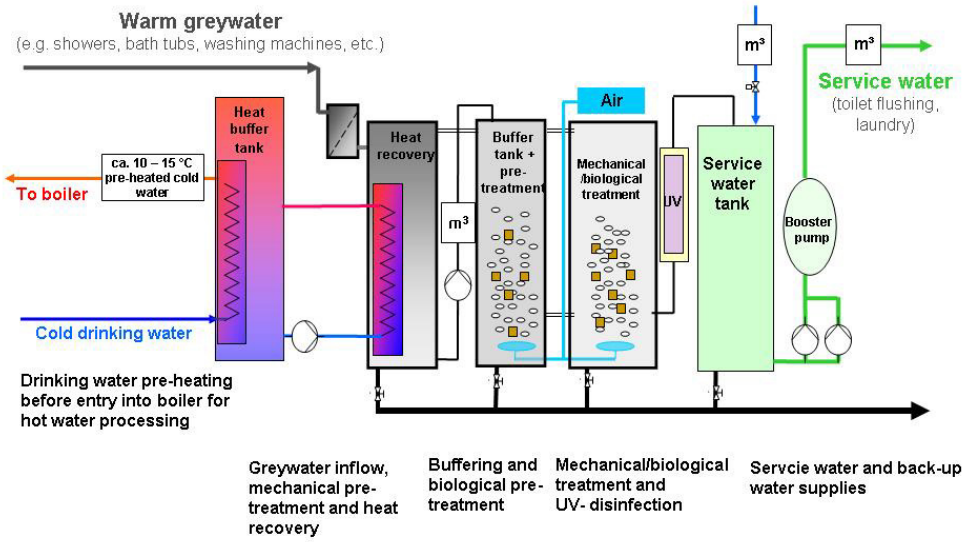

Figure 2: A schematic diagram of the greywater recycling system coupled to heat recovery in a passive residential house in Berlin, Germany.

3. Results and discussion

One essential technical aspect is that the generated greywater is not cooled down strongly before entering the recycling system. For this reason, the use of modern plastic pipes which also possess a good noise insulation is advantageous over conventional cast iron pipes. Even in winter, the mean temperatures of the influent greywater did not drop below 30 °C.

During winter when drinking water temperatures are relatively low (ca. 8.5 °C), it was possible to withdraw over 15 KWh of thermal energy per cubic metre of greywater with the combined system without the use of a heat pump. This energy was used to pre-heat the cold drinking water before it entered the decentralised combined heat and power plant (CHP) to be heated to 60 °C end temperature. During the first summer of operation when higher drinking water temperatures were measured, the recovery potential was only about 10 kWh/m³.

A monitoring study also showed an optimisation potential that would increase the future heat recovery performance of the system.

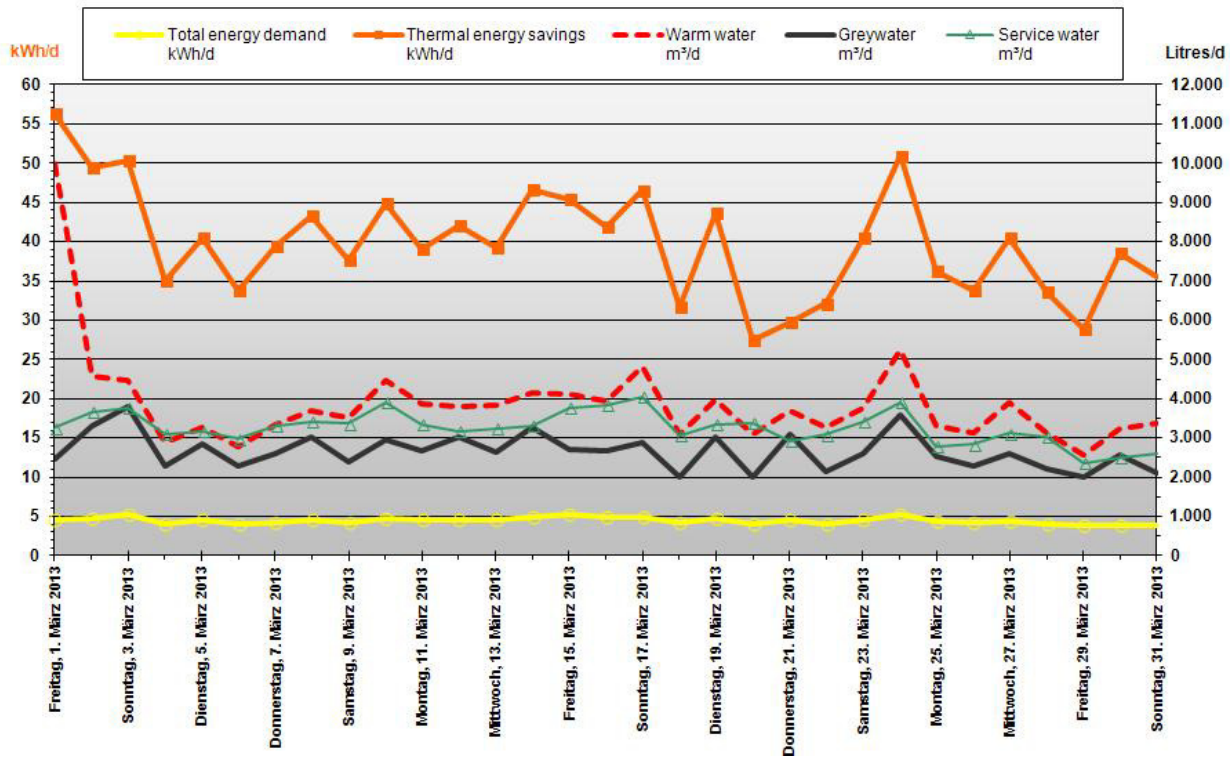

Figure 3: Monitoring results of the water and energy input and output during March 2013 in the greywater recycling plant at Arnimplatz.

Figure 3 shows that dependent on the amount of inflow greywater and freshwater demand more than 40 kWh/d of thermal energy can be often recovered from the system (orange line), compared to the electric energy demand for the entire system which lies constantly around 4 kWh/d (yellow line). Comparing the primary energy gains, this decentralised approach achieves a relatively higher degree of efficiency than centralised systems, where only about 1.5 °C can be withdrawn from municipal wastewater using heat pumps.

The results also show that the amount of greywater (black line), originating in this case only from showers and bathtubs, is not sufficient to cover the demand for toilet flushing (green line). It is therefore recommended to utilise additional greywater sources in buildings, for example, from handwash basins and laundry and even the high load greywater from kitchens (including fats and solids) to increase the availability of greywater and in turn the system's efficiency

Figure 4 shows the measurable benefits of greywater recycling coupled to heat recovery exemplified by the project "Arnimplatz". It is clear from the above results that the benefits of greywater recycling coupled to heat recovery are multiplied exerting eventually a significant positive impact on the greenhouse emissions.

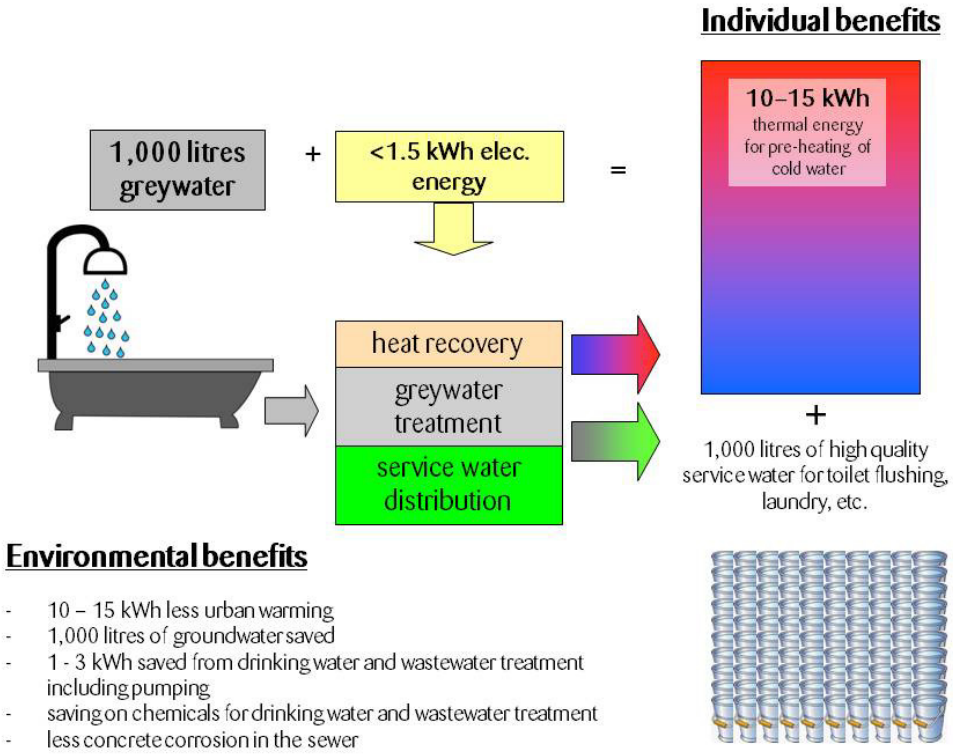

Figure 4: Individual and environmental benefits of greywater recycling combined with heat recovery based on an inflow of 1,000 Litres of raw greywater.

4. Conclusions and recommendations

Greywater recycling and heat recovery from greywater can be viewed as an ideal system combination to increase the total efficiency of the system. Fresh greywater has relatively high temperatures (up to 35°C) and therefore a potential for heat recovery already exists in the system.

Compared to outdoor installation, compact indoor installation systems using the warm heating room has several advantages since no additional insulation of all pipes and the recycling system is necessary and the plant is also more easy to maintain. An advanced monitoring system with access to the internet is very helpful to optimise the system and save operation and maintenance costs.

The additional costs for greywater recycling schemes of 10 €/m² of floor space (excluding second pipe system), compared to the real estate costs (3,500 - 4,000 €/m²), are very low (< 0.3%) and these costs will further decrease if individual plant design and engineering moves on to industrial and modular production. The inclusion of high load greywater, which can be also successfully recycled as had been already shown in a preceding project [6], should be practised at a larger scale in order to increase the efficiency of the system.

Also the increased use of service water for cooling purposes, such as in adiabatic cooling, would result in significant energy savings; about 630 kWh of cooling capacity can be generated from one cubic metre of water [7].

Especially for the area of Berlin the introduced greywater recycling system in combination with heat recovery saves as much energy which is equivalent to a thermal solar energy system of about 35 m² and even exhibiting best performance during the cold winter months.

The separation of blackwater and greywater in buildings should become a standard. Well planned greywater recycling systems can contribute considerably to water and energy savings in buildings and should therefore be marketed in future urban context as sustainable, environmentally friendly and safe technologies.

Therefore, it is essential to establish mandatory guidelines and standards for water and energy efficient systems especially for new buildings. Certification and rating schemes for buildings (e.g. LEED, BREEAM, DGNB, etc.) are only one step in the right direction.

SB13 Graz – ELIH-Med Full Paper

Dr. Anna Moreno
Head of the
Information and
Training unit at
ENEA
Anna.moreno@enea.it

Short Summary

ELIH-Med is a Strategic Project co-financed under the MED Programme, focused on the development of energy efficiency policies in Low Income Housing (LIH) in the Mediterranean area based on sustainable building principles and the involvement of residents in the energy retrofit in order to reach the EU2020 objectives.

The main objective of the project is to identify and test, through large scale actions, the feasibility of cost efficient innovative technical solutions and financial mechanisms backed with ERDF which could then be extended taking into account the specificities of the region.

The target is the low income houses because:

- Represent 30 to 40% of Mediterranean households.
- Have poor thermal performance.
- Is a key segment in order to reach EU2020 objectives.
- Are not a focus of traditional and current EE policies.
- Residents have limited access to credit.

A participative process has been used to organize two groups constituted of the relevant stakeholders at a local level:

A) The Territorial Management Group (TMG): Local stakeholders representing the key institutions that deal with energy efficiency and LIH. In charge of analyzing the innovative financial and technical options and monitoring the implementation of the energy retrofit in the selected dwellings.

B) The Pilot Project Participative Group (PPCG): Residents affected by the pilot projects, social workers, social landlords, local associations etc. which express the real life needs and problems that are experienced in the selected buildings, helping the TMG to develop and adjust the Action Plan to the reality of the situation.

In order to carry out the large scale experimentation of the technical and financial solutions analyzed, a total of 420 dwellings have been selected and divided into 10 pilot projects across 6 partner territories. Furthermore, the promotion of intelligent energy management systems at local and regional level will be carried out through the experimentation of multi-energy smart meters in 135 dwellings.

The objectives established for the pilot projects include:

a) A cut in energy consumption of 40%.

b) A decrease in energy expenditure of 20%.

c) An increase of 2 energy grades.

d) An investment for energy retrofitting of less than 30.000 euro per dwelling.

e) Development of strategies and policies that address EE and sustainable building approaches in LIH.

f) Identification of financial and technical mechanisms adapted to LIH, to be deployed in the Mediterranean area.

g) Improve energy consumption habits and reduce energy bills thanks to smart metering.

The partners involved in the project belong to 7 different countries while the pilots will be realized in Italy, France, Spain, Greece, Cyprus, Malta. Slovenia also participate to experimentation but only for the smart metering part.

The experimentation will produce several guidelines related to technical and financial solutions as well as the awareness campaign.

The project has also produced a policy paper which is still under development and which foresees joint capitalization activity with other two projects, such as MARIE and PROFORBIOMED, which are other two projects of the MED program related to energy efficiency and Renewable energy production by biomass. The final document will be endorsed by all the political stakeholders at European, National and regional level.

All the guidelines and the policy paper, as well as other useful information can be found in the project web site: www.elih-med.eu

Keywords:
Energy Efficiency; Low Income Housing; Mediterranean; Smart Metering

1. Introduction

ELIH-Med Project (Energy Efficiency in Low Income Housing in the Mediterranean) is one of strategy projects supported by the European Commission under the framework of the Med Program – Objective 2.2. The project runs from April 2011 to the end of 2014, with 18 partners from 7 countries (Italy, France, Spain, Greece, Cyprus, Malta and Slovenia) covering the whole Northern Mediterranean seacoast.

ELIH Med main aim is the selection of innovative technical solution and financial mechanisms as well as the implementation of a large scale experimentation, ELIH Med addresses the problem of energy efficiency in Low Income Housing (LIH) in a Mediterranean context.

Economic, social and environmental urgencies are today, maybe more than ever, strongly interrelated. A broad consensus exists on the necessity of developing new economic models and standards of living based on energy efficiency and the European Union adopted common patterns to achieve the ambitious target of an increase in energy efficiency of 20% up to 2020.

This challenge, common to all the European countries, has a specific resonance in the Mediterranean space, where the economic crisis is stronger than elsewhere in Europe with a greater rate of unemployment. Households, enterprises and also public bodies have little solvability and need to reduce substantially their expenses, including the energy bills.

The second common characteristic is the connection between climatic conditions and an important and ancient existing building stock. Energy efficiency renovation of buildings in the Mediterranean face expensive investments in the context of a lower potential of savings (particularly concerning heating), older building stock and poorer population than in Northern Europe. Moreover, the Mediterranean space faces a specific issue, not taken into account till now: the summer comfort challenge.

In this complex Mediterranean framework, it makes sense to test, at a transnational level, new approaches and tools that may contribute to overcome the main barriers that today prevent from a clear improvement of energy efficiency in buildings. It is one of the topics that have achieved legitimacy as an essential axis of the territorial cooperation, because it requires, more than other topics, a multilevel coordination.

The EU Consultation Paper (Financial support for Energy Efficiency in Buildings, released in February 2012) says, “buildings must be central to the EU energy efficiency policies as nearly the 40% of final energy consumption (and 36% of the greenhouse gas emissions) is in houses, offices and shops”. Now, the increase of the global sustainability of building stock and construction sector will depend on the ability of energy efficiency policies to deal with the diversity of the building stock. Furthermore, the ancient building stock in the Mediterranean is characterized by low renovation rates (2-3 times lower than the average energy refurbishment rate in north-western EU countries; BPIE and FI 2011). To transform this energy saving potential in real energy and economic savings, the ancient building stock has to become a priority topic in policies and strategies, which have to target all the relevant public and private stakeholders.

Nowadays, policies mainly impact public social housing, through specific credit lines, ERDF funds and ambitious objectives of renovation. Nevertheless, the low-income housing sector in the MED space is characterized by the importance of the private housing. Now, private owners are “far to reach” by existing policies: a particular effort has to be made, in awareness and financial formulas, as a priority to adapt policies to low-income owners and create innovative incentives.

Apart from the direct impact foreseen in energy and monetary terms for users, large scale energy refurbishment operations should also create positive economic and social externalities. Several studies and analysis from the European Commission and other European institutions have demonstrated the enormous potential of buildings energy efficiency improvement in the MED space economy. The investment needs per year for EU 27 countries, indeed, are valued at 60 billion Euros and the related job creation is estimated at 800.000. However, actually there are important barriers that impede the development of this captive market. The Mediterranean countries should understand how these barriers can be unblocked according to other countries and sectors’ experiences.

Territorial cooperation is a key option to overcome as quickly as possible the enormous barriers that prevent from developing the energy renovation of buildings in MED space. ELIH-Med has therefore concentrated all the efforts to find solution to remove the barriers and promote a policy paper through Europe.

2. The ELIH-Med project

The ELIH Med project has started in December 2011 and it is considered a strategic project because of the large experimentation foreseen on 450 dwellings in six countries. This experimentation will be used to set up guidelines and policy paper for the next programming period of structural and cohesion funds as well as any other action which could influence the development of strategies useful to increase the energy efficiency of low income housing.

2.1 ELIH Med partnership

Eighteen partners from eight countries participate to the project which is coordinated by ENEA, the Italian National Agency on Energy, New Technologies and Economic Sustainable Development

with the support of the French Mediterranean Institute based in Marseilles. The partnership is therefore constituted by the following partners with specific competences:

2.1.1 Italy

a) ENEA.

b) ISNOVA.

c) Genoa Municipality (Liguria Region).

d) Frattamaggiore Municipality (Campania Region).

The countries involved by the HELIH Med partnership

e) LAORE Sardinia.

2.1.2 France

a) Mediterranean Institute (IM).

b) 13 Habitat.

c) CSTB.

d) Languedoc-Roussillon Region.

e) GERES.

2.1.3 Spain

a) The Malaga City Council, through the Municipal Energy Agency, the Urban Environment Observatory (OMAU) and the Local Housing Institute.

b) Valencia Institute of Building-Foundation (IVE), Comunitat Valenciana.

2.1.4 Greece

a) The Centre for Renewable Energy Sources and Saving (CRES).

b) Democritus University of Thrace (DUTH).

2.1.5 Cyprus

a) The Cyprus Energy Agency (CEA).

2.1.6 Malta

a) Malta Intelligent Energy Management Agency (MIEMA).

2.1.7 Slovenia

a) Jozef Stefan Institute, Energy Efficiency Centre, (JSI/EEC).

2.1.8 Belgium

a) The Conference of Peripheral Maritime Regions (CPMR).

2.2 The main objectives

The main objectives of ELIH Med project are:

A. To identify and demonstrate through a large scale experimentation the feasibility of cost efficient innovative technical solutions and financial mechanisms backed with European Regional Development Fund (ERDF).

B. To promote changes in the inhabitants behaviour to reduce energy waste.

C. To experiment the use of smart monitoring systems to rationalize the use of energy.

D. To develop energy efficiency policies in low income households in the Mediterranean area which could, then, be extended to all Mediterranean territories. The policies start from the territory where the experimentation is made.

2.2.1 The pilots

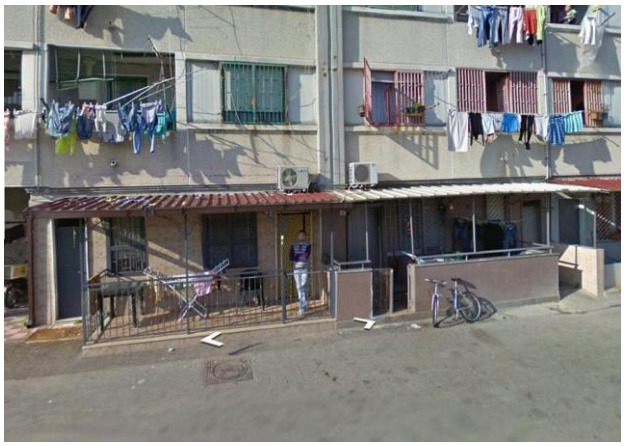
Energy refurbishment of pilot low income households are located in 6 partner countries (Cyprus, France, Greece, Italy, Malta and Spain). The experimentation will bring to the development of concept, approach and policies adapted to low income housing in the Mediterranean area. At the same time the dwellings would achieve the following immediate results:

- A cut in energy consumption of 40%.
- A decrease in energy expenditure of 20%.
- A gain of (at least) 2 energy grades (Example: from class F to class D).
- An investment for energy retrofitting of less than 30,000 euro per dwelling.

To obtain these results the pilots are identifying and experimenting, on a large scale, a set of practical and innovative technical options and financial mechanisms targeted to develop energy efficiency in low income housing. The target includes:

a) Energy performance: theoretical energy characteristics of the building, including heating and cooling system, hot water and lighting.

b) The summer comfort will be considered in order to make the temperature not exceed 28°C more than 10 days per year.



c) Energy charges for heating, cooling and hot water (considering a typical comfort level of19°C in winter, and the summer comfort as described above).

d) Payback period: payback of retrofitting investment by energy charges gain.

The complete set of improvements for sustainable building construction.

In the next two figures there is the representation of low income houses in Frattamaggiore municipality. On the left the situation as it is now and, on the right, the situation after the refurbishment. In this case a small courtyard in front of the house as many objectives: increase safety for children who are now leaving on the ground floor just “on the street” without any protection, increase the shadow in summertime, use the roof for installing photovoltaic and thermo

solar plants for electricity and hot water.

	
Before the refurbishment	After the refurbishment

2.2.2 The guidelines

As the project last step, the results of ELIH-Med large scale experimentation will be analyzed and discussed in various capitalization workshops in order to reach a final set of conclusions and recommendation which could then be extended in the whole Med area.

The results will be collected in different guidelines addressed to different target groups like LIH tenants/owners, building sectorial technicians and other sectorial professionals. It is expected to work out an Operational Plan, giving a visibility at political level as a component of a macro regional strategy for a coordinated use of Structural Funds for the next programming period 2014-2020. The ELIH-Med guidelines which will be widespread in all Med countries are:

a) Guideline on cost-effective refurbishment solutions in Med LIH with the good experimented cost-effective advanced retrofitting solutions in Med LIH.

b) Guideline on innovative financings. The financial guideline contains information on good successful examples of advanced financing schemes and subsidy schemes verified during ELIH-Med pilot actions. The guidebook is addressed to financial institutions and private investors; of course the information will be very useful for housing companies as well as energy agencies, consultants and planners.

c) Guideline on energy efficiency policies in LIH in the Mediterranean. Based on the analysis on current EE polices in ELIH-Med countries made during the first phase of project, in this guideline, ELIH-Med proposes specific EE policies in Med LIH addressed to local and regional authorities.

2.2.3 The smart metering

One of the ELIH Med project aims is to identify the possibilities of energy Smart Metering systems to boost the energy efficiency in LIH, as Smart Metering is a technology where end-use energy efficiency can particularly be encouraged through its impact on tenants' behaviour.

Five partner countries (Cyprus, France, Greece, Malta and Spain) are involved in the pilot experimentation.

The smart metering experimentation

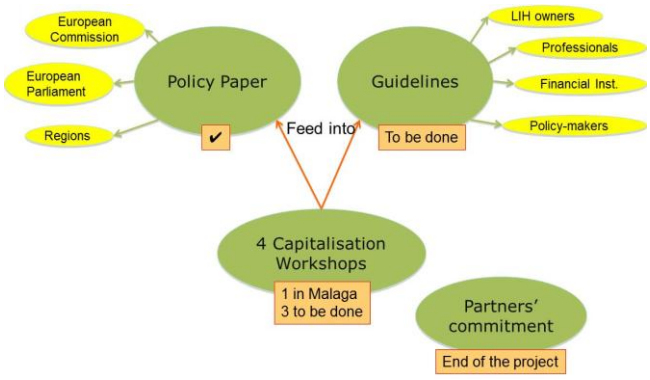
The data will be collected till the end of the project in December 2014 from 765 pilot dwellings selected for the installation of smart meters.

2.2.4 The awareness campaign

For selecting fruitfully pilot dwellings and setting up TMG and PPCG two groups, it is essential to make LIH owners/tenants and the related stakeholders aware of ELIH-Med, of energy efficiency concept/energy saving behaviours and of related technical-financial solutions.

ELIH-Med partners have adopted different methods to implement their awareness raising activities, such as participating social events, organizing technical workshops and making LIH visits. The figure on the right side gives some idea about awareness raising activities carried out by ELIH-Med partners. Especially, Spanish partner IVE has produced a set of Energy Saving tips to change energy consumption behaviours of LIH owners/tenants, which is very appreciated by readers.

Example of “tips” produced by IVE for the awareness campaign



3. The capitalization

The Med program give a large importance to the exploitation of results through capitalization activities which would bring together different project dealing with similar or complementary activity. The result is a common policy paper addressed to all decision makers of Mediterranean area. This policy paper will consider both: energy efficiency policies and territorial cooperation, trying to pave the way for an empowerment of them as central topics at the next programming period operational programs.

It also aims to reinforce the linkage between territorial cooperation initiatives on energy efficiency, public policies and access to new sources of funding. A greater cooperation on energy efficiency issues and specific efforts to test, innovate and fundraise ambitious projects and policies are necessary if we want to make the 20% energy efficiency increase objective more realistic. Currently, the energy renovation of buildings is considered by investors as a difficult question, with unclear profitability and with a long administrative process to reach public subsidies or grants. More than the context of economic crisis and environmental pressure, the EPBD Directives implementation starts nevertheless to open the mind of the main stakeholders in considering energy efficiency improvement of buildings as an important and mandatory challenge.

However, important gaps still remain between countries and regions in the implementation of the European legal framework. And this framework will not be sufficient to compel all the stakeholders to endorse their responsibilities. In this context, transnational cooperation projects could actively contribute to create a local and regional movement towards a better implementation of this framework and an involvement in EE policies, which could encourage investment, and, on the long run, jobs creation. Moreover, cooperation projects should also facilitate citizens’ awareness concerning the importance of energy renovation and buildings opportunities. Territorial Cooperation would facilitate:

a) Benchmark and comparative analysis between different realities. In this sense, territorial cooperation can facilitate the production of more complete analysis and knowledge of reality.
b) Create uniform criteria for assessing the effects of EE measures and evaluation of achieved savings.
c) Share of solutions and measures and integration of the achieved experience based knowledge.
d) Generation and share of common approaches to overcome common barriers.
e) Achievement of economies of scale in investment and efforts development.
f) More dynamic markets in quantitative and qualitative terms.

Energy efficiency in buildings could become a strong pilot sector for transnational cooperation in the Mediterranean. This topic is particularly relevant not only because it is in line with the EU2020 strategy and priorities, but also because experience-sharing opportunities are numerous and policy development in this sector is complex and requires pilot action and innovation. In this domain, multilevel coordination and governance issues are the main barriers and transnational cooperation can facilitate this multilevel dialogue.

The capitalization framework

Nevertheless, transnational cooperation is still a marginal source of funding and projects have difficulties to directly innervate policies at local and regional level. In this sense, preparing, sharing and developing a common MED strategy to improve energy efficiency of buildings is a clear positive example of the usefulness of territorial cooperation approach, even if efforts should be continually done to combine transnational projects with an efficient multilevel governance system able to generate consequent impacts up to the EU2020 objectives. This Policy Paper is a key tool to combine both vertical (multilevel governance) and horizontal (territorial cooperation and policies) approaches and to avoid the usual fragmentation and barriers in EU policies implementation.

As the ongoing programming period for European territorial cooperation is coming to an end, the preparation of the next programming period for 2014-2020 is currently in discussion. Now, ELIH-Med and MARIE are persuaded that both projects, as well as PROFORBIOMED and others belonging to European programs related to these issues, can bring results and lessons of their experiences as a real added value to the next programming period. This is the object of this Policy Paper that aims to propose to the Managing Authority of the MED program a consensus based set of recommendations to contribute to the next programming period preparation, providing answers to the challenges related to energy efficiency in buildings shared by the Northern Med regions and countries. The policy paper of ELIH-Med, which can be downloaded from the web site (www.elih-med.eu) presents a review of the current situation in the Med area, by analyzing the gap between the objectives and the real ongoing investments and mutations. Investigations have allowed MARIE and ELIH-Med partners to agree on strategic lines aiming to improve energy efficiency in buildings that are the skeleton of the shared vision both projects advocate for. In addition, the policy paper proposes recommendations on improving cooperation on energy efficiency issues in the Mediterranean area. PROFORBIOMED, a strategic MED project that pursues the promotion of the residual forest biomass for energy, sustains the same Policy Paper elaborated by ELIH-MED and MARIE projects.

4. EU Directives related to EE of Buildings.

a) The 2002/91/EC introduces an energy certification scheme, a methodology for the calculation of the energy performance, applying in the same time minimum requirements of new buildings.

b) Its recast, directive 2010/31/EU, comes to reduce the large differences between Member States' practices in this sector.

c) The co-generation directive 2004/8/EC establishes a general transparent framework to promote and facilitate the installation of cogeneration facilities.

d) The directive 2006/32/EC on energy end-use efficiency and energy services aims to make the end use of energy more economic and efficient in Member States.

e) The directive 2009/28/EC is a useful instrument for improving energy efficiency in buildings, by promoting the use of energy from renewable sources.

Life Cycle Assessment for sustainable buildings during the planning phase

Abstract

Since the main efforts in decreasing ecological impact of buildings in the last decades mainly focused on reducing energy demand during operation, used construction materials are receiving more importance in a comprehensive Life cycle assessment (LCA). Decisions about construction materials and systems are often made in an early planning phase regardless of their ecological impact. In analogy to life cycle costing where the influence of decision in the early planning phase has been proven [1], the importance of decisions in an early state of planning influencing the construction and its ecological impact can't be neglected. Regardless its increasing importance, at the moment no tools are available to support such decisions in preliminary planning process. The purpose of this work is to show an approach for estimating the ecological impact of buildings in an early phase (architectural competition or preliminary design phase) in order to support decisions in the design phase.

To do so, the former developed life cycle costing tool "LZK- Tool" [2] has been extended by the possibility of LCA. In the "LZK-Tool" construction elements are used to calculate the costs of an entire building as well as the follow-up-costs during life time. To estimate the ecological impact it was necessary to define more detailed used materials or available products for those elements. Consequently, ecological impacts where estimated either on the basis of available environmental product declarations (EPD) or, for elements with lacking EPDs , with ecological databases. With this approach ecological impacts for about 500 elements were calculated.

To validate the calculations, LCAs calculated by third parties on the basis of drafts have been compared with LCAs calculated by the above described approach. The results show that for a selected group of impact categories adequate results are achieved (a variation of approximately +/- 15% occurs).

It can be concluded that this method successfully manages uncertainty regarding ecological impacts in very early design and concept phases with an established top-down process. On the one hand it can be used to support important decisions concerning the most important elements in a building (facade, primary construction, etc.), and on the other hand it gives the opportunity to compare entries of an architectural competition from ecological point of view besides the already established monetary assessment. Therefore, this approach provides reliable support for decisions in an early planning phase influencing impacts ecologically and monetarily during the lifetime of a building.

Keywords

LCA, sustainable buildings, early planning phase, LZKTool

1. Introduction

Efforts, undertaken after the first energy crises in the late 1970s, in decreasing the ecological impact of buildings have led in the last decades to a tremendous decrease in energy demand of buildings. The main topic of interest was the reduction of energy for heating. While in the 1970's energy demand was around 200-300kWh/m² modern buildings can achieve values below 15kWh/m². A term strongly related to this reduction is "Green Building" which generally describes buildings with low ecological impact considering all phases of a buildings lifetime. As this term not only refers to the energy demand in operation other topics like location in terms of environmental quality, connection to public transport or soft facts like work place quality, acoustic quality in the building etc. are also relevant for green buildings. A topic becoming increasingly important due to the reduced energy demand during operation is the energy demand and ecological impact of the used construction materials. Most of the building certification systems do rate the ecological impact in at least one or sometimes several impact categories of used materials in a building.

The most important certification systems in Austria are the German Sustainable Building Council certification [4] and the so called "Total Quality Building" certification system [5]. In these two certification systems impact categories like Primary energy demand (renewable and non renewable), Global Warming Potential, Acidification Potential and others are part of the evaluation. International certificates like BREEAM or LEED do not take as many impact categories into consideration but limit themselves to Primary Energy Demand and Global Warming Potential.

The importance of these indicators has been shown in "Haus der Zukunft" projects, as it has been calculated that due to the minimization of grey energy (energy needed to produce and provide construction materials till they are on construction site) it is possible to save an amount of CO_2-equivalents which is equal to those of the a heating of a passive house.,. Only in the last 20years research has begun to calculate the values for grey energy for processes and materials and other indicators of interest for ecological impacts.

Nevertheless, even though data is available, the obstacle to overcome is to make decisions, which are influencing the economic, energetic and ecological performance of a future building at an early stage in a planning process.

Also, when an architectural competition is undertaken, decisions about facades and energetic concepts - highly influencing the energetic and consequently the economic performance of a building – have to be made. These decisions are based on the experience of architects and its technical consultants. Because these systems are becoming more complex and, due to the technical innovations in the last decades, the possible solutions are manifold, architectural entries in a competition are difficult to compare. Even after an architectural competition when an architect with its team is chosen, first drafts have to be developed and optimized with regard to economic, energetic and ecologic performance.

As Developers do usually not have the experience to validate proposed technical solutions, important decisions can't be made on the basis of hard facts. This uneasiness in the planning process and the urge to receive high security about construction and operation costs, energetic performance and knowledge about the possibilities for a future building certification during the planning phase, can only be tackled with proper tools. These tools must deliver more or less accurate figures (costs, ecological impact) but work with parsimonious input data as most of the construction and building details are not known by that time.

Unfortunately, most of the available tools to calculate indicators for these issues need detailed information of the future building which can't be provided. As outlined in Hofer et.al 2011 [2] and shown in the figure below there is a lack of tools during the conceptual phase of a building.

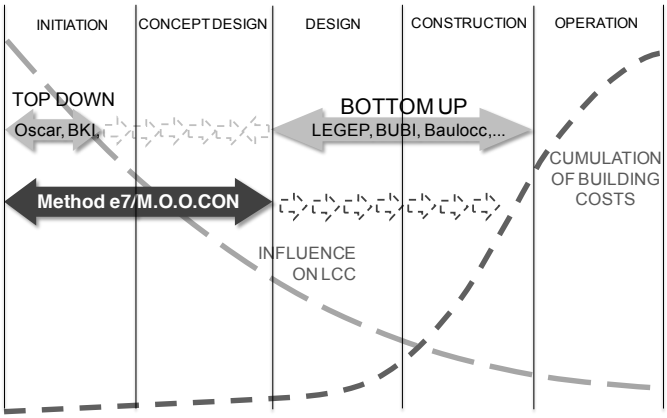

Figure 1. Missing link in models for calculating life cycle costs during the design phase (Source: [2]).

With the growing pressure for buildings being sustainable and growing importance of building certification, not at least to guarantee high marketability as outlined in Fuerst & Allister [3], it has become more important for developers to receive assurance for a high building quality as early as possible in the planning process of a building which in turn increased the need to develop proper tools for this period in planning.

One tool developed in recent years, to make competition entries comparable and to support decision during the early design phase, was the LZK TOOL developed by M.O.O.CON and e7. Till now with the LZK TOOL economic and energetic performance of buildings can be calculated. The main focus of this research project was to extend the LZK TOOL by the possibility to calculate the ecological impact of a building with basically the same method. The first step was to give indications about the ecological impact of the construction materials used in a building and in a next step to calculate the impact of the operational phase of a building. Other indicators like water use and emissions of construction site related transport will be estimated with already calculated output of the LZK TOOL in combination with available emission data.

The following part mainly focuses on the first aim – the calculation of the ecological impact of used construction materials – as this was the main focus of recent research and is most relevant for the use in certification systems and of interest for developers and planers.

2. Method

To calculate the ecological impact in an early planning phase neither a bottom up approach which prerequisites detailed information of a the building nor a top town approach which only can deliver results for the entire building but not parts of it were suitable. Therefore in analogy to the developed "LZK TOOL" described in [2] this approach has been developed.

The Tool described in [2] uses "elements" of constructions which can be aggregated to an entire building. The main advantage of this approach is that with few, known or assumed, parameters in an efficient and time saving way a model of a building can be made. The basic idea is that the sum of elements multiplied by the amount of a related functional unit can be aggregated to a building.

$$building = \sum_{i=1}^{n} element_i * amount\ of\ functional\ unit \qquad (I)$$

In this regard the main focus has to be lied on the definition of elements and a proper functional unit which can be quantified in an easy way.

For example, in the mentioned tool an element is the opaque part of the facade and another one the transparent part of the facade. The related functional units would be one square meter opaque facade and one square meter transparent facade. These two elements together already describe an entire facade. At this point it is clear that an element can have different forms. In case of the transparent facade different types of windows can be used but at least one has to be chosen to fulfil the requirements of the model.

Therefore, functional units can be different for different elements. Functional units in the mentioned tool are for example m² gross floor area, m² facade area or number of workplaces. Not all functional units have to be independent as one can determine another one. For example, a facade usually divides into an opaque and a transparent part. By knowing only the entire facade area and the transparent area the opaque area consequently is a result of the other two areas. Obviously, some functional units can also be input parameters but most are derived from input parameters. Basically, the LZK TOOL works with around 50 input parameters of which some 200 functional units are derived.

In first place the aim of the LZK TOOL was to calculate the construction and operation cost and therefore equation (I) was extended to equation (II)

$$cb = \sum_{i=1}^{n} e_i * \sum fu_e * c_{e,fu} \qquad (II)$$

cb	cost of building
e	element
fu_e	functional unit related to element
$c_{e,fu}$	cost of element based on the functional unit

As the aim of the tool is to estimate the ecological impact of a building, equation (II) had to be altered the following way

$$eib = \sum_{i=1}^{n} e_i * \sum fu_e * ei_{e,fu} \qquad (III)$$

eib	ecological impact of building
e	element
fu_e	functional unit related to element
$ei_{e,fu}$	ecological impact of element based on the functional unit

Whereas impacts of an element could be all known and calculated ecological impacts.

Besides the definition of the element and the functional unit, the system boundary had to be defined. In a first approach it has been decided that in a first step only the construction of the building should be calculated. For validating the tool this was a necessary step because on the one hand the definition of these elements is unique and can't be compared to other systems and calculating the impact over the lifetime of a given building strongly depends on the life time of an element. Therefore, assuming that elements are renewed or at least refurbished several or at least one time, lifetime is a crucial parameter in calculating the economic and ecological impact. As life times differ widely across literature and as already mentioned the used definition of elements in the "LZK TOOL" is unique, it would be nearly

impossible to receive the same results as there is no guideline how to calculate ecological impact of the lifetime of a building. To make the calculations of this method comparable with other tools, first calculation were undertaken without accounting the life cycle impacts of the building. Therefore for the first calculations only the impact of the established building has been considered.

To make this approach operational the database created for the “LZK TOOL” has been further extended. The mentioned database comprises of around 1100 elements of which around 500 elements are used for estimating the ecological impact of the building. Elements concerning the primary construction, the thermal envelope, separating walls and floor constructions are considered within these 500 elements. Elements concerning HVAC (the heating, ventilation and aircondition system) and furniture where not considered.

As the elements have no or only minor information about the used materials and its weights, it was necessary to define all used materials for each element. This was an easy task for the primary construction as the elements are quite simple whereas other elements needed more attention and further research.

After defining used materials the ecological impact of an element related to its functional unit could be calculated. For this purpose mainly data from “ecosoft” (a product of the IBO institute) was used. As ecological impacts are manifold it has been decide to concentrate to only a few of them. In detail for each element the following categories have been chosen:

- Primary energy demand (PE) - because of its overall importance and comparability for buildings
- Global warming potential (GWP) – because of its importance and significance in the global warming discussion
- Acidification potential (AP) – even though this indicator hast lost importance in Europe because most of industry facilities have DeNOx plants, it is still important for mass products like cement which are dealt globally and therefore not necessarily are produced in Europe
- Photochemical Ozone Creation Potential (POCP) – This indicator is especially of importance because it can be highly influenced at the selection of construction products because of the emissions of used solvents

Two often used indicators, Eutrophication Potential and Ozone Depletion Potential, have been discussed but not calculated because of lacking relevance in these days.

For the above mentioned four indicators the impact for an element related to the functional unit has been calculated for the construction and the end of life phase. The distinguishing between these two phases is of major importance as elements have different life times and the ecological impact of a building will be calculated over a predefined building lifetime. Therefore as elements are going to be changed at different times in a building lifetime ecological impacts occur a different time. At the end of the buildings lifetime all ecological impacts are summarized including the demolishing of the building.

3. Preliminary Results

After calculating ecological impacts to 500 elements and importing the data to the database first calculations with the "LZK^{ÖKO} Tool" have been undertaken.

As the input data does not differ from the input data in the LZK TOOL, calculations for several projects could be undertaken. For practical reasons, in a first run only five projects have been calculated which have been chosen by considering the difference in gross floor area and the aim to achieve a certification (either after TQB or DGNB certification system). The projects were proposed by M.O.O.CON and are known under the project titles: WES Smart Campus (Vienna), E+E (upper Austria), Garant (lower Austria), Immorent (Vienna), Windkraft Simonsfeld (lower Austria).

First validation of calculations showed no unreasonable results, afterwards comparisons with calculations based on finished drafts have been done.

	LZK^{ÖKO}	**third party calculation**	**deviation**
Inventory	3756 [t]	3745 [t]	+0,31%
PEnr	2229 [MWh]	2053 [MWh]	+7,88%
Per	332 [MWh]	1083 [MWh]	-225,81%
GWP	574 [t CO2]	255[t CO2]	+55,62%
AP	1774 [kgSO2]	1414 [kg SO2]	+20,30%
POCP	203 [kg C2H4]	163 [kg C2H4]	+19,70%

Table 1: Ecological Impact calculations for a 2100m² GFA building

The figures in table 1 show first results of one of the projects and compared with calculations of third parties. Considering the system boundary it can be said that for the inventory the two approaches deliver approximately the same result. Unfortunately, the different impact categories show results with wider variation. While the results for AP, POCP and PE non renewable show results in an acceptable variation the important indicator for the renewable primary energy demand as well as the global warming potential show substantial variations. As a deeper validation of the data is still in progress only first assumptions about the variations can be made which still have to be validated. Reasons for the variations can be:

- even though the inventory on an overall level shows the same result, shifts between used materials are still possible.
- use of different databases for calculating the ecological impact of the used materials. Whereas for LZK^{ÖKO} Tool mainly Environmental Product Declarations (EPD) were used the calculations of third parties are based on other databases. Differences for the same material can therefore be relevant
- The use of EPD's may cause a general bios as the considered calculation of the third parties do use databases which can better take into account local differences influencing the ecological impact of a relevant product.
- As in the analysed building a substantial amount of renewable materials are used (straw for the insulation, wood for secondary construction, foam glas gravel for perimeter insulation) the fact of using different data sources in this case seems to be predominant

4. Conclusion

Nevertheless, at the given stage of research it can be concluded that the "LZK^{ÖKO} Tool" can be used to calculate the ecological impact in an early planning phase. The inventory shows approximately the same results at a variation below +/- 10%.

As especially the inventory deals as a fundamental prerequisite for calculating the ecological impact, differences in the impact categories can be tackled and brought to an acceptable level. Current differences in some of the chosen impact categories must be further investigated but first insight anticipate that one of the main obstacles is the use of different databases.

The aim of this research, to support decisions for developer in an early planning phase, has been achieved. The first results show, that the chosen method, aggregating ecological impacts of elements to the ecological impact of a building can be used to give a first indication and support developers decisions.

5. Outlook

To assure an accurate calculation, a deeper analysis of used databases must be undertaken. As at the time given only a few buildings could be calculated and compared with third party calculations more calculations have to ensure resilience for the calculated results. Furthermore, one of the main weaknesses of the most tools, regardless of the time used in the planning or construction phase, is the lacking consideration of the HVAC system. Especially in these parts of a building, most of elements are used which usually have high ecological impacts. A focus of future research will be to estimate the relevance of used metals (besides the already calculated reinforcement steel) for the ecological impact of a building.

6. Acknowledgement

The research project to further develop the “LZK TOOL” to the “LZK^{ÖKO} TOOL” was funded by the FFG under the “COIN” program in the field of “Kooperation und Netzwerke”. The authors and the engaged companies bauXund, e7 and M.O.O.CON thank for the financial support.

Short Summary

Material thermal properties are essential in calculating thermal energy losses through out a building's shell. Exact values, especially regarding the material thermal transmittance co-efficient, also known as U-value, are critical for the correctness of calculations predicting a building's thermal energy demand, both for heating and cooling, thus enabling engineers in designing, dimensioning and evaluating the building's necessary heating and cooling systems in order to optimize the final building/system integration and maximize efficiency, resulting in decreased consumption. The aim of this study is to establish, under real weather conditions, the thermal characteristics and actual thermal behaviour of typical residential houses in Cyprus.

For this purpose, a wireless web-based monitoring system has been deployed covering 44 different houses, geographically selected all over Cyprus. Construction materials varied amongst each house, resulting in a theoretical U-value range of 0.467 to 1.389 W/m^2K. Calibrated temperature sensors were installed and measurements were conducted at 30-minute intervals for each individual house. The internal house air temperature, the external air temperature, as well as, the internal and external wall surface temperatures, have been continuously monitored for a period of fifteen months.

Processing the above mentioned data has led to the establishment of the mean internal temperature of the typical Cypriot residence and calculation of the U-value for each individual wall, facing north, south, east and west, including the roof, comprising the building envelope. Variations of the calculated U-value of up to 25% for each wall orientation are observed, even though construction materials of each wall remain the same. Furthermore, deviations of up to 30% from the theoretical U-value calculation are also observed.

The utmost aim of this study is to provide experimental evidence and accurate measurements of the thermal characteristics and behaviour of the typical building envelope in Cyprus, providing thus a more accurate tool for the engineering calculations.

Keywords: Heat Losses; Energy; Building Envelope; U-value; Thermal Transmittance co-efficient.

1. Introduction

Energy consumption in buildings accounts for approximately 40% of the total energy consumed in EU annually [1]. Furthermore, it has been established that households, in developed countries, spend slightly more than half (53%) of their total energy needs for space heating and cooling [2]. Taking also into account studies showing that there is major room for improvement on the energy saving of the building sector in general [3], as well as for the residential buildings in Cyprus in particular [4], it is evident that correct analysis of the building envelope and determining the critical sources of thermal losses for a residential building is of great importance. Establishing the actual thermal losses of the typical Cyprus residence, and identifying the dominant mechanisms and elements that contribute the most to the total residential thermal energy demand can become a useful tool in the hands of policy makers, engineers as well as academia involved in the building sector in general. Even though previous studies have been conducted in modelling the Cypriot residence and its energy consumption [4] and also identifying the energy behaviour of the residential buildings stock in Cyprus [5], this is actually the first time that in situ measurements were performed in such a large scale in order to check the accuracy of such theoretical predictions. Theoretical predictions are based on methodologies developed mainly in the US and northern European countries, thus, their direct implementation cannot be fully relied on due to the difference in climatic conditions, building architecture and materials used for construction.

Better knowledge and understanding of the major building elements contributing to the majority of the building's thermal losses, as well as the actual construction materials behaviour and thermal properties, can lead policy makers into improved legislation and EU directives implementation, drafting of measures and targeting government subsidies regarding energy efficiency and saving, thus maximizing the overall used energy reduction in the household sector and the building industry in general. Architects and engineers can also benefit greatly from such knowledge resulting in better building design, more accurate cooling and heating systems design and dimensioning and optimized building/systems interaction resulting in higher efficiencies and energy savings to the benefit of the end user.

In this study, the findings from the collection and analysis of actual in situ measurements in 44 different houses spread all over Cyprus are presented. Specifically, the typical behaviour of the Cypriot user and his habits regarding the use of his residence heating system is identified, the U-value of typical wall structures used in the Cyprus building sector are derived and the actual thermal losses during winter are calculated. Finally, the phenomenon of the radiating roof is presented in detail and its impact in increased energy losses during night time is investigated.

2. Methodology

The methodology followed by the research team participating in this project was based initially on two main axes. At first, a representative sample of houses to be monitored had to be selected based on the following criteria: geographic location and climatic conditions, building type, population density, construction materials and building characteristics. Four major climatic zones are acknowledged in Cyprus; coastal, low-land, semi-mountainous and mountainous. Also, based on population density, three main area categories are distinguished; urban, suburban and rural areas, within the provinces of Nicosia, Limassol, Paphos, Larnaca and Famagusta.

Data acquired from the National Statistical Service of Cyprus [6] regarding the geographical distribution of licensed residential buildings in the above areas for the period of 1991-2006 coupled with identified construction characteristics led to the selection of 44 residential buildings for monitoring, spread all over the island, as shown in Fig. 1. Most of the houses were selected in the Nicosia region since it is the most populated province, followed by Limassol and then Larnaca, Paphos and Famagusta as shown in Fig. 2. Furthermore, as shown in Fig. 3, most of the selected houses have no thermal insulation as this was the common case in Cyprus, before the implementation of the legislation on compulsory thermal insulation in buildings. However, a substantial number of thermally insulated houses were chosen in order to check current construction trends and techniques used in compliance with the recently voted legislation.

Fig. 1: Location of the monitored houses all over Cyprus (marked with red pins)

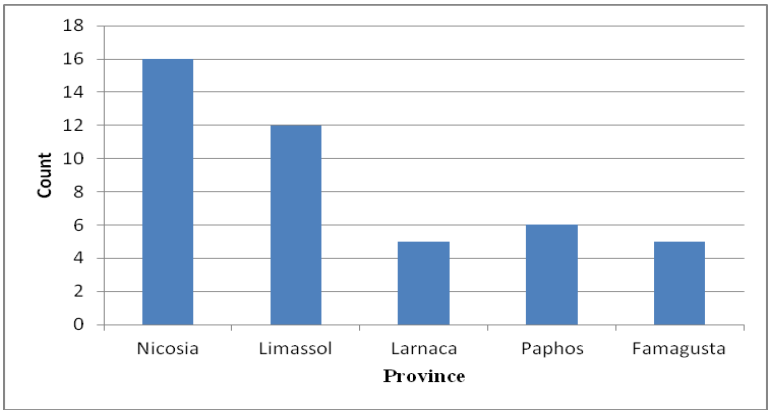

Fig. 2: Geographical distribution of monitored houses

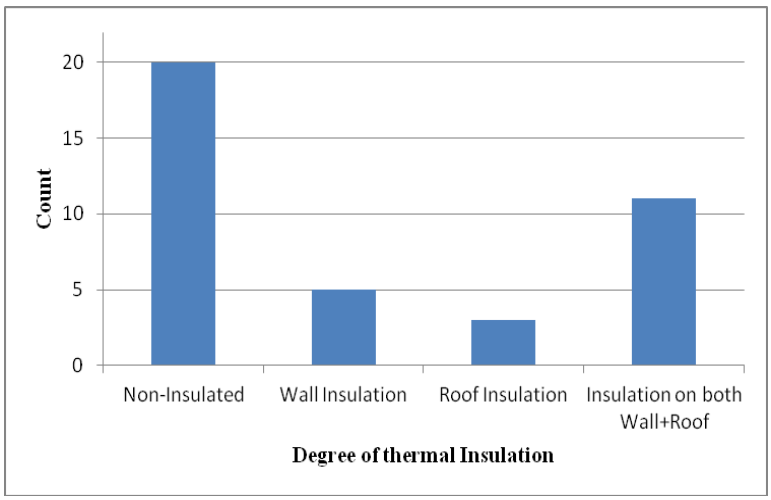

Fig. 3: Degree of thermal insulation of monitored houses

Secondly, a custom temperature monitoring system, mainly due to budget constraints was locally developed for the project's purposes. The temperature sensors consisting of thermistors mounted on wireless and energetically autonomous data acquisition end-notes, were designed, assembled and calibrated at CNE Technology accredited laboratory. The sensors developed were installed in the selected houses, at appropriate surfaces and locations (selected using thermal image photography) in order to monitor the internal and external surface temperatures of the walls and the roofs, as well as the internal room air temperature. Furthermore, air temperature sensors were used for monitoring the outside (ambient) air temperature. Six out of the total 44 selected houses were fully monitored; temperature sensors have been placed on each wall direction (north, south,

east and west), as well as on the roof. The rest of the selected houses were partially monitored; temperature sensors have been placed on walls facing only two directions (e.g. walls facing south and west). Finally, four meteorological stations were installed in order to track local weather conditions and microclimate irregularities as detailed as possible. The meteorological stations were installed in the provinces of Nicosia, Limassol, Paphos and Famagusta where the majority of the monitored houses are situated and their location was carefully selected in order to be as close to the monitored houses of each province as possible.

In addition to the above measurements, a questionnaire was prepared in order to gather further information and details on the selected houses. Information regarding the construction materials of the walls and roof comprising the building envelope, type of windows and glazing, the cooling and heating systems installed as well as the months in use and set temperatures, the number of occupants and the hours that they were absent of the house, electrical appliances and their use and many other that would provide a consumed energy profile, were also gathered.

3. Analysis of Results

3.1 Typical behaviour of the Cypriot resident

The selected buildings have been monitored on a continuous basis and data has been recorded for a period of fifteen months. These data were used to investigate the internal temperature profile of the monitored houses. An example is given in Fig. 4, where the fluctuations of the indoor and outdoor air temperatures of the monitored “House 02” are shown. The study of such graphs provides useful information regarding the usage of the residence’s installed heating system by the occupants. For the given example, it can be noticed that the heating system is turned on twice a day, morning hours and night time, and the set temperature is close to 22 ^{o}C. The above procedure was repeated for every monitored house and the results were summarized as shown in Table 1.

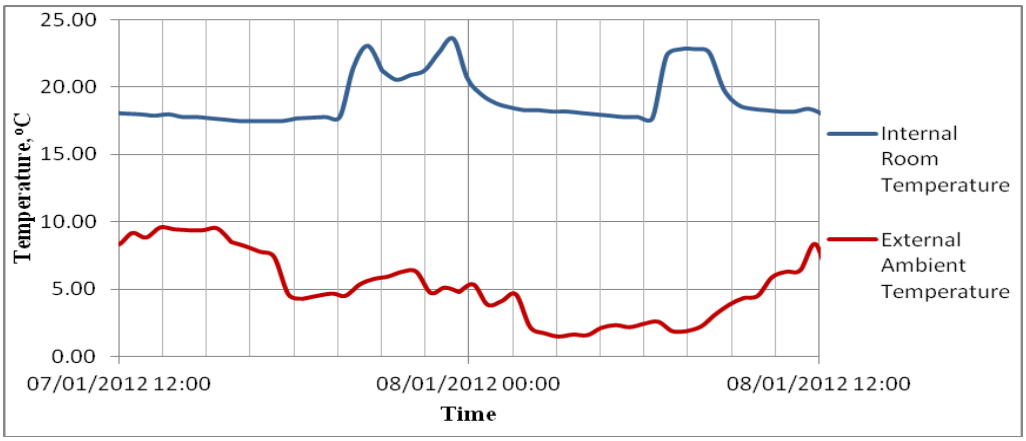

Fig. 4: Air temperature inside and outside of “House 02”

Table 1: Heating hours and room set temperatures at selected houses

House Name	Heating System	Building Use	Heating System Working Hours	Set Temperature
House 01	Boiler	Residential	06:30-08:00, 18:30-21:00	20-21
House 02	Boiler	Residential	05:00-07:00, 18:00-20:30	22
House 05	Boiler	Residential	20:00-08:00	18
House 09	Boiler	Residential	05:00-07:00, 19:00-21:00 (weekdays) 07:00-09:00, 19:00-21:00 (weekends)	21
House 03	Split Units	Residential	07:00-07:30, 21:00-22:00	23
House 07	Split Units	Office Space	09:00-16:00	23

Statistical analysis of the results obtained from all 44 monitored houses, lead to the drafting of the typical behaviour of the Cypriot resident. Most users set their heating systems to run for a short period during the very early morning hours, prior going to work, and then again during late afternoon / evening hours, when they arrive back home and before going to bed. Small variations of the above mentioned working hours and habits can be seen depending the day (weekday, weekend, public holiday, etc). For example, most users shift slightly the working hours of the heating system for the weekends. They set the system to start and stop a bit later during the morning and also to stop at a later hour on Friday and Saturday night. Finally, it can also be observed that they turn off the system in case they are away.

Also, depending on the type of the heating system used, the set temperature that the user considers most appropriate for thermal comfort varies. For boiler based systems, where heat is transferred into the residence using floor heating or radiators/convectors, a set temperature around 18 to 21 ^{o}C is considered as appropriate. An overall average set temperature of 20.5 ^{o}C has been measured in the houses monitored. For heating systems, where heat is transferred into the residence by circulating hot air (e.g. split unit or fan coil systems), a higher temperature of around 23 ^{o}C was noticed.

3.2 U-value measurements

In order to derive the U-values of the monitored houses, the following equation (1) was used:

$$U = \frac{1}{R_{swall}} \frac{T_{si} - T_{so}}{T_i - T_o} \quad (1)$$

deriving from the theory [7] of one-dimensional heat flow, under steady conditions and assuming any heat transmitted through radiation to be negligible.

Knowledge of the wall's construction materials and using the measured temperatures in each monitored house, the U-value of building elements in each house can be calculated. Results for the fully-monitored houses are presented in Table 2, while for the partially-monitored houses are presented in Table 3. The wall thermal resistance co-efficient (R_{swall}) and the theoretical U-value were calculated following the methodology [8] and the Guide [9] issued by the Cyprus Energy Service.

Table 2: Measured U-values at fully-monitored houses

House Name	Theoretical Wall U-value	Theoretical Roof U-value	Calculated U-value through measurements				
			North Wall	West Wall	South Wall	East Wall	Roof
House 01	0.850	0.510	0.615	0.615	0.605	0.755	0.329
House 02	0.516	0.773	0.334	0.375	0.414	-	0.512
House 09	1.389	3.098	0.995	1.253	1.368	1.005	2.887
House 10	0.467	-	0.313	0.313	0.320	0.320	-
House 12	1.111	0.648	0.840	0.855	1.020	0.987	0.476
House 16	0.516	-	0.327	0.320	0.253	0.143	-

Further statistical analysis of the results shows that the measured U-value is on average 20 % lower than the theoretical U-value. The relative standard deviation of these calculations is 12.3%, so it can be safely stated that the current methodology of calculating the U-value of a wall overestimates the actual mean effective value. It is also evident that the U-value varies depending on the wall direction. These are in agreement to the findings of a similar study carried out for historical buildings in Scotland [10].

Table 3: Measured U-values in partially-monitored houses

House Name	Theoretical Wall U-value	R_{wall}	Derived U-value through measurements	Derived /Theoretical U-value Ratio
House 03	0.680	1.302	0.441	0.648
House 04	1.389	0.550	1.318	0.949
House 05	0.398	2.343	0.310	0.779
House 07	0.249	3.851	0.148	0.594
House 08	1.111	0.730	0.794	0.715
House 14	1.389	0.550	1.029	0.740
House 15	1.389	0.550	1.082	0.779
House 17	0.269	3.545	0.184	0.684
House 18	0.515	1.772	0.372	0.722
House 19	0.516	1.950	0.427	0.828
House 20	1.111	0.730	1.011	0.910
House 21	1.389	0.550	1.008	0.726
House 22	1.389	0.550	1.256	0.904
House 23	0.515	1.772	0.378	0.733
House 24	1.156	0.695	0.998	0.863
House 25	0.516	1.770	0.324	0.628
House 27	1.389	0.550	1.302	0.937

3.3 Thermal Losses & Thermal Gains

Out of the six houses that were fully monitored in all four directions, enough valid data were collected for four of them in order for the thermal losses they sustain during the winter months, as well as any thermal gains, they may have during the same period due to solar radiation, to be calculated. The above mentioned houses are situated in the wider district of Nicosia (House 01, House 02 & House 10) and Limassol (House 09). The results are summarized in Tables 4 & 5.

Table 4: Heat Losses & Heat Gains during February 2012

	House 01	House 02	House 09	House 10
U-value (Measured)	0.648	0.374	1.155	0.317
U-value (Theoretical)	0.85	0.516	1.389	0.467
Total Heat Losses during February 2012 (MJ)	4000	6000	9000	5000
Total Heat Gain during February 2012 (MJ)	500	400	1250	600
Heat Losses during February 2012 (kJ/m2/day)	400	400	900	350
Heat Gain during February 2012 (kJ/m2/day)	50	30	120	50
Energy Gain due to Solar Radiation (% of Losses)	12.7%	6.7%	13.7%	11.4%

An analysis of the results concerning the monitored houses shows that, on average, there is a slightly more than 10% heat gain (see Table 4) from the daily solar radiation. The deviation of “House 02” results from the above percentage is due to severe shading of the south wall of the house due to the neighboring building. Also, paying a closer look to Table 5, it can be observed that the greatest contribution to the above thermal gain, results from the south wall being directly exposed to solar radiation, thus further explaining the deviation in the results obtained from “House 02”.

The actual energy gain or loss for each house depends on the wall structural characteristics and thermal properties (U-value) of each house as well as the use of the heating system (set temperature, hours of operation) but it can be observed that for houses with similar wall structures, it is more or less identical.

Table 5: Heat Losses & Heat Gains during February 2012 for the four basic directions

	House 01	House 02	House 09	House 10
Mean East Wall Energy Losses during February 2012 (kJ/m^2/day)	600	300	570	300
Mean East Wall Energy Gain during February 2012 (kJ/m^2/day)	36	30	165	100
Energy Gains due to East Wall’s Exposure to Solar Radiation during February 2012 (% of Losses)	6.1%	8.7%	30.0%	31.7%
Mean West Wall Energy Losses during February 2012 (kJ/m^2/day)	440	360	900	300
Mean West Wall Energy Gain during February 2012 (kJ/m^2/day)	40	10	40	1
Energy Gains due to West Wall’s Exposure to Solar Radiation during February 2012 (% of Losses)	9.0%	3.0%	4.3%	0.2%
Mean South Wall Energy Losses during February 2012 (kJ/m^2/day)	490	268	990	245
Mean South Wall Energy Gain during February 2012 (kJ/m^2/day)	130	30	200	60
Energy Gains due to South Wall’s Exposure to Solar Radiation during February 2012 (% of Losses)	28.2%	10.9%	19.0%	24.8%

Mean North Wall Energy Losses during February 2012 (kJ/m^2/day)	90	330	550	1100
Mean North Wall Energy Gain during February 2012 (kJ/m^2/day)	0	0	0	0
Energy Gains due to North Wall's Exposure to Solar Radiation during February 2012 (% of Losses)	0.0%	0.0%	0.0%	0.0%
Mean Roof Energy Losses during February 2012 (kJ/m^2/day)	250	600	1200	400
Mean Roof Energy Gain during February 2012 (kJ/m^2/day)	7	55	150	57
Energy Gains due to Roof's Exposure to Solar Radiation during February 2012 (% of Losses)	2.8%	8.6%	12.5%	14.2%

3.4 Radiation of flat Roofs

Analysis of the data collected throughout the test period from the monitoring system in each house and a closer look at the results, led to an overlooked outcome. Specifically, it was noticed that in a considerable number of nights, the roof's external surface temperature dropped considerably below the external ambient temperature in certain houses as can be seen in Fig. 6. This contradicts to the basic heat transfer scenario (mechanism) that is used in calculating heat losses from the interior of a building to the exterior.

In the standard model used today, for a heated room, heat is transferred to the inside surface of the room's external wall through convection from the room air, then to the wall's external surface through conduction, and then again by convection from the outside surface of the wall to the ambient air. This mechanism assumes that the room temperature is higher than the wall's inside surface temperature, which in turn is higher than the wall's outside surface temperature, which is normally higher than the ambient air temperature.

In the monitored cases, this was not the case during nights where there was a clear sky. To quantify this phenomenon, the temperature sensors were re-calibrated and surface thermometers were used to verify their readings. Secondly, a literature search was performed, verifying that flat roofs tend to radiate heat to the sky on sky-clear nights, thus resulting in increased losses through radiation and their surface temperature dropping below the ambient temperature [11]. Another interesting observation was the fact that the above mentioned phenomenon occurred frequently in houses in the Nicosia region, but very rarely in houses in the area of Limassol and Paphos.

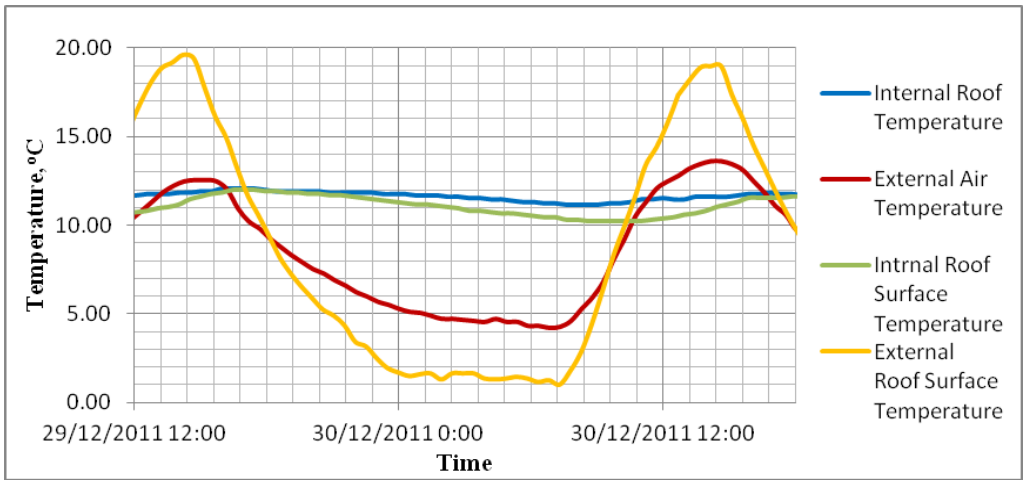

Figure 6: Typical temperature distribution on roof section – "House 01" (Nicosia)

The special climatic characteristics of Limassol and Paphos, with quite high levels of humidity, could be an explanation to the above mentioned observation. On the contrary, Nicosia's climate is much dryer, a fact that increases the possibility of a clear night sky radiation, and thus the occurrence of the flat roof's temperature drop.

Further focus on the houses situated in Nicosia area, where the temperature drop of the radiating roof is much more intense, and detailed data analysis, achieved a quantification of the roof's external surface temperature drop. Statistical analysis of the results shows that there is an average temperature drop of approximately 2.5 ^{o}C as shown in Table 6.

Furthermore, it appears that there is a linear relationship between the ambient air temperature and the external roof surface temperature, since the data are highly correlated (Fig. 7). Establishing a "best-fit" linear curve through the available data (approx. 4000 points), the following linear equation can be derived, which can be used to predict the roof's external surface temperature for a house in Nicosia, for a given external air temperature.

$$T_{roof} = 1.015 T_{air} - 2.786^{o}C \quad (7)$$

where
T_{roof} : is the temperature of the flat roof's external surface.
T_{air} : is the environment ambient temperature.

Table 4: Average temperature drop of flat roof external surface in ^{o}C.

Month	Temperature drop of Roof's External Surface		
	House 01	House 02	House 10
December 2011	2.50	2.90	-
January 2012	2.27	-	-
February 2012	2.46	2.19	2.30
December 2012	-	2.99	2.12
January 2013	-	2.53	-

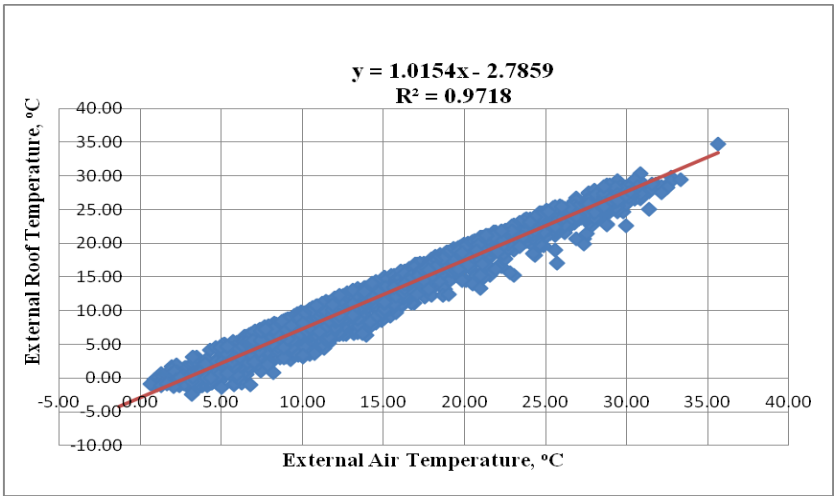

Fig. 7: Correlation between outside (ambient) air temperature and external roof surface temperature for houses with a flat roof in the area of Nicosia

4. Conclusions

In the present study, the outline, methodology, and goals of the corresponding research work have been presented, along with the findings, resulting from the analysis of the collected data, with regards to the typical behaviour of Cypriot resident, the actual U-values of the typical Cypriot houses, the actual thermal losses and gains during the winter season and particular behaviour of the building's flat roof under specific conditions. Also, some critical conclusions regarding the above are presented.

From the analysis of the collected data shown above, it is evident that in the typical Cypriot house the heating system operates at specific periods of the day, in contrast to the northern European countries where heating systems operate for much longer hours. Another interesting result is the fact that users perceive an average temperature of 20.5 ^{o}C as adequate for thermal comfort in water based/radiant heating systems, while a higher temperature of 23 ^{o}C is needed in systems circulating hot air. These findings can prove quite useful for engineers involved in the design of such systems.

Another critical finding of the present work concerns the overestimation of the U-value of a building's envelope that is calculated from current theoretical models. This could be used by the engineering community performing energy simulations and system design in order to decrease the safety factors used in their design calculations.

Furthermore, heat gains due to solar radiation account to approximately 12% of total energy demand for heating during winter. Also, it has been shown that a satisfactory thermal insulation of a building's outer shell results in decreased heat losses of 50 % or more compared to the typical non-insulated house constructed in Cyprus until recently.

Finally, the phenomenon experienced in flat roofs could help policy makers in targeting legislation and possible subsidy schemes in order to countervail the increased energy losses resulting from the above mentioned combined mechanism which amounts to a range of 15-45% of the residentially consumed energy for space heating, depending on house geometry and degree of thermal insulation of the walls and the roof.

Acknowledgements

This work was compiled from data recorded within the framework of the project with title "Establishing the Energy Losses of the typical Cypriot Residence, a Pilot Study" and acronym "ΤΕΧΝΟΛΟΓΙΑ/ΕΝΕΡΓ/0609(ΒΙΕ)/09", which is co financed by the Regional Development Fund and the Research Promotion Foundation of Cyprus. The authors would also like to thank the Cyprus Meteorological Service for providing useful information on the temperatures around the island.

Short Summary

The environmental awareness in politics and society is becoming increasingly important. The reason for this development is on the one hand the awareness of limited resources, but also the potential consequences of the greenhouse effect. In the field of energy efficiency of buildings increasing obligations exist in this context for European countries to construct energy-efficient and environmentally friendly buildings that are implemented by several national policies since the early nineties.

One example is the amended EU directive for energy-efficient buildings (EPBD) of the year 2010. It requires, amongst other things, that the greater use of renewable energy sources and energy storage systems should be promoted. Through the implementation of several directives and the consequent increased use of renewable energy sources, energy storage gains more economic and strategic importance because of the time gap between production and demand of this energy. Through the use of storage systems supply and energy demand can be balanced and power spikes covered.

In the European project MESSIB ("Multi-Source Energy Storage System Integrated in Buildings") exactly these new developments and their effects are investigated. The project focuses on the integration of innovative energy storage systems in buildings, based on the development of new materials and technologies. Objective is to show that energy storage systems can reduce the total energy demand of buildings, whereby end users can reduce their energy consumption and save costs equally. A life cycle cost analysis is necessary to assess this aspect and to take the varied cost savings for the different energy storage systems into account.

The presentation focuses on the Life Cycle Costing of building integrated energy storage systems using the example of a geothermal heat exchanger (thermal storage technology) and a vanadium redox flow battery (electrical store technology). Based on these insights and analysis it can be predicted what kind of storage can be usefully integrated into buildings and to what extent savings of both technologies can be achieved.

Keywords: Life Cycle Costing; Energy Storage; Geothermal Heat Exchanger (GHEX); Vanadium Redox Flow Battery (VRB)

1. Introduction

It is the goal of the European Union to enhance the energy efficiency of buildings until 2020 and to increase the usage of renewable energy sources for heating, warm water supply and air conditioning. The reason therefore is the amended EU directive for energy-efficient buildings of the year 2010 (EPBD) and many European governments have committed to use more renewable energy sources. With a higher share of renewable energy sources in the electrical and thermal energy supply, the significance of storage systems rises accordingly, because the production and use of renewable thermal and electrical energy in the building may be temporally distinct. The integration of energy storage systems in buildings is a necessary step in order to use renewable energy sources in buildings efficiently. [1]

With the help of energy storage systems, it should be possible to reduce the load of peaks and the exchange with the grid. End users can reduce their energy consumption from the grid and costs equally. To consider and to interpret these aspects, it is necessary to perform life cycle cost considerations for energy storage systems.

2. Life Cycle Costing

2.1 General Overview

Life cycle costing analysis is a method to estimate the total costs that occur during the whole lifetime of a product. The costs are considered along the single phases of a product during its life cycle (cradle to grave). That means that all costs of the different life cycle phases, the production stage, the usage and the end-of-life stage are taken into account.

Depending on approach and reasonable detail, each phase has different costs. The initial costs are due at the beginning of the life cycle in the development phase, the running costs and disposal costs incurred as a result of the initial costs. The breakdown of costs is different for each object of observation. Using the LCC, statements can be made about whether to pay off higher investment costs / disposal costs, because they can be reduced by the running costs. It can also be stated that the running costs must be reduced to make it worthwhile. The life cycle costs analysis will identify the parameters that have a great impact on the cost and where optimization potentials are. [2]

The various costs will be most affected at the beginning of the life cycle, especially in the development phase, because at this phase a high percentage of cost assessment and costs incurring are made. In the operating phase, the costs can only slightly or not be affected because there are incurred operating costs, which constitute the largest part of costs.

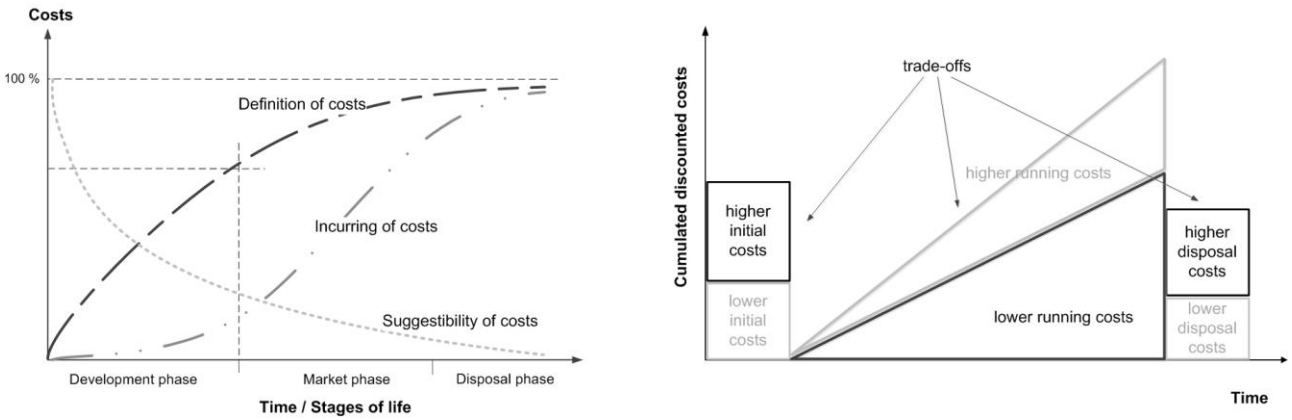

Fig. 1: left – definition, suggestibility and incurring of life cycle costs / right – Trade-offs between initial costs, running costs and disposal costs

In summary it can be said that the goal within the LCC is to identify the utility-maximizing alternative in terms of the maximum economic benefit.

2.2 Approach

Depending on the perspective the life cycle cost analysis is based on two different methodologies. Depending on the available data, life cycle costs can be determined with the support of the Bottom-Up or the Top-Down method. The Bottom-Up method works out the life cycle costs along the life cycle starting with the production to the cost of the usage and the end-of-life. In comparison, the Top-Down method is used when the production costs are unknown.

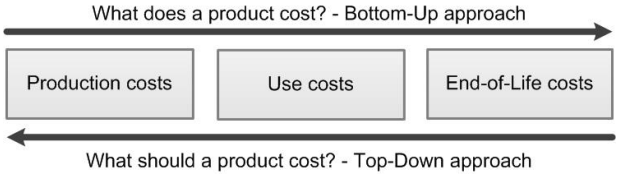

Fig. 2: Different approaches of the analysis of life cycle costs

3. Energy storage technologies

3.1 General Overview

Energy storage systems gain due to the increasing use of renewable energy and the time gap between production and demand this form of energy more and more economic and strategic importance. Through their use, the supply and demand of energy is balanced and power peaks are covered. The different energy storage technologies can be differentiated by their storage time, loading and unloading, saved energy (power) or their size and weight. [3]

The use of renewable energy is always combined with a limited aspect of the storage and any energy conversion is associated with energy loss. Renewable, fluctuating energy sources (solar, wind) are usually only temporary and short-term available in abundance at this moment but not directly stored. For storage and later use it must first be converted into a storable form of energy that is associated with losses.

3.2 Geothermal heat exchanger (thermal storage technology)

Geothermal energy and heat from the earth’s crust means the energy form, which can be used for direct or indirect heat in buildings. In addition, the earth's crust can be used as a cold source and can thus contribute to the cooling of rooms.

To use geothermal energy more effectively, a heat exchanger (Ground Heat Exchanger - GHEX) has been developed which is designed to prevent unwanted heat transfer in the soil to a great extent. This consists of an insulated pipe at the center and four surrounding smaller pipes with the highest heat conductivity as possible. Thereby there is only a low thermal resistance between the fluid flowing through the probe and the surrounding soil.

In order to increase the thermal conductivity between the base and the heat exchanger is introduced into the soil while an inert, conductive liquid material CFM (Conductive fluid material). This will contribute to improved heat storage capacity of the soil.

3.3 Vanadium Redox Flow Battery (electrical storage technology)

Vanadium redox flow batteries are a type of electrochemical storage, which have a high efficiency in a simple and modular construction. The advantage of vanadium redox flow batteries is that a separation of power and amount of energy due to the separation of energy conversion and storage medium takes place. The energy to be stored is determined by the amount of electrolyte, the battery's performance and the size of the active electrode surface. This is the shutdown of the plant instead of practically no self-discharge.

The developments were concentrated in the vanadium redox flow battery on improving the stability of the vanadium and reduction of self-discharge. Furthermore, a compact system for use in buildings is possible.

4. Life Cycle Costing of the storage technologies

Within the EU project MESSIB both GHEX and the VRB were connected or integrated into an existing building. The storage technologies have been studied in terms of energy consumption, the exchange with the grid and its utilization during the use phase. The scenario assessed is based on an office use.

4.1 Life Cycle Costing of the geothermal heat exchanger (thermal storage technology)

Since there are costs data for the GHEX and the conventional borehole (investment and installation) available, the bottom-up approach is applied for the calculation. This means that the life cycle cost analysis can generate a statement, if the higher investment costs of the GHEX can be amortised by lower operating costs over the life cycle.

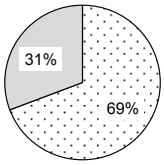
As yet there are no costs for the CFM available only a statement about the possible investment costs can be made.

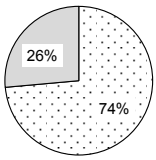
The borehole is used in combination with the heat pump as heat and cooling source for the building. For the operation of the heat pump a connection to the grid is necessary. The different scenarios which are considered are shown in table 1. [4]

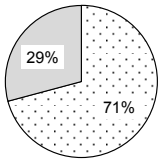
Table 1: Scenarios of the borehole

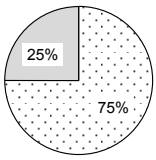
Boundary Conditions	Case I	Case II	Case III	Case IV
Thermal Conductivity ground	1 W/(mK)	1 W/(mK)	3 W/(mK)	3 W/(mK)
Thermal Conductivity CFM	No CFM	5 W/(mK)	No CFM	5 W/(mK)

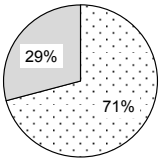
4.1.1 Scenario A

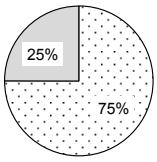


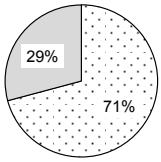


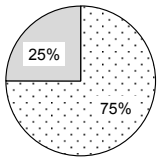












In this scenario the behavior of the two boreholes is investigated at a location with a high heating and low cooling demand. The lengths of the boreholes are 70m and were determined by using an approximation method.

The thermal simulation of the two boreholes has shown that no operating costs can be saved by using the GHEX. Through the introduction of CFM in a ground with low thermal conductivity the operating costs can be reduced by 130 kWh/a. For comparison the costs can be reduced in a ground with good thermal conductivity by introducing CFM only by 11 kWh/a.

The assumed use phase of the scenarios is 20 years. It is furthermore assumed, that the energy costs increase by 4% per year. Capital costs are calculated on a basis of a capitalization interest rate of 5.5%.

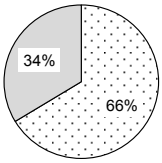
The amount of investment and operating costs are depicted in the following table:

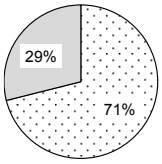
Table 2: Scenario A - Life Cycle Costs of the boreholes (amount of investment (grey) and operating (dotted) costs)

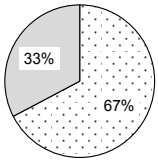
Scenario A - Life Cycle Costs			
Case I		Case II	
Convent.	GHEX	Convent.	GHEX
			
18,000 EUR	21,000 EUR	17,600 EUR	20,600 EUR
Case III		Case IV	
Convent.	GHEX	Convent.	GHEX
			
17,600 EUR	20,600 EUR	17,600 EUR	20,600 EUR

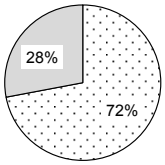
The difference of the life cycle costs between the conventional borehole and the GHEX can be explained only by the high investment costs of the GHEX because the operating costs for both are identical.

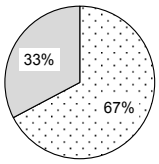
4.1.2 Scenario B

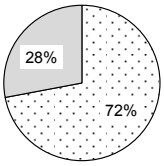


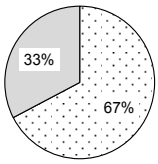


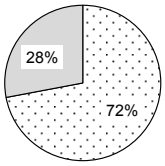












In this scenario the behavior of the two boreholes is investigated at a location with a low heating and high cooling demand. The lengths of the boreholes are 40m and were determined by using an approximation method.

The thermal simulation of the two boreholes has shown that no operating costs can be saved by using the GHEX. Through the introduction of CFM in a ground with low thermal conductivity the operating costs can be reduced by 38 kWh/a. For comparison the costs can be reduced in a ground with good thermal conductivity by introducing CFM only by 6 kWh.

The assumed use phase of the scenarios is 20 years. It is furthermore assumed, that the energy costs increase by 4% per year. Capital costs are calculated on a basis of a capitalization interest rate of 5.5%.

The amount of investment and operating costs are depicted in the following table:

Table 3: Scenario B - Life Cycle Costs of the boreholes (amount of investment (grey) and operating (dotted) costs)

Scenario B - Life Cycle Costs			
Case I		Case II	
Convent.	GHEX	Convent.	GHEX
			
10,400 EUR	12,000 EUR	10,200 EUR	11,900 EUR
Case III		Case IV	
Convent.	GHEX	Convent.	GHEX
			
10,300 EUR	12,000 EUR	10,200 EUR	11,900 EUR

The difference of the life cycle costs between the conventional borehole and the GHEX can be explained only by the high investment costs of the GHEX because the operating costs for both are identical.

4.2 Life Cycle Costing of the Vanadium Redox Flow Battery (electrical storage technology)

The VRB within in the MESSIB project is a prototype and therefor no reliable data for investment costs are available. By using the top-down approach a statement should be generated which level investment and disposal costs can occur. The integrated VRB in the following scenarios has a storage capacity of 6 kWh and an efficiency of 0.7.

The building in which the VRB is integrated is equipped with a PV power plant. As soon as the generation of the electrical energy exceeds the demand, the battery is charged. When the battery has reached its maximum storage capacity and the generation exceeds the demand, the supply of energy is injected in the public grid. If the generation of electrical energy decreases among the necessary demand, the demand will be covered by the battery in a first step. Only when the battery is completely discharged, there is a cover of the demand on the public grid.

The total energy demand of the building is 21,482 kWh/a without battery and 21,794 kWh/a with battery. The amount for covering the demand is shown in table 4. [4]

Table 4: Coverage of the energy demand for scenario I and II

	reference scenario	scenario
PV power		
feed-in	12%	5%
consumption	88%	95%
coverage of demand		
PV power	45%	48%
grid at day	55%	52%

The boundary conditions of the two scenarios are described in the scenarios themselves. Each of those scenarios will be compared to a reference scenario without an electrical storage unit (VRB).

The difference of the reference scenario consist only on the storage technology, which means that even in the reference scenario has got a PV power plant which covers the electrical energy demand and the excess can be feed into the grid.

4.2.1 Scenario I

Table 5: Parameters of scenario I

Feed-in tariff	Power tariff	Efficiency	Storage capacity
44.00 EUR cent	24.34 EUR cent	0.7	6 kWh

In this scenario the energy costs per year are 2,267 EUR/a without battery and 2,496 EUR/a with battery.

The time of consideration for the life cycle calculation is assumed with 20 years. Furthermore a price increasing rate for energy is assumed with 4% per year. Capital costs are calculated on a basis of a capitalization interest rate of 5.5%.

The net present value of the compared scenarios is depicted in the following table:

Table 6: Scenario I – Net present value of the energy costs over the life cycle

Reference Scenario I	Scenario I	Delta costs
39,150 EUR	43,103 EUR	-3,953 EUR

The results of the life cycle cost analysis of scenario I show that the installation of the VRB generates no benefit. Instead the reference scenario generates a benefit of 3,953 EUR. This means that it is not advantageous to integrate a VRB into a building under these boundary conditions.

4.2.2 Scenario II

Table 7: Parameters of scenario II

Feed-in tariff	Power tariff	Efficiency	Storage capacity
0.00 EUR cent	24.34 EUR cent	0.7	6 kWh

In this scenario the energy costs per year are 2,857 EUR/a without battery und 2,744 EUR/a with battery.

The time of consideration for the life cycle calculation is assumed with 20 years. Furthermore a price increasing rate for energy is assumed with 4% per year. Capital costs are calculated on a basis of a capitalization interest rate of 5.5%.

The net present value of the compared scenarios is depicted in the following table:

Table 8: Scenario II – Net present value of the energy costs over the life cycle

Reference Scenario II	Scenario II	Delta costs
49,334 EUR	47,376 EUR	1,958 EUR

The results of the life cycle cost analysis of scenario II show that the installation of the VRB generates a benefit of 1,958 EUR. This means that the investment and disposal costs for the VRB have to be lower than this benefit.

4.3 Comparison of both storage technologies

The innovative developments of the ground heat exchanger in the MESSIB project have not lead to energy savings during the operating phase. However the CFM enables to save energy costs over the life cycle. The comparison of scenario A and B of the boreholes shows that the CFM generates higher savings in a ground with a low thermal conductivity. Furthermore, it can be concluded that CFM at a location with high heating and low cooling demand has a greater impact to reduce operating costs than at a location with high cooling and low heating demand.

The innovative development of the VRB with a storage capacity of 6 kWh which is integrated into an office building could only be analyzed based on the energy costs over the life cycle. The comparison of scenario I and II of the VRB shows that in scenario I no costs can be saved with the integration of the VRB. In scenario II it is possible to save energy costs over the considered life cycle but there are still no investment or disposal costs taken into account. But the saved costs will be not high enough to cover the investment and disposal costs for the VRB. For example a lithium battery, which is already available on the market with a comparable storage capacity has investment costs of 10,000 EUR.

When you compare the two innovative developments of the technologies, it can be seen that it is possible to save the most energy costs under certain boundary conditions (no feed-in tariff) with a VRB. Summarized it can be noted that the boundary conditions (integration and economic parameters) have a great influence on the amount of energy costs savings regardless of the technology.

5. Conclusion

Both technologies allow, under certain conditions, to generate energy costs savings. Decisive boundary conditions are amongst others the political boundary conditions and the setting with the other components of the installation engineering in the building. The feed-in tariff as one political boundary condition has a high impact on how the VRB can generate cost-savings. If the feed-in tariff is too high and the payment of the feed-in electricity makes the integration of a VRB unattractive, this form of energy storage will not be able to enforce in width and apply. Also it is equally important for both technologies to synchronize them on the building, which means that the storage technologies have to be sized in the right way and the other components of the installation engineering (e.g. the PV power plant has to produce enough electricity to charge the battery in all seasons) have to be synchronized with them.

Real-time Energy Simulation for Advanced Building Control

Donal Browne
Senior Research Engineer
University College Cork, Ireland
d.browne@ucc.ie

Prof Karsten Menzel, IRUSE Group, University College Cork, Ireland
Mr Siyu Deng, IRUSE Group, University College Cork, Ireland

Short Summary

In general, current Building Energy Simulation Tools are used for pre-construction design and comparison of designs rather than a full exact varying representation of reality. To provide the best level of detail full CFD analysis for the entire building would be required. However this is currently by far outside the scope of standard computing power and labour efforts for a building energy system. Because these simulation tools are designed for comparison of potential designs and because of the difficulty in predicting occupant behaviour, very often the predicted results do not correlate with the real actual performance when buildings are in operation. Questions arise in relation to occupant comfort when a building space is serviced with a constant level of heating and ventilation. In addition, a cost saving could be realised if intelligent systems know to what level should a building space be heated or cooled.

This paper describes a methodology being developed to combine building energy simulation results with accurate and real sensor and meter data with the purpose of better understanding the relationship between energy simulation and real building operation for better occupant comfort and to guide efficient operation. Real life measured occupancy data from four building spaces in UCC's Civil Engineering Building have been recorded using a novel occupancy system to develop relevant indicators concerning occupancy levels. Two technologies are used to detect occupancy, proximity card access and RFID detection. A contrast of results from both systems is expected while also using both systems to quantify as exact as possible an occupancy level based on scheduled events involving the mentioned rooms.

Results gained from the occupancy detection systems will be utilised as input for commercial building energy simulation tools for the purpose of obtaining a better understanding of real time conditions within the occupied spaces and improving building control of HVAC systems within the experimental building.

Keywords: Simulation; Building Control; Energy Efficiency; RFID; Occupancy.

1. Introduction

As new and retrofitted buildings are developed with more complex monitoring, control and automation systems, vast quantities of data is being produced. A goal of the scientific and engineering community is to provide a holistic and integrated building information solution which can utilise this information and provide value by reducing building energy consumption. Better use and more integrated use of building energy information can contribute to meeting requirements of both the European EPBD and the European 20-20-20 targets which require the EU to reduce Greenhouse Gas levels by 20%, reduce domestic home energy consumption by 20% and increase Renewable Energy by 20%, all by 2020.

A key part of this holistic energy information solution is the integration of building energy simulation tools. Energy analysis plays an important role in developing an optimal HVAC and Architectural design for new buildings and in determining optimal retrofit and commissioning measures for existing buildings [1]. However a barrier to this integration is that the majority of commercial

building simulation tools are developed for design solutions rather than absolute accurate representations of detailed or near real time building performance. Therefore, pre-construction simulations often do not exactly correlate with operating building performance even though building simulation tools operate with accurate physics algorithms [2]. The reason for this mismatch is that detailed input information is required to produce the correct output [3]. To calibrate a dynamic building simulation, measured data from buildings can be used. Calibrating computer models to actual metered data is not a new practice [1]. For over 40 years, recommendations were made to calibrate models based on measured data [4]. Most calibration procedures require months of measured data [1]. Previous studies have developed a calibration procedure based on developing archetypes whereby patterns of similar buildings which operate alike would be developed and used for future similar buildings. This can be used to calibrate buildings to better predict future similar buildings [5].
Comparison of simulated cooling and heating energy simulation against time of day is a very important step in model calibration [5]. Furthermore short term cooling load forecasting with lead times from 1h to 7 days can play a key role in the economic and energy efficient operation of cooling appliances [6]. The study under development presented in this paper is based on calibrating accurate building information models and associated simulation models with real measured sensor data procured from existing buildings.
From previous EU-FP7 project experience a deficit has been encountered whereby the correlation between simulation results and measured data is not entirely accurate. This paper discusses a method of validation, which will provide a means of comparing measured data (e.g. sensors and weather data), and simulated data (e.g. near future simulations).
This method for validation of building simulation results initially involves a comparison of data from building simulation and respective measured sensor readings. From this comparison, value is added from correction of simulation results, and/or input to simulation parameters. Further worth can also be provided by gaining knowledge for creation of simulation profiles which are difficult to predict before construction and operation. Additional value can also be derived from identifying conditions of poor results and other relevant input factors which can be corrected. Simulation data and actual data is available from various campus buildings of University College Cork, Ireland. Simulations are undertaken using readily available commercial products and use practical and straightforward data analysis methods so that results and further development can be implemented by building engineers who may not have extensive IT or coding experience.

2. Research Building Description

This study focusses on UCC's Civil and Environmental Building (CEE) which is located on the main campus of University College Cork. The CEE Superstructure consists of brick walls, concrete ceilings and wood flooring. The windows are wood-framed single glazing. Efforts to upgrade these windows have been refused due to the semi protected nature of the building on the central Victorian style Campus. The building is approximately 2500m^2 consisting of experimental and IT laboratories, offices, seminar rooms, and lecture theatres. Heat is supplied from the University Combined Heat and Power plant through a connection to Campus Distribution System. Within the building a single pipe heating systems exists with cast-iron type radiators. Thermostatic control valves have been retrofitted in most rooms. The building is naturally ventilated with an air handling system installed to ventilate 2 IT Labs only. Lighting consists of zoned control through presence detection sensors. A moderate upgrade to the building was undertaken in 2009 consisting of:

- Modification of heating system and incorporation of bldg. control systems
- Lighting (fitting replacement, appropriate re-wiring, improved controls)
- Heat recovery ventilation from IT Laboratories

Of particular relevance to this paper is the installation of an occupant tracking system concentrating on 4 key rooms. The occupant tracking includes 2 no. independent systems consisting of;

- "Gate Reader" or RFID solution. This solution works with the readers/antennas fixed to the building. Users and inventory items are "tagged" with different forms of either HF or UHF passive RFID-tags. Tracking will be executed on "item"-level. The emphasis is on the integration of "security data" into Building/Energy Management systems. Additionally, we consider aspects of privacy and security in our research.
- Access Control or Proximity Card solution. This can be considered to be a more active solution whereby close proximity to an access control reader is required to gain access to a

building or room. In the research described here access control was installed in for key rooms within the research building.

Figure 1. Exterior View of CEE Demonstrator Building

The Building Management System installed consists of primarily of monitoring with numerous wireless sensors and heat metering. This data has been recorded for a number of years and is available for research purposes. This provides a concentrated wealth of information relating to building performance in greater detail than typical buildings. The CEE building therefore is an ideal demonstrator to conduct energy simulation study.

3. Demonstrator Building Information Model (BIM)

A detailed BIM model of the Research building has been developed for study within the authors' research group. This model has been independently verified and checked for accuracy of all dimensions, materials, etc. This same BIM is utilised for various research projects and experiments to allow for easy comparison and cross checking of all results. A key part of a holistic energy information solution is the integration of building energy simulation tools. Therefore, rather creating a simulation model within the simulation tool, the calibrated and verified BIM was used. For the research conducted for this paper, the verified BIM model was exported from Autodesk Revit MEP 2012 as gbXML format to be utilised by IES-ve energy simulation software.

The BIM to Simulation Process for this can be summarised as follows;

1. Creation of BIM model with accurate dimensions, geometry, materials, etc.
2. Definition of spaces within model.
3. Definition of type of spaces.
4. Export as gbXML.

As mentioned previously, it is a goal of the scientific community to have seamless interaction between software processes. And indeed, a dedicated import tool to allow easy transfer between the two software modelling packages utilised here. However, a number of time consuming problems occurred which had to be corrected before simulation could occur.

These problems included existence of holes between rooms and external spaces. Whilst not in the BIM model a number of holes appeared only in certain rooms. It is not possible to perform simulations with holes between internal and external spaces. The solution involved checking each individual room/space (44 no.) and deleting any external holes which had appeared. Other problems included;

- Certain building information properties not imported and had to be specified.
- Unusual spaces resulted from non standard building shapes e.g. roof lights.

- Awkward and unnecessary shaped features within rooms.

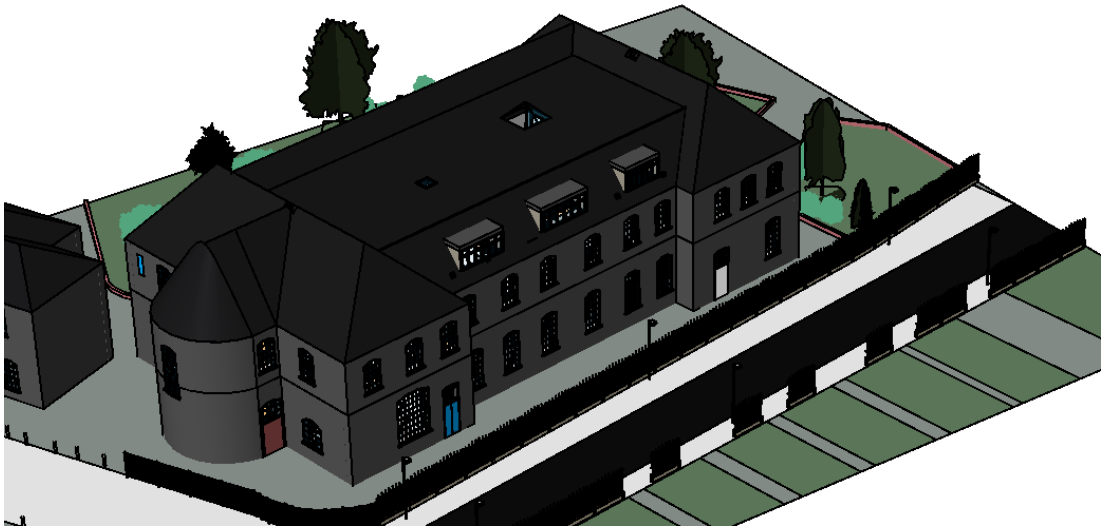

Figure 2. Overview of Detailed BIM Model

Some unnecessarily complex geometry was produced when exporting from BIM as gbXML. This geometry was not altered before simulation to minimise the number of time consuming corrective measures to be undertaken. However it is likely that these anomalies increased the time taken for simulation process to occur. For example what should be a simple 90° angle in a room instead resulted in walls overlapping to produce an unnecessary complex arrangement.
Whilst the BIM should provide geometry, it is likely that when the time taken for corrective measures is taken into account it would have been quicker to recreate the building model for simulation from scratch as the building modelled in this instance is composed of relatively straightforward geometry and materials.
A better solution is more careful creation of BIM solely for the aim of export. The downside of this is that the BIM needs to be utilised for other functions and may be less accurate. The BIM should function as the hub for all information for the project. It cannot be altered to optimise simulation if this interferes with other functions such as construction or facilities management. The original or record BIM needs to be entirely accurate. It therefore would be better if the BIM was modified post export before simulation. This would maintain the central BIM hub method whilst still optimising the simulation process.

4. Building Simulation

After adjustments were made dynamic building energy simulation was carried out using IES-VE (Integrated Environmental Solutions Virtual Environment). This simulation software was chosen as it is commonly utilised in commercial design in the UK and Ireland. Because it is an aim of this researcher not to be confined to a single software product or suite previous research has been carried out using Vabi Simulation, a popular Dutch dynamic building simulation tool and future comparative studies will be carried out using Energy Plus, the comprehensive U.S. simulation software.
A typical simulation procedure was carried out. For this particular simulation software steps taken include, setting correct weather file, running simulation of sun features for building location (Suncast), and adjusting materials schedules (Building Template Manager). Unlike typical preconstruction building simulations whereby building operation schedules, occupancy and timing schedules are estimated based on proposed building usage, this building has the benefit of known and recorded operation schedules and is closely monitored. Therefore efforts were made to match the simulation inputs as best as possible to reality.

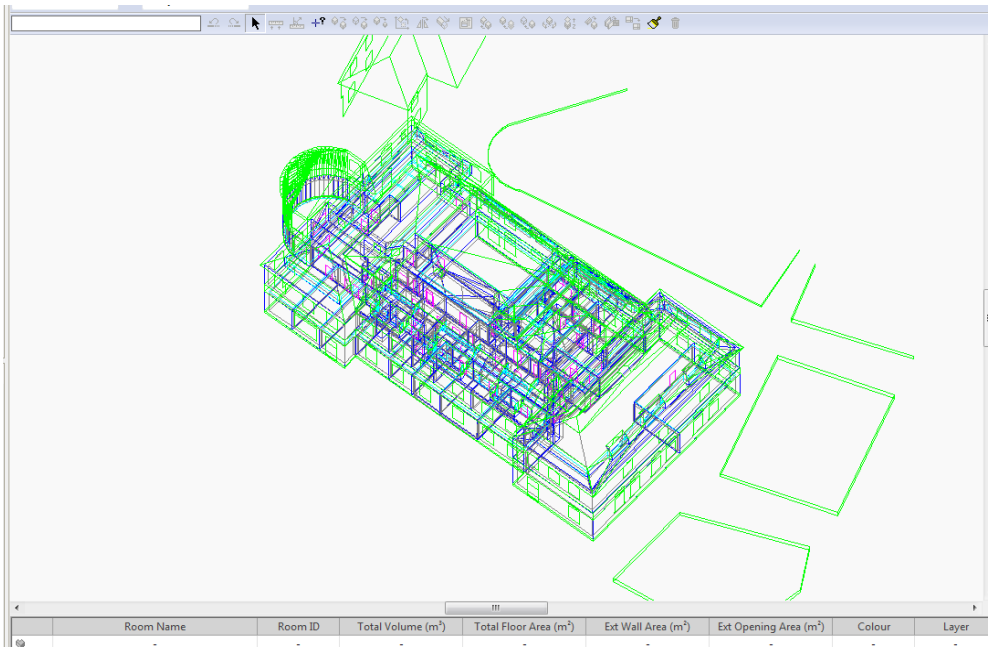

Figure 3. Wireframe View of Simulation Model

Simulations results were undertaken using two of the methods provided by the IES software, ApachSim (Dynamic Simulation) and the CIBSE loads methodology.
Steady state heat loss is the equivalent of running a 24 hour heated building with no internal heat gains for a long period of weather at a constant outside air temperature and no solar income. This process removes the internal heat gains from a Tas dynamic simulation model, runs the model using a weather file with constant outside air temperature and no sunshine and at the end of a 30 day period the simulated heating load is exactly the same as the steady state heat loss calculation. [7]. The steady state method used to design the building analysed is based on the CIBSE admittance method. This method uses idealised (sinusoidal) weather and thermal response factors (admittance, decrement factor and surface factor) that are based on a 24-hour frequency. [8].
Dynamic Simulation Models can be defined as models which are based on first principles and are capable of replicating dynamic heat trans fer in a building, in response to external and internal influences on the time scale of one hour or less [9].
From the simulation process a full and detailled set of results was created which are to be used for comparison to real data as described in the following section.

5. Building Performance Sensor and Meter Data

As mentioned in the Building Description section, a large body of real building sensor and meter readings procured from the CEE building exist for research purposes. These readings are stored on an Oracle data warehouse used for various research purposes within the authors' research group. This data can be accessed using a number of interfaces of varying complexity, from direct data warehouse queries to a web based tool, described below. This web based tool provides intuitive access to data and records from a graphical overview of the CEE building on a floor by floor basis showing where any wired or wireless sensors or meters are located. Overviews of other important areas such as the plantroom are also included in this tool.
Figure 4 shows the view of one floor of the building with the location of all sensors and meters located on that floor. From this view, any of the sensors or meters can be clicked upon to be analysed further. Other floors or areas can be chosen from the drop down menu located on the top left of the screen. When a sensor is chosen, a summary of the previous week is displayed in graphical and tabular form as per Figure 5.

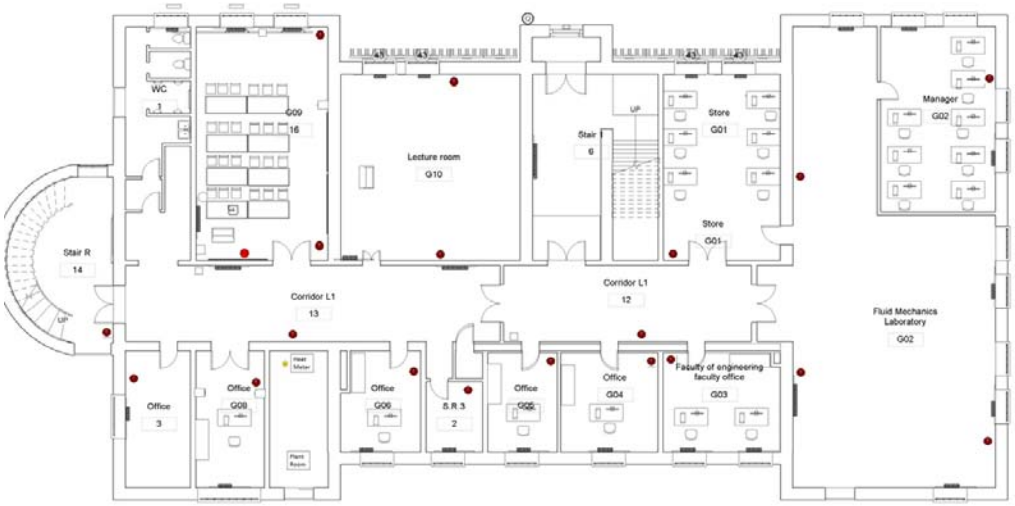

Figure 4. Screenshot of CEE Data Access

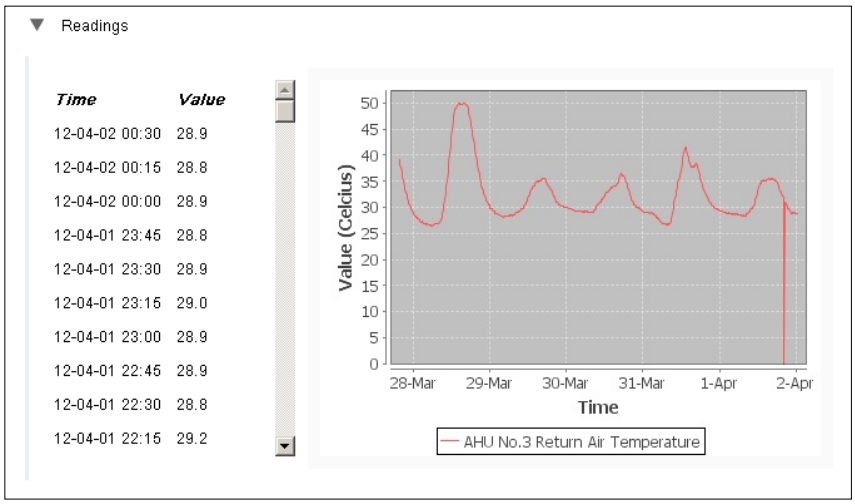

Figure 5. Detail of Temperature Sensor Information interface from the ITOBO Research Project

Furthermore the option is given to download a set of data in excel or csv format. This provides straightforward access to data without knowledge of data warehouse operation.
For more analytical tasks data can be aggregated in the Data Warehouse implementing "Materialised Views". However for the purposes of this research this is not required and the web access tool provides access to all required data.

6. Access Control and Occupancy Monitoring

Modern buildings are built to 'sense' their indoor environments and 'react' accordingly based on various internal factors and the outdoor environment. [10]. However one weakness of building control systems is the ability to capture the precise quantity of human occupation. Typically, human-Sensing is defined as the process of extracting any information on people in an environment in [11]. Many industries, research studies and academic institutes have carried out occupancy monitoring and analysis either based on indoor environmental data [12], post occupancy of a building [13] or through various sensors [14]. For dynamic building energy simulations this is also one of the most difficult parameters to determine and quantify.
As a method of overcoming this deficit a hardware-software platform has been developed at UCC. This consists of two elements a proximity card access control system and a RFID card system.

6.1 Proximity Card Access Control

The University has introduced access control systems using staff/student cards as swipe cards. All access control readers are connected to the Campus' IT-network and data is recorded in a centrally managed IT-system. Client software enables each unit to manage access rights for their

zones in a flexible way. For research and occupancy purposes the advantages of this system are that it is possible to know if a space is occupied (not possible to enter with card) and allows a general idea of occupancy. Negatives are that it cannot measure departure from a space (for fire safety reasons) and could possible underestimate the number of occupants if one occupant used a swipe care and others entered whilst the door remained open.

6.2 RFID Card System

The RFID Card system in operation in the Research Building consists of occupants carrying passive RFID cards in their wallets/purse. Gateways set up at entry and exit points to selected rooms can capture readings with a good degree of success. This is a proven system developed over a period of 4 years of research on now completed research projects. For research and occupancy purposes the advantages of this system over the Access Control system are that it measures both entry and exit quantities. The main disadvantage is that carrying of the RFID cards is entirely voluntary and not essential to gain access to the rooms. Therefore uptake of this system is less than the Proximity Card Access Control system.

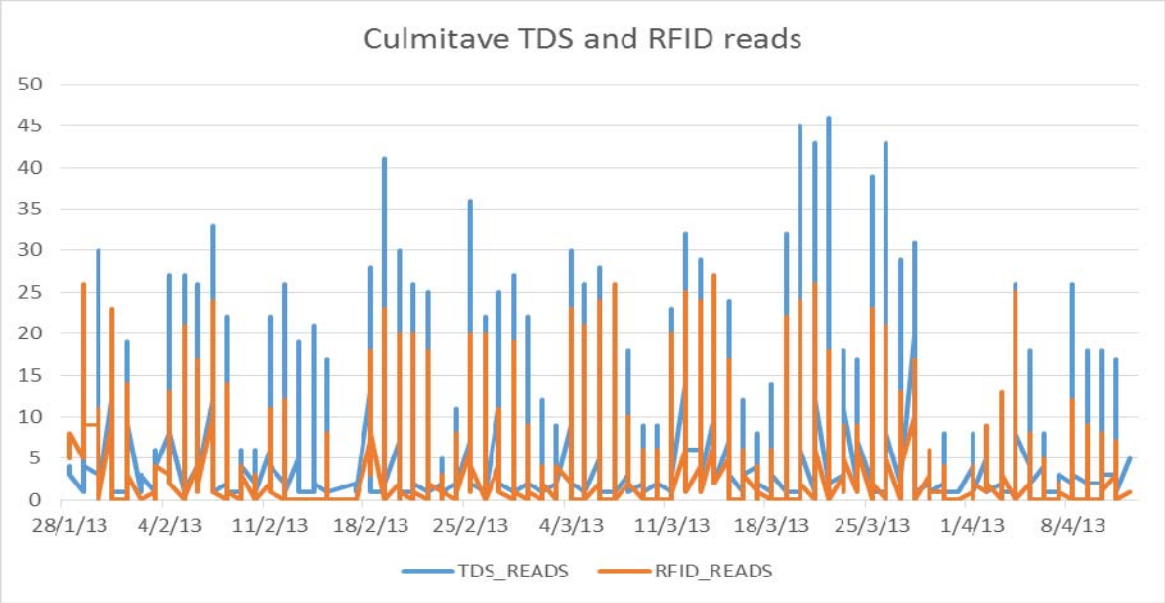

Figure 6. Example of Raw Occupancy Data before Correction

6.3 Further Quality Control of Occupancy detection

Because both methods described above have certain flaws, further quality control was undertaken at certain intervals over the period of research. This involved undertaking physical audits of occupancy in the rooms along with surveys of the percentage of occupants carrying their voluntary RFID cards. Whilst time consuming it allows for statistical adjustments to be made to the results of the occupancy data from both systems to provide a correction for actual occupancy at all times. Furthermore it should be noted that both occupancy detection systems complement each other quite well insofar that the deficits of both described above are somewhat cancelled out by their strengths.

6.4 Value of Occupancy Detection for Dynamic Energy Simulation

Having an accurate and detailed understanding of occupancy in key rooms and spaces in the building over a period of months has allowed the author to produce more accurate input for simulations and to create templates for individual rooms. This overcomes one of the most difficult to quantify inputs of dynamic building energy simulation.

7. Early Findings

Thus far this paper has described a process for providing detailed simulation inputs and results from an accurate and verified BIM model and providing access to a considerable body of building sensor and meter records. The next stage of the process to provide value from comparison and aggregation of this simulated and real data. The comparison concentrated on heating because of the building type and relative cool nature of the Irish climate. The first point of comparison is to determine for which the same simulation results and measured data exists. Next statistically and graphical comparative analysis is conducted.

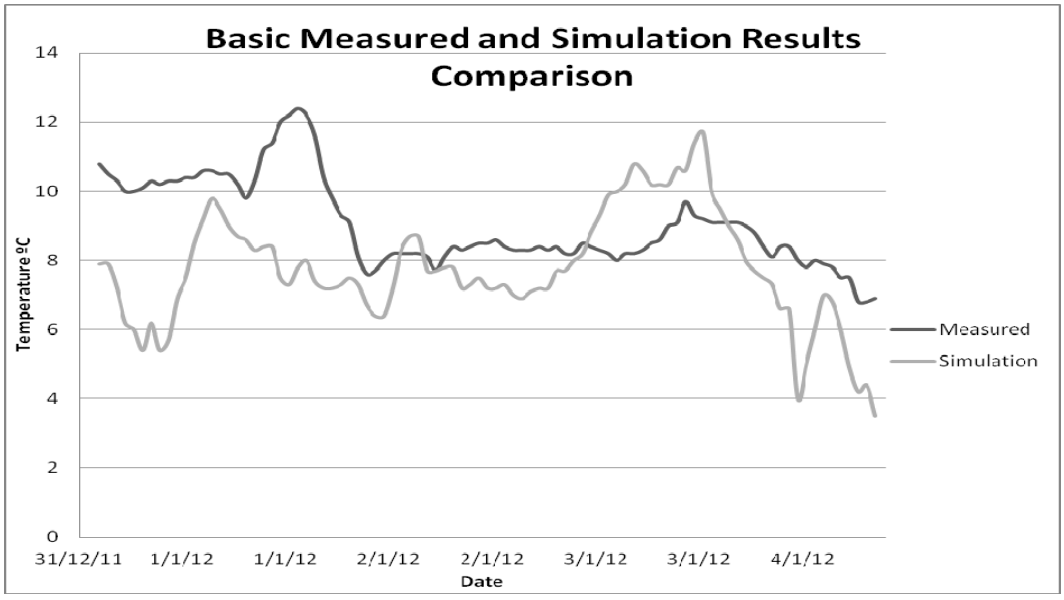

Figure 7. Example of comparison of Measured and Simulation Data

Figure 7 shows an example of a graphical comparison for measured results from one particular temperature sensor and corresponding simulation result. At the time of writing detailed analysis is still being undertaken. However some general trends have been observed to date.
Reasons for differentiation include many of the typical factors for building simulations not exactly adhering, in particular weather conditions. Improvement and validation of these is discussed in the Future Research Section.

8. Future Research & Discussion

The expected result to be derived from this method is to give an indication of quality of simulated data results and provide feedback. If the difference between simulated and real data is too large, steps to improve results will be suggested. In future it is envisioned that automated adjustments may be performed to simulation inputs to correct results.
Live instantaneous simulation can provide benefit from tuning BMS for near future tweaking of BMS/control systems (continuous commissioning), building certification, energy profiles and design performance review.
Possible scenarios which could be implemented include:
Design Review and comparison: During design phase, inputs for Design Simulation Models are estimated future building usage, occupancy density, etc. For Operational Simulation Models, inputs can be real functional data, from BMS and observation. Operational Simulation Models can provide a design check on the Design Simulation allowing feedback to designers for future Design Simulation improvements.
Trend Data Analysis: Trend key system parameters to detect problems early and assess system performance. As above.
Recommissioning or Continuous commissioning: Perform ongoing recommissioning activities to ensure that the building meets its current needs. Identify and correct deviations from “Ideal” initial operating conditions.
Further worth can also be provided by gaining knowledge for creation of simulation profiles which are difficult to predict before construction & operation. Additional value can also be derived from identifying conditions of poor results and relevant factors which can be corrected.
Aside from near future simulation validation, the tool may be able to provide long term commissioning feedback to detect and alert users to long term degradation of systems and possible maintenance or repair remedies. As a distant research goal, it is envisioned that results can be used to provide automated feedback to the Building Management System and further improve control.
Furthermore an explicit process of Knowledge Management has been undertaken by turning data

(simulation results & measured data) into information (basic comparison of key results) and future plans for creating useful knowledge (improve building operation for key results, energy, comfort and CO2). This will ensure that the process can be clearly documented to allow results to be achieved on other buildings in future.

9. Conclusion

Effective building performance simulation can reduce the environmental impact of the built environment, improve indoor quality and productivity, and facilitate future innovation and technological progress in construction [15].
The procedure described in this paper describes a clear methodology for creation of accurate dynamic simulation and comparison with real measured results with the goal of providing better understanding of building operation for the ultimate goal of improving building control. Whilst detailed post occupancy simulations comparisons to building simulations are difficult due to the lack of data, the tools and building being discussed in this paper provide a rare opportunity to do so. Future research to develop this methodology will be undertaken as part of the EU FP7 project Campus21.

10. Acknowledgements

Part of the research discussed in this paper is supported in by a fund from Seventh Framework Programme -ICT "CAMPUS 21" (Project-Nr: 285729). Previous research has been supported by the EU FP7 project “IntUBE” and the Science Foundation Ireland funded “ITOBO” project.

chniek.nl

Dr.ir. Gaby Abdalla, BAM Techniek bv, the Netherlands, gaby.abdalla@bamtechniek.nl

Short Summary

This paper focuses on business challenges and opportunities related to the adoption of integrated ICT system that will be developed in the framework of EU-FP7 CAMPUS-21. CAMPUS-21 aims at identifying opportunities for reduced energy consumption in public buildings and spaces through integration of different building automation systems. The integrated ICT platform will optimise renewable energy use, multiple building systems, optimise indoor air quality and consider occupancy of the building. For the purpose of this study a questionnaire has been developed in accordance with the business Model Canvas as suggested by Osterwalder and Pigneur. Business and contracts related data have been collected from the demo-sites, results have been analysed, discussed and conclusions have been drawn.

Keywords: Integrated ICT Systems, Energy Efficiency, Business Models, CAMPUS-21

1. Introduction

Interconnectivity of building automation systems, data collection, data analysis and automated control requires a holistic integrative approach to the management of the energy used by building systems. Integrated ICT Building Automation Systems can extend the functionality of already installed isolated systems and allow the synergistic usage of different data sources. This can result in reduction of life cycle cost by reduction of energy demand (demand-supply improvement) as well as lower maintenance requirements (increased equipment longevity). This poses significant opportunities for service providers and facility managers to create added value for their clients, to contribute to Corporate Social Responsibility and to enter new markets.

Within the framework of the EU-FP7 project CAMPUS-21, an integrated ICT system will be developed in three European public demo-projects. The aim of the integrated ICT platform is to integrate multiple building systems to optimise energy demand-supply, renewable energy use and indoor air quality. This paper analyses business challenges and opportunities related to successfully adoption of this platform in current businesses. Based on the Business Model Generation approach, introduced by Osterwalder and Pigneur, a questionnaire has been designed. Service providers and owners of the demo-projects provided data on used contract, involved partners, existing HVAC systems, energy purchase, energy generation and financial models. Results have been analysed, discussed and recommendations for business improvement have been given.

2. The Business Model Canvas

For a better understanding of existing business models, the business model canvas of Osterwalder and Pigneur [2010] has been used. This framework consists of nine blocks describing business models and introduces five important approaches to build new or to innovate existing business models. These approaches (resources-driven, offer-driven, customer-driven, finance-driven and multi-epicentres) are based on improving one or more blocks and tracing the changes in the other blocks.

3. Methodology

To answer the research question, a case study research has been performed. The Business Model Generation approach, introduced by Osterwalder and Pigneur, has been used to design a questionnaire. Service providers and owners of the demo-projects provided data on used contract, involved partners, existing HVAC systems, energy purchase, energy generation and financial models. Results have been analysed, discussed and recommendations for business improvement have been given.

4. Discussion and conclusions

Existing business models in the three campuses could characterised as very traditional. The three campuses grew in the course of years where buildings have been built or renovated, HVAC systems have been maintained or replaced, business partners have been changed and Energy Management has been implemented. This change process has resulted in segmented business developments and disjointed business models. This segmentation improved business components but mist a holistic improvement. It is also very important to mention that the three existing business models are driven by price instead of added value in terms of thermal comfort, higher productivity of employees, lower environmental impact and corporate social responsibly by greening products and services. Nowadays, governmental bodies, commercial partners and also the society are focusing in adding more value to their business, low price is only one of these added value strategies. Business models have to take into account making their added value or their performance more visible to their customers. This could be achieved by presenting energy savings in the entrance of the swimming pool or the lodges in the football arena or by surveying employees or students satisfaction after implementing new measurements. In order to make achievements and performance more visible, business models have to consider clearly defined key performance indicators in their contracts.

Besides, business models have to consider a life-cycle cost approach instead of initial cost approach. Energy saving measures needs initial costs while gains are can be achieved in also in the use phase yielding lower life-cycle costs. Energy Service Companies have considered this point very well in their business model. They engage with building owners in energy performance contracts that consider a total cost of ownership approach. They pay the initial costs needed to implement energy saving measures and get paid back through the saving they guarantee during the contract. Energy efficiency could be achieved by implementing technical or ICT solutions. However, users' behaviour is a very important factor in realising good energy performance in the use phase. Users have to be taught how to deal with HVAC systems and to be made partners in achieving efficiency. This could be achieved, when possible, by sharing gains from energy saving or by sharing losses that resulted from their behaviour. Suitable business models Energy Service Contracts or Desigh & Build.

Short Summary

This paper presents a comparison of different environmental assessment methods in sustainable office façade renovations. The assessment methods applied have both weighted and non-weighted systems to combine energy and material performance. The comparison is based on the south facing facades of three realized office renovations in the Netherlands, and based on the MAXergy method the 'best' renovation project has been further developed to minimize environmental impact. In MAXergy, energy and material performance is calculated to the indicator land-time necessary to create the resources. Based on the comparison of environmental assessment methods in this paper and based on the developed façade renovation version, energy focused optimization of office renovation may result in material performance sub optimization emphasizing the need for a joined and non-weighted assessment of energy and materials.

Keywords

sustainable office façade renovation – environmental assessment methods – building envelope – MAXergy

1. Introduction

Energy consumption is increasing worldwide, mainly based on fossil fuels. As fossil fuels are exhaustible resources, methods to lower fossil fuel consumption are investigated elaborately, amongst others in the built environment. Of all energy consumed worldwide 40% takes place in the built environment. Measures being taken might have a positive effect on the operational energy performance of a building and are often implemented in the building envelope, for instance by adding insulation materials. But these measures have an effect on material performance, which might cause a negative effect on the environmental performance of the building. The material performance can be calculated in embodied energy. With respect to operational and embodied energy, it is possible to calculate an offset between the two, and generate insight in the optimum. But only energy calculations do not offer us the complete picture of combined material and energy impact, as for instance availability and depletion of materials is not incorporated in the calculation. Existing sustainability tools, such as BREEAM and the Dutch GreenCalc+, use weighting factors for combining energy and material performance to arrive at a total score. Currently, methods are investigated to combine material and energy performance on an equal scale without weighting. In this

paper three methods are applied, one based on a weighting of indicators, one based on embodied and operational energy, and one based on land-time impact. The land-time impact might be an useful indicator to generate insight in the combined impact of both materials and energy performance based on the carrier capacity of the system. In this time-space calculation method, called MAXergy, the time and space necessary to fulfill the energy and the material demand for a certain function in a certain environment can be calculated.

Within the Netherlands, approximately 15% of all office buildings are vacant. This leads to a market driven situation in which the demanding party has a wide selection of possibilities. The costs associated with the energy performance is one of the criteria on which potential tenants decide. A better energy performance lead to less vacancy and higher rents. Besides this aspect, the policy of the Dutch government is to only rent high energy performance office buildings. As a third aspect, there is a tendency of commercial and non-commercial organizations to green their real estate to contribute to a positive impression. Currently, numerous assessment methods to calculate the level of sustainability are applied, such as BREEAM, LEED, CASBEE, SBtool, and Greencalc+. These tools have a number of advantages, such as the distinction in the level of sustainability of a building compared to other buildings, providing a communication tool, encouraging stakeholders to define sustainability requirements, and providing a vehicle for policymaking. In this paper, three assessment methods are applied to compare three different office façade renovation projects in the Netherlands. Based on one of the assessment methods, the 'best' office renovation has been further developed to minimize the combined impact of materials and energy.

2. Method

Based on different environmental assessment methods three realized office renovation projects in the Netherlands are compared on their level of sustainability. The assessment methods applied are the Dutch environmental assessment tool Greencalc+, the land impact calculation tool, MAXergy and embodied energy/operational energy calculations based on the program VABI 114 and the ICE database of the University of Bath. The case studies consist of three existing office renovations, where a comparison is made between the situation before and after the renovation related to energy use of the building (operational energy), materials of the facade (embodied energy) and the associated land impact (embodied land).

3. Conclusions and discussion

- The comparison of different assessment methods indicates a large bandwidth of results between the methods and between the projects. In future, a common language should be developed to tackle the difficulties that will arise due to the application of different environmental assessment methods.

- In the Dutch environmental assessment tool Greencalc+ all three renovations score relatively high on sustainability and show comparable total results.

- The embodied energy increased and the operational energy decreased in all three renovations, and in all three cases the cooling load remains the largest energy factor during the technical lifespan of an average office facade (30 years). Based on energy calculations, optimizing energy performance seems logical.

- The embodied land increased in all three renovations, but the results show large differences between the projects. The lowest impact of the WNF building is due to the choices in material application based on renewable materials.

- It can be concluded that material use becomes the determining factor with respect to operational energy in NZEB's.

Comparison of sustainable office façade renovations in the Netherlands

Short Summary

This paper presents a comparison of different environmental assessment methods in sustainable office façade renovations. The assessment methods applied have both weighted and non-weighted systems to combine energy and material performance. The comparison is based on the south facing facades of three realized office renovations in the Netherlands, and based on the MAXergy method the 'best' renovation project has been further developed to minimize environmental impact. In MAXergy, energy and material performance is calculated to the indicator land-time necessary to create the resources. Based on the comparison of environmental assessment methods in this paper and based on the developed façade renovation version, energy focused optimization of office renovation may result in material performance sub optimization emphasizing the need for a joined and non-weighted assessment of energy and materials.

sustainable office façade renovation – environmental assessment methods – building envelope – MAXergy

1. Background

Between 1990 and 2005 global final energy consumption increased by 23%, while the associated CO2 emissions increased with 25% (1). This consumption is expected to grow with another 45% between 2002 and 2025 (2). 20% to 40% of this global energy consumption is consumed in the built environment (3), for more than 86% based on fossil fuels (4). Between 1995 and 2005, extraction of fossil fuels increased with 24% (5). To lower overall energy consumption in the built environment and to lower dependency on fossil fuels, it is agreed within the EU that all new buildings in 2020 have to be (nearly) zero energy buildings (NZEB) (3, 6). A Zero Energy Building produces all necessary operational energy in the building itself during its operational phase. The target of NZEB can be reached by improving the energy efficiency in the operational phase of the building. This requires adding material to the building for thermal insulation, building services and energy generation products. Worldwide, extraction of construction minerals increased between 1995 and 2005 with 30% (5). This underlines that the realization of a less energy consuming built environment is largely depending on an increase of material consumption, and consequently an increasing con-

struction material extraction. Building environmental assessment tools should take both the energy aspect and the material aspect into account.
The Dutch office market, consisting of 52.2 million square meters, had a vacancy percentage of 14.6% in 2012 (7), corresponding with 7.62 million square meters. The average energy label for the Dutch office market is E (8), corresponding with an operational energy performance of 1.49 GJ/m2a for heating and cooling, lighting and hot tap water. To improve the market value of vacant and occupied office buildings, these can be energy efficient renovated, underlining the necessity of an effective building environmental assessment tool.

2. Introduction

As the market situation of office buildings in the Netherlands is not in equilibrium, renters have a wide variety of real estate to choose from, and are in the position to select offices with a high energy performance. Besides this market development, policy of the Dutch government dictates that the Dutch government itself, responsible for around 20% of office space occupation in 2010 (9), only rents offices with minimum energy label C since 2010. Already a number of NGO's and companies have joined this agreement, and it is expected that more organizations will join this government agreements in the framework of Corporate Social Responsibility (CSR). As a result, many offices are renovated to improve their energylabel to a minimum of C, in order be attractive again in the office market. In these renovations, the facade is often replaced to improve the operational energy performance of the building. After the renovation the operational energy consumption of the building is significantly lowered.

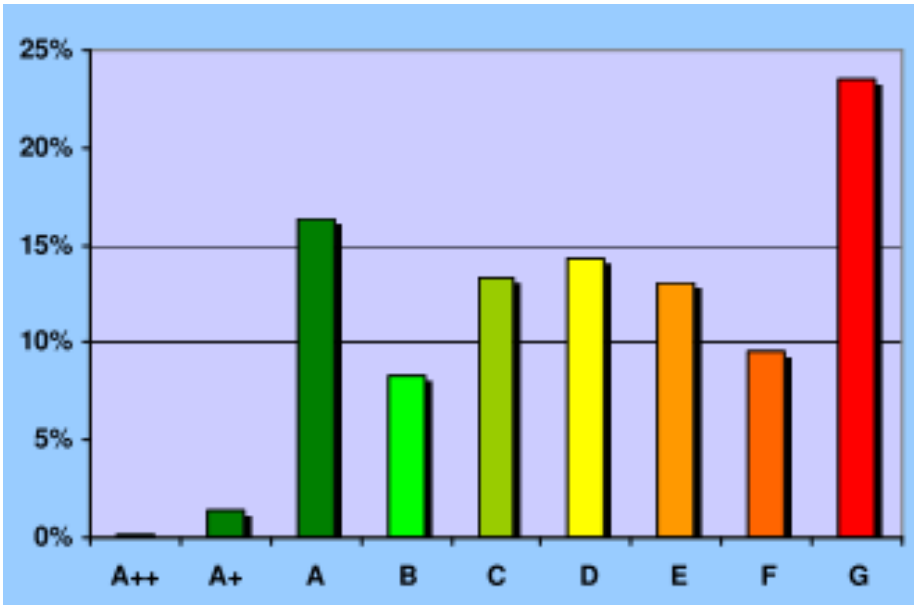

Fig. 1: Energy label distribution Dutch office market 2010 (source: (8)).

Currently, a wide range of tools is available to calculate the operational energy performance of buildings. Frequently, these tools are embedded in building environmental assessment tools. These tools have a number of advantages, such as the distinction in the level of sustainability of a building compared to other buildings, providing a communication tool, encouraging stakeholders to define sustainability requirements, and providing a vehicle for policymaking (10). Increasing requirements, the Dutch government only rents office buildings with an energy label of C or better, contribute to a higher energy efficiency performance of buildings (8). However, the improvement of energy performance may have as a negative effect an increased material consumption. As building are becoming more energy efficient towards the level of zero energy the impact of materials is increasing relative to the energy (11). This indicates the need for an building environmental as-

sessment method in which material performance and energy performance are non-weighted combined assessed.

The material consumption is often only translated in embodied energy: the amount of energy necessary to process raw materials, modify materials and transport materials. The embodied energy in materials can be seen as a 'rebound effect' of energy performance improvement, and has in current practice a negative impact on the calculated operational energy performance improvement of up to 30% in household heating and cooling(12). By calculating material consumption using only the embodied energy, the operational energy aspect and the material aspect are translated in a corresponding quantity; energy. For instance, Belgian residential low energy buildings with a primary energy consumption for heating of ca. 900 MJ/m^3 building volume over 30 years have a total embodied energy of 1400 MJ/m^3 building volume over 30 years, which is higher than the energy consumption for heating (13). For these embodied energy calculations various definitions, methodologies and system boundaries are used (14). An example of the latter is that there is a distinction between methodologies in which only the amount of fossil based energy is part of the calculation as it is 'added' to the product and methodologies in which the total amount of embodied energy, both fossil based and renewable based, which comes from 'natural sources' such as the sun, is calculated. Besides the different calculation methodologies, most results have uncertainties due to temporal, spatial and technical circumstances (location, weather, societal and energy generation), which are in many cases not shown in databases underlying the calculation tools (14). A third aspect of embodied energy calculations is the varying system boundary of the calculation. All these aspects have resulted in databases which face the problem of incomparability and variation (14). Besides these considerations, all embodied energy methods do not take into account the actual availability of resources, both renewable and non-renewable. As the extraction of construction materials increased between 1995 and 2005 with 30%, worldwide (5), it is worth exploring a method to be able to assess energy and materials equally.

Due to the increase of material consumption and due to the associated increase of raw materials extraction more and more land is needed for winning and producing building materials. In addition, raw materials, which are necessary for the production of the building materials, do not have an infinite stock, such as copper. Besides land use required for extracting raw materials, there is also land needed for generating non-renewable and renewable energy. As we have a limited amount of land and also the potential productivity of this land is limited, it seems logical to base our consumption pattern on the land necessary for production and extraction of (building) materials, generation of energy, water production and food production. In future, land necessary to produce renewable energy might compete with land necessary for food production and material production, which may lead to other choices in the design and realization of buildings (15). According to Rovers et al (15), sustainability needs to be based on what can be generated and consumed in equilibrium within the system, implying an indicator based on the carrying capacity necessary to materialize and operate a function, instead of on impact calculations without any relation with the system itself. The carrying capacity is the maximum persistently supportable load of a system (16), and can be indicated by the amount of land necessary to sustain the functioning of the system and the time this land is necessary, embodied land.

In this research the comparison of environmental assessment methods and an improved relationship between the operational energy performance and material performance in office renovation is investigated. Through three case studies, a comparison is made between the situation before and after the renovation related to the energy use of the building (operational energy), materials of the facade (embodied energy) and the related land use (embodied land). The results given here focus on south facing office spaces, and the aim of the research was to generate insight in the effect of embodied land calculations on the environmental performance improvement of office renovations in the Netherlands.

2. Method

In this project, the environmental impact of the south facing façade and the office space behind this façade of three realized sustainable office renovations in the Netherlands was investigated. The situation before and after the renovation was compared, and the results of the three projects were compared. Of the 'best' renovation, the office façade has been further optimized using MAXergy.

The following calculations were made:

- VABI 114 calculation before and after the renovation. VABI 114 is used for the calculation of the operational energy (heating and cooling) for the different buildings before and after the renovation. VABI 114(17) is a building simulation software which can calculate the annual heating and cooling load in MJ.
- Embodied energy of the facade before and after the renovation. The embodied energy refers to the energy, which is necessary for the total life of a material (extraction, production, and transport). In this study, the "Inventory of Carbon & Energy" (ICE) database of the University of Bath(18) is chosen to use for the determination of the embodied energy of the facade. The ICE database is an inventory of the embodied energy of materials data, originating from LCAs, books and papers.
- GreenCalc+ calculation of the buildings after renovation. GreenCalc+(19) expresses the sustainability of a building in an environmental index. The environmental index of the building (Milieu Index Gebouw - MIG) is calculated by the sustainability of the building compared with the sustainability of a standard building realized in 1990. The standard reference building from 1990 has a value of 100 MIG. When a building is more sustainable than the reference building from 1990, then the value becomes above 100 MIG. Buildings with a MIG-value below 100 are less sustainable than a building realized in 1990.
- Embodied land calculation of the facade and space behind the façade before and after the renovation; amount of land and time needed to generate the necessary materials and operational energy, in m^2-year. There are two embodied land calculations made. A calculation, whereby all energy is generated by solar energy (solar panels and solar collectors), and a calculation in which the embodied energy and operational energy is generated by fossil fuels. Calculated with Maxergy(20). Maxergy is a sustainability tool which represents material use and energy use of a building by using the same physical quantity by means of embodied land; time and space necessary to fulfill the energy and the material demand for a certain function in a certain environment. The total Embodied Land (EL) of a product is calculated using several databases as input the amount of new and recycled materials. The total embodied land calculation can be divided into direct embodied land (land and time required for the creation of a raw material), indirect embodied land (embodied energy converted into land and time) and operational energy (converted into land and time).

For the case studies the following projects are chosen:

- DHV office, Amersfoort; renovation during which the façade was totally replaced and the interior was preserved largely.
- WNF office, Zeist; renovation during which the façade was totally replaced and the building was partially demolished, stripped and refurbished.
- Central Post, Rotterdam; renovation of an existing post office, during which the façade was partially replaced.

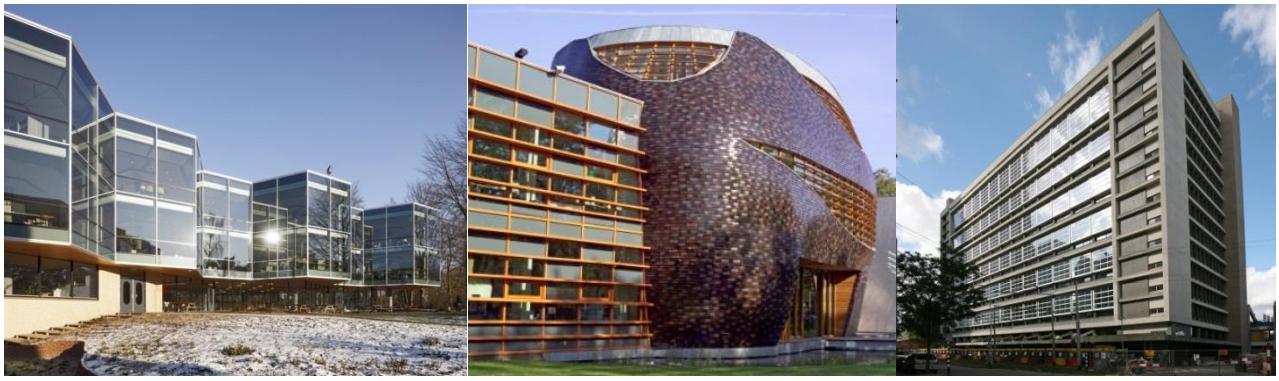

Fig. 2, 3, 4: DHV, WNF and Central Post after renovation (source: vd Meijden).

Of all three renovation projects, in this research project a same south facing part with similar properties of each building was investigated, to generate comparable results. Although the office buildings have the same function and are partly comparable, investigating the complete building is outside the scope of this research. Two office spaces divided over two floors behind the south facing façade are selected for this research, because office spaces are the most relevant spaces in the buildings and the south facade has the biggest effect on the annual cooling and heating load. The selection of two floors is made for a relevant comparison between the three buildings. The facade of the Central Post building in Rotterdam is in fact repeated per two floors and the facades of the other projects are repeated per floor. The simulated space has a width of 8 meters, a length of 8m and a total height of 7m over 2 floors. The length and width of the investigated office space is larger than a standard Dutch office space, because the office lay out of all three projects consists of open office landscapes in this research. For each building the same technical installations are applied, for a relevant comparison of the influence of the façades on the operational energy performance. For all cases, only the material performance of the façade has been taken into account. Installation, lighting, and all other interior building components are out of the scope of this research. For the calculations of the office facades a technical lifetime of 30 years (21) was chosen as reference.

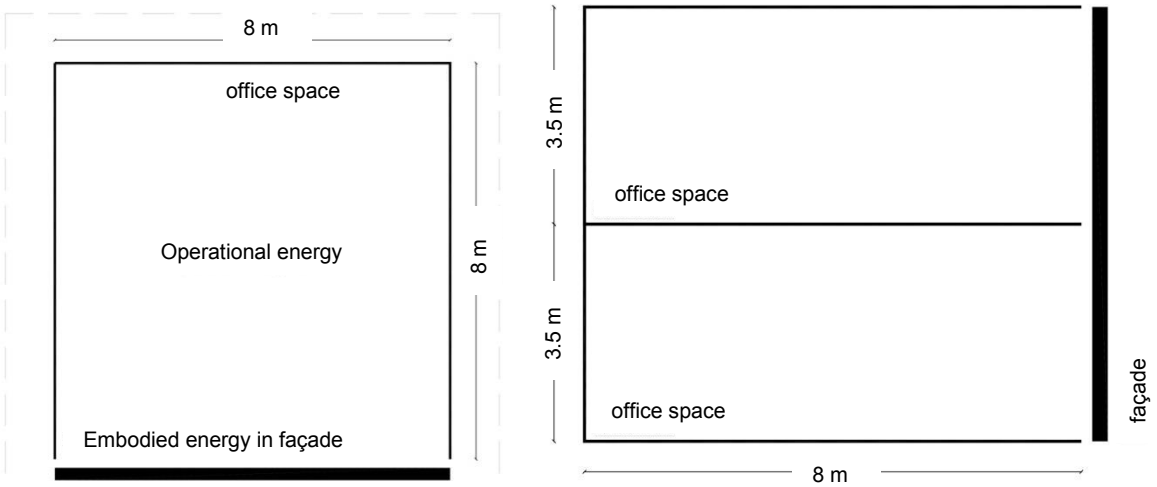

Fig. 5, 6: Floorplan and section of investigated office space.

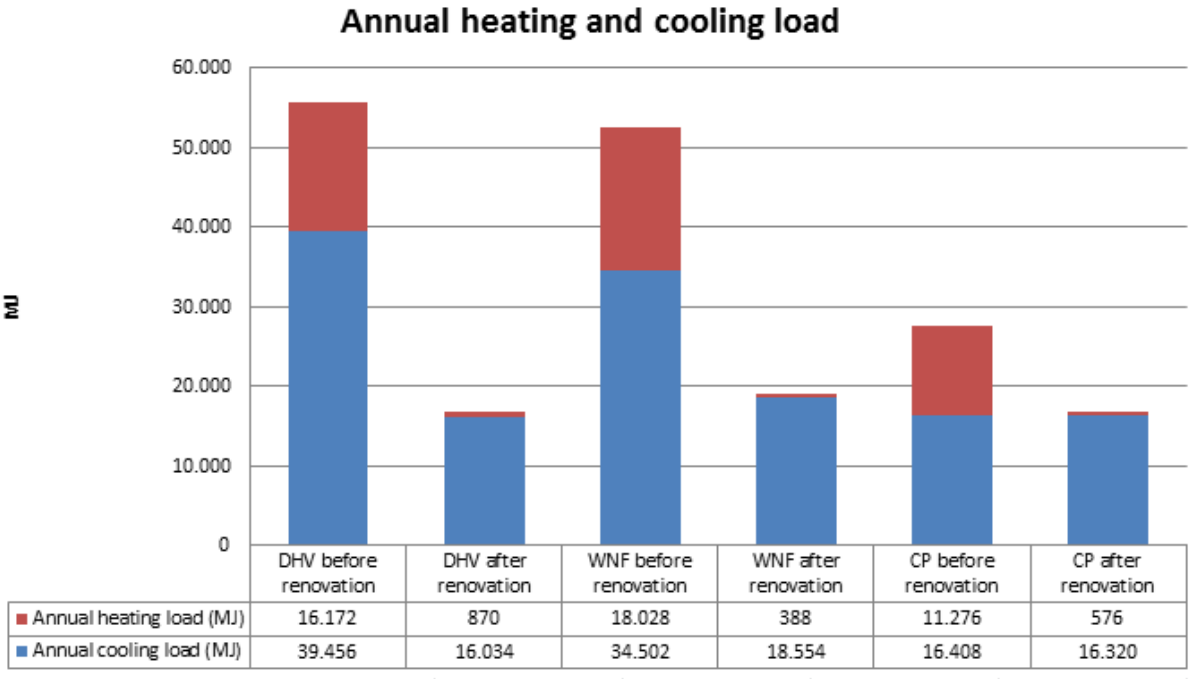
3. Results

In the following subchapters, the calculated results of the different applied assessment tools, Greencalc+, operational energy, embodied energy and embodied land are presented and combined.

3.1 GreenCalc+

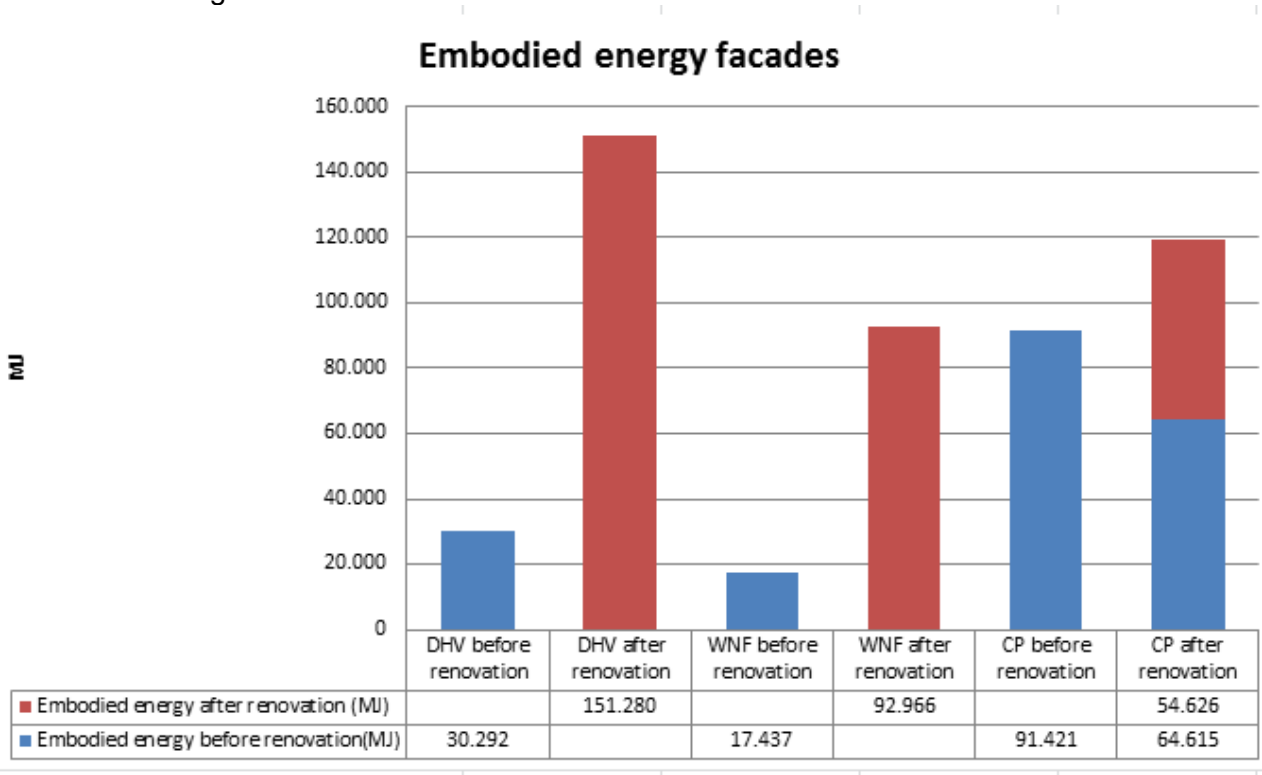


The results of all projects (table 1) show a final score above 200 and all projects score both in the field of energy performance and material consumption an A, which is good. In the results there is no difference between the various projects in the field of energy performance and material consumption. The WNF office has the highest total score, probably because the building generates energy by itself and the other buildings don't.

Table 1: Greencalc+ score of all projects.

	DHV office, Amersfoort	*WNF office, Zeist*	*Central Post, Rotterdam*
Material	A	A	A
Energy	A	A	A
Water	E	F	G
Total	*239*	*269*	*252*

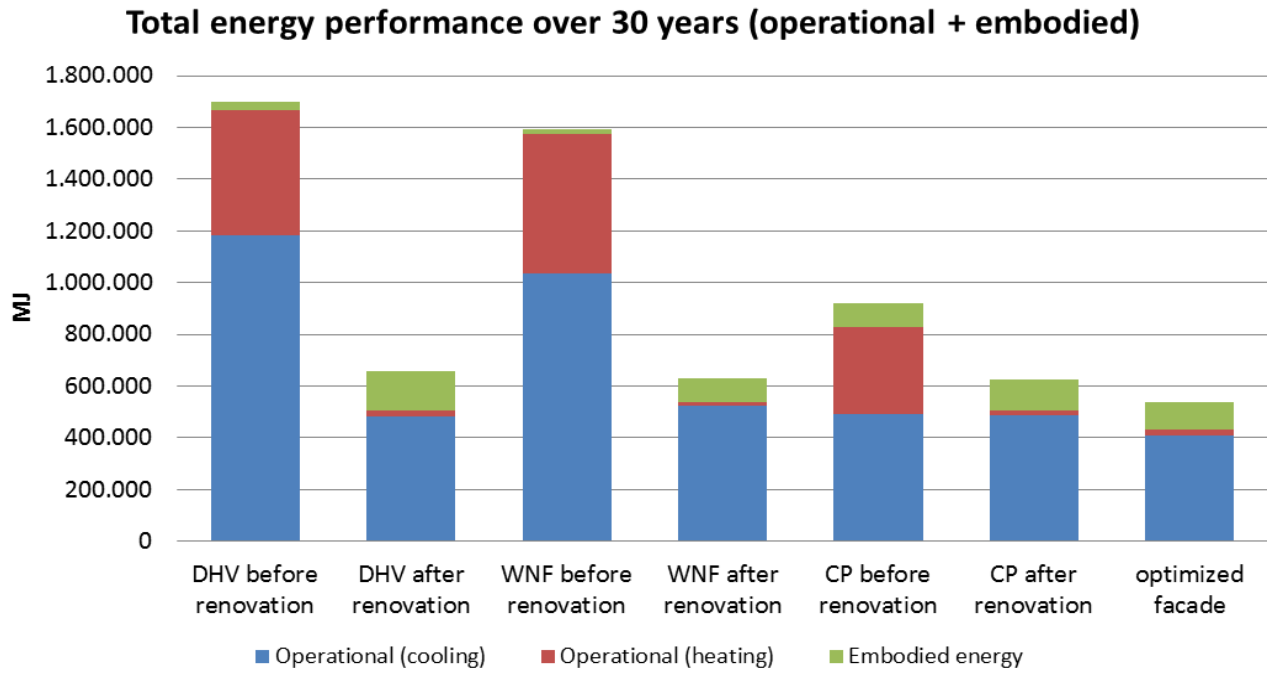
3.2 Operational energy



Graph 1 shows the results of the annual cooling and heating load of each project before and after the renovation, calculated with VABI 114. The heating and cooling load of all three buildings after the renovation is almost equal. The cooling load of the investigated south orientated space is in all buildings the largest energy factor both before and after the renovation. The renovation of the façade has mainly impact on the heat load of the building. The heating load is strongly reduced after the renovation. This is achieved mainly by increasing the R value of the façade, applying materials with higher values of thermal insulation, and the application of high insulation HR++ glass.

Graph 2: Annual heating and cooling load.

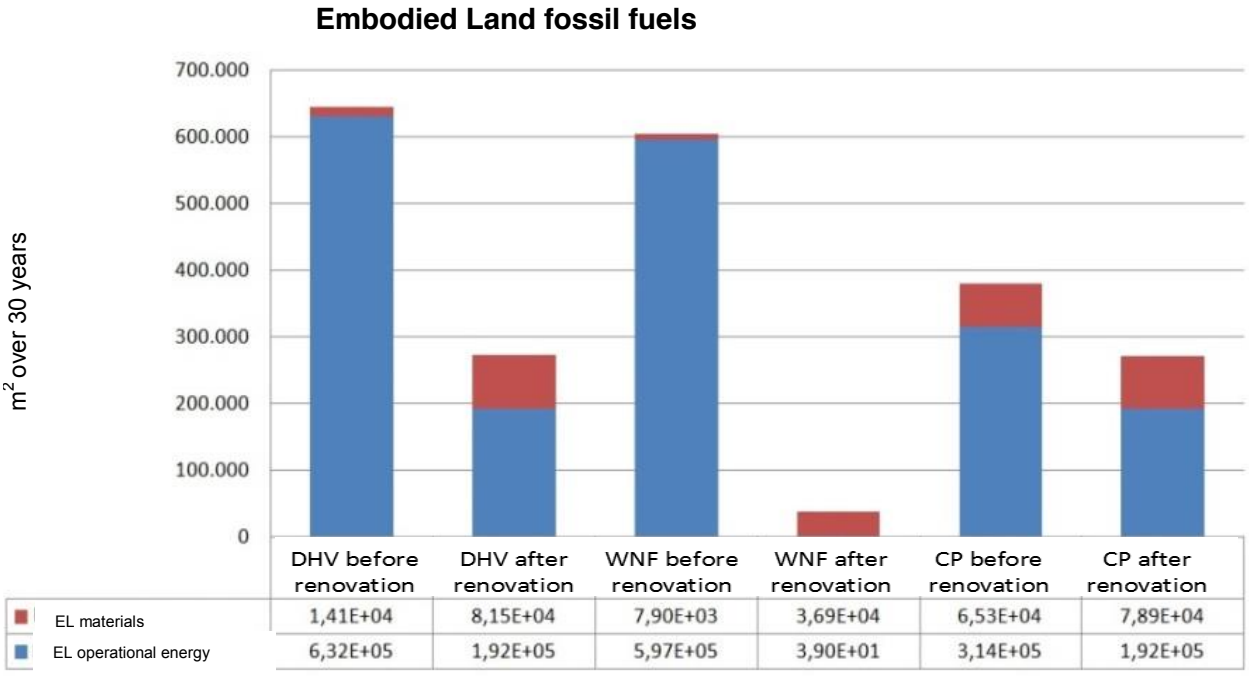
3.3 Embodied energy



Graph 2 shows the results of all embodied energy values of the facades of the three projects before and after the renovation. The blue columns show the results before renovation and the red columns after renovation. The embodied energy required for the facades of the DHV office and the WNF office after the renovation is many times higher than the embodied energy of the facades before the renovation. After renovation, the DHV office has a new aluminum curtain wall obtained with HR++ double glass and the WNF office has new wooden curtain wall with triple HR+++ glazing filled with krypton gas. The embodied energy required for the new facade of the Central Post building is relatively small compared to that of the other buildings. This is because this façade was only partly replaced and remained largely unchanged. Furthermore, the embodied energy required for the original façade was already very high due to the large amount of the heavy materials concrete and steel. The existing aluminum facade with single glazing is replaced by a new aluminum front with HR + + glass.

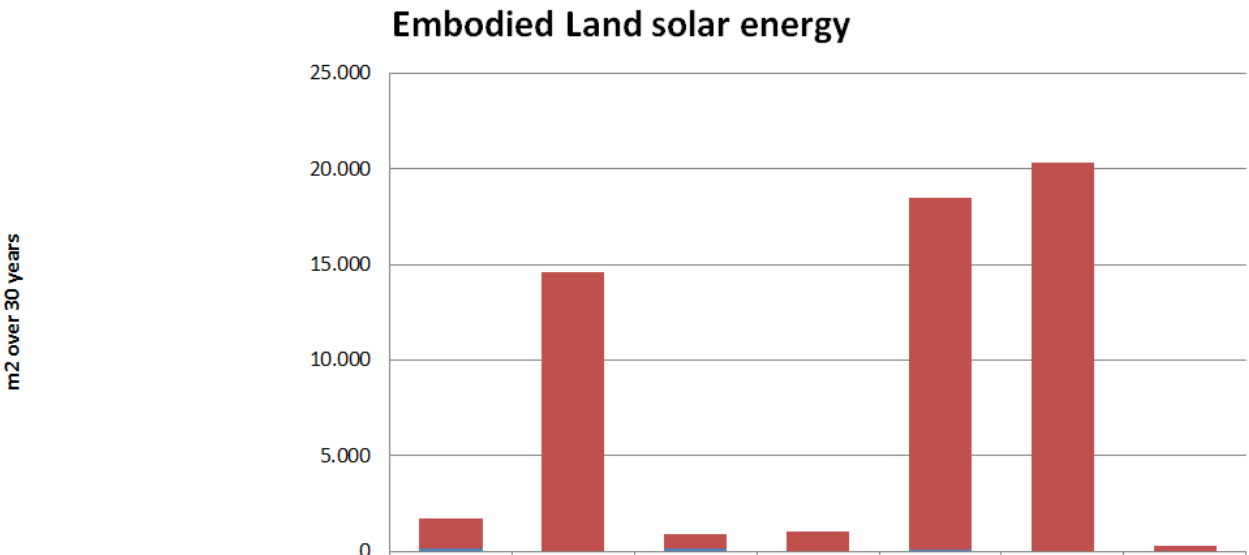
Graph 2: Embodied energy before and after the renovation.

3.4 Relation between operational energy and embodied energy



In graph 3 the results of total energy consumption are shown (operational energy of the office and the embodied energy of the façade) before and after the renovation, for a total technical lifetime of 30 years. The results indicate that, for the investigated south facing office space, the cooling load has the largest energy demand, both before and after the renovation. It also shows that the heat load of the office space after the renovation is minimal, which is a result of the improved thermal properties of the facades after the renovation. To achieve these improved thermal properties more embodied energy is required for the facades. In general the embodied energy of the facades increases after renovation, but the cooling load remains the largest energy demand. An exception is the WNF office because this building has become self-sufficient after the renovation. If in this case the operational energy (total heating and cooling load) is not included, the total energy consumption of the building consists of embodied energy so material use will become the determining factor.

Graph 3: Total energy performance over 30 years.

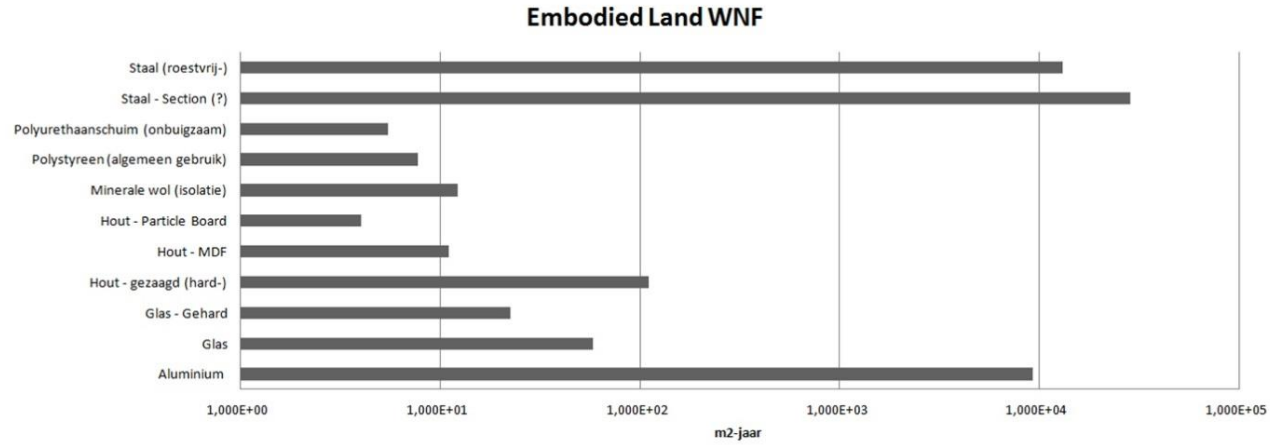


3.5 Embodied land

Graph 4 show the calculated Embodied Land of facade materials and the calculated Embodied Land of operational energy of the office space, when all energy required for the operational energy, is based on fossil fuels. In this case the embodied land of the operational energy is the determining factor with respect to the embodied energy for the materials of the façade. Only the results of the WWF office show a different situation where the material use is the determining factor. This is because after the renovation operational energy in this building is generated by solar energy.

Graph 4: Embodied Land based on fossil fuels over 30 years.

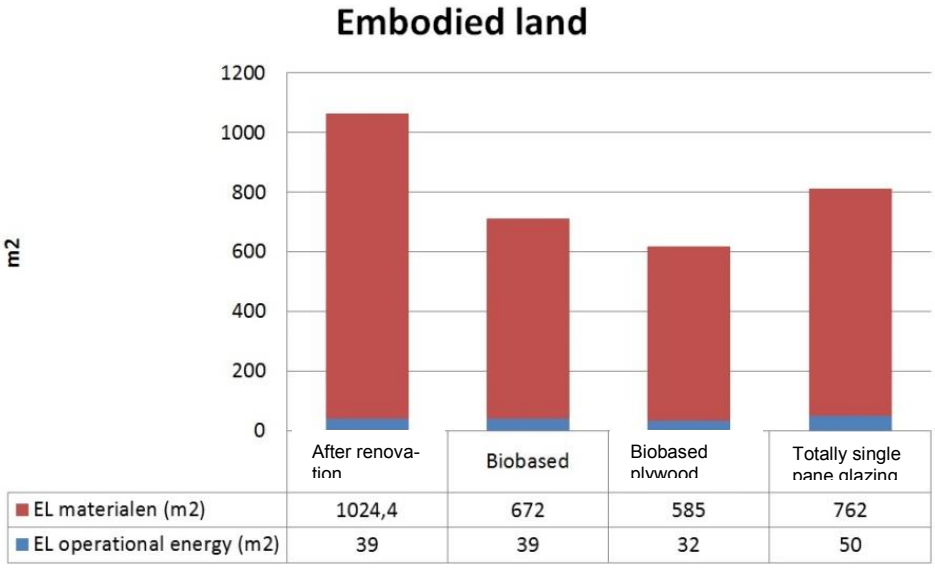
Graph 5 shows the results of the Embodied land, when all energy is generated by solar energy (solar panels and solar collectors). In this calculation, the total embodied land for all projects is much smaller than with a similar calculation using fossil fuels, due to the large time-land impact to generate fossil fuels. Secondly, the embodied land for the façade materials is much greater than the embodied land for the operational energy. The embodied land of the operational energy is in most cases negligible compared to the embodied land for the façade materials.



Graph 5: Embodied Land based on solar energy over 30 years.

The results also show that the facade of the WNF office after renovation scores very good in comparison with the other facades in all assessments. The facade of the WNF office consists mainly of wood, a natural material with low embodied energy. Natural (biobased) materials score very well in the embodied land calculation, because these materials can grow back naturally by themselves, so a closed-loop system is created without adding energy.

A closed-loop system for the materials is created when a material that is used as a building product has grown back within the lifetime of the façade, and all energy to realize the building product has been generated. The aluminum, concrete and steel that are used in the facades of the DHV and the Central Post Office are non-biobased and cannot grow back. These materials are however recyclable and partially reusable. The recycling percentages of these materials are not 100%, for aluminum it is 94% (22). According to the MAXergy calculation a lot of energy is needed to win back the non-recycled percentage of these material.



4. Analysis and optimization of the WNF façade

Based on the results presented in chapter 3, the façade of the WNF building has been further investigated and optimized. Analysis on the material consumption (graph 6) in the WNF facade shows that most of the Embodied Land of the facade originates from non-renewable materials. In the first place these are the metals in the facade used for connections, steel profiles, glass profiles, etc. and in the second place the glass and the insulation materials.

Graph 6: Embodied Land of different materials in the WNF façade.

Based on this analysis, a first comparison has been made, in graph 7, between the current façade after renovation; a 100% biobased version of the façade with the current openings; a 100% biobased version of the façade with no openings; and a 100% open version of the façade with single pane glazing, all without external blinds.

Graph 7: Embodied Land of different façade options for the WNF façade.

The Embodied Land of the materials is in all versions still larger than the Embodied Land of the operational energy, indicating the importance of material performance in this assessment method. Even when the facade consists of a minimum amount of biobased materials (only a plywood sheet), the Embodied Land required for the operational energy is small.

Optimized design

To improve the environmental performance of the office façade within the Dutch Building Regulations, the maximum possible use of renewable energy sources should be made for power generation. Optimally would be a maximum energy output with minimal material use. To minimize the embodied land of the facade a maximum use of bio-based materials should be made. The non-biobased materials, like metals, need to be recycled as much as possible. When metals are used, they need to be 100% recycled so it does not need to be recovered.

The optimized façade design of this research aims at minimizing the embodied the land of the façade materials, within the Building Regulations. The façade design consists for 93% of biobased materials, in which most of the metals have been replaced by the fiber-reinforced composites. The facade needs 70% less embodied land than the WNF façade (see graph 3 and 5). In addition, in the design is taken into account that materials are easy to separate.

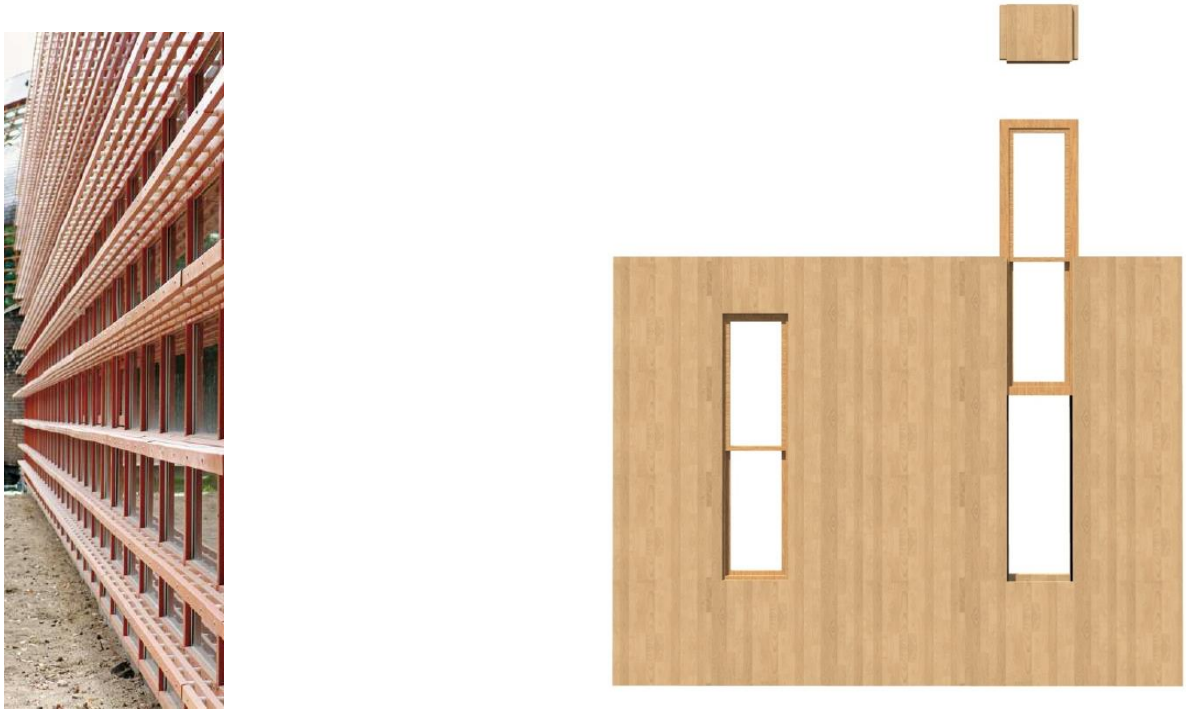


Fig. 7, 8: Picture of the existing renovated WNF façade and optimized design (vd Meijden).

4. Conclusions & discussion

Based on the case studies and on the optimized façade design, the following conclusions concerning operational energy performance, material performance and the related land use are drawn.

- In all projects the embodied energy of the facade after renovation has increased compared with the situation before the renovation. The operational energy performance has improved in all cases.
- Besides the amount of materials also the choice of materials determines the embodied energy of the façade.
- The cooling load is the largest energy part of total energy performance both before and after the renovation and the embodied energy of the facades is a small portion of the total energy demand for a lifetime of 30 years.
- The embodied energy of the building becomes the largest energy aspect, when the operational energy is fully generated by renewable energy sources (e.g. solar and wind) on-site, as at the WNF office after the renovation.
- The Embodied Land calculations indicate that the amount of materials and the choice of materials in nearly all situations determine the land-time impact. Biobased materials like wood score very well in this calculation because the low amount of embodied energy and because these materials are renewable.
- The Embodied Land calculations based on fossil fuels show in almost all cases that the operational energy is the determining factor compared to materials. An exception is the WNF office after the renovation because in this case the operational energy of the building is generated by itself through solar energy. In this situation, only the embodied energy is generated by fossil fuel so the material use becomes the determining factor.

- It can be concluded that material use becomes the determining factor with respect to the operational energy when energy in a building is generated by renewable energy sources. Through the increasing requirements for sustainability of buildings in the future the use of renewable energy sources to generate energy will increase strongly. The materials use and the required land use to create the materials for generating the renewable energy will also increase.

Based on this research project, the following discussions concerning the MAXergy tool are drawn to suggest further research in this direction.

- The embodied land calculation by Maxergy is based on the surface of solar panels and solar collectors, which is necessary for generating electricity and heat. The results of the embodied land calculations are therefore highly dependent on the efficiency of the solar panels and solar boilers used for this.
- The embodied land calculation is realistic if all energy (operational and embodied) is generated by solar energy. This is not always corresponding with the reality. Operational energy is in some cases generated by solar energy, but the majority of embodied energy is not. Therefore, a comparison is made between the land use by means of fossil energy and solar energy. It is interesting to do further research into land use by using the current energy mix (fossil fuels, nuclear and renewable energy). It would also be interesting what the difference is in land use between the current energy mix.
- An important part of the MAXergy calculation is the recovery of raw materials (especially metals). In many cases this is the decisive factor for the final result. For the recovery of metals for example a method is chosen, in which metal particles are filtered from seawater. This includes a number of assumptions. Further research should be done on the recovery of metal particles.

The environmental footprint of plastic pipe systems within the built environment

Short Summary

The European Plastics Pipes and Fittings Association (TEPPFA) deems it important to have an insight into the integral environmental burdens encountered during the life-span of particular plastic pipe system applications within the built environment. With this framework in mind, TEPPFA has set up a project with the Flemish Institute for Technological Research (VITO). The aim of this project is to carry out several life cycle assessment (LCA) studies from the cradle to the grave. The LCAs of several plastic pipe systems outline the various environmental aspects which accompany the pipe systems, from the primary extraction of raw materials up to and including the end of life (EoL) treatment after their reference service life time. To get a better view on the advantages and disadvantages from an environmental point of view of a pipe system in plastic compared to its main competing non-plastic material, LCA comparisons were made. The conclusions of the comparative LCA studies show that the average environmental impact of plastic pipe systems in general are lower than the average environmental impact of piping systems made out of traditional materials.
This paper reports on the LCA of some specific plastic pipe systems with the final aim of providing a clear environmental product declaration (EPD), thus raise the awareness amongst developers, installers and users, of the potential environmental impacts and benefits over the complete life cycle. In addition some comparisons for the environmental impact category global warming (CO2 footprint) are presented and discussed.

Keywords

Plastic pipe systems, life cycle assessment (LCA), environmental product declaration (EPD), European sector approach, sustainable construction and housing.

1. About TEPPFA

TEPPFA stands for The European Plastic Pipes and Fittings Association. It is a trade association representing the key manufacturers and national associations of plastic pipe systems. TEPPFA is actively involved in the promotion and acceptance of plastic pipe systems for all applications. It has a

voluntary initiative, commitment to develop EPDs for several types of plastic pipe systems. The EPD initiative of TEPPFA aims to measure the environmental impact of plastic pipe systems throughout their entire life cycle and to communicate about the results by means of EPDs.

2. Life Cycle Assessment (LCA) of plastic pipe systems

LCA is a standardized tool that assesses the environmental impact of products, processes and/or systems throughout their entire life cycle. LCA quantifies the potential environmental effects of a product, a process or a system over its entire life cycle, meaning that the extraction of raw materials, the production of materials and the product, the use and the end-of-life treatment are taken into account.

TEPPFA created cradle-to-grave LCAs consistent with ISO 14040 [2], ISO 14044 [3] and the pre and final EN 15804 [4] and EN 15942 [5].norms. The overall objectives of the TEPPFA LCAs are:

- to analyse the environmental impacts of different applications of plastic pipe systems in selected application groups;
- to investigate the relative performance of various plastic pipe systems at the system level in order to show that material choices cannot be made at the product or material level only;
- to use the results of the LCA-studies of the plastic pipe systems for business-to-business communication by means of EPDs;
- to compare the environmental footprint of the plastic pipe systems with the environmental footprint of non-plastic pipe systems.

Within the TEPPFA framework the environmental impact categories as defined in EN 15804 are considered [4].

Table 1: The environmental impact categories considered in the LCAs

Abiotic depletion:	exhaustion of natural resources
Acidification potential:	emissions from manufacturing processes resulting in acid rain
Eutrophication:	over-fertilisation of water and soil
Global warming:	insulating effect of greenhouse gases, such as CO_2 and methane
Ozone layer depletion:	depletion of the ozone layer in the atmosphere caused by emissions of pollutants
Photochemical oxidation:	photochemical reaction of sunlight with primary air pollutants, that leads to chemical smog

3. Environmental Product Declaration (EPD) of plastic pipe systems

The EPDs for plastic piping systems provide LCA-based information from the cradle to the grave. The EPDs are provided in a standard communication format according to the EN 15942 [5]. The EPDs can be downloaded from the TEPPFA website (http://teppfa.eu/sustainability-a-environment/-epd.html). TEPPFA created the EPD framework. The member companies that produce plastic pipes and fittings provided their life cycle inventory (LCI) data to TEPPFA. Then the LCAs are carried out by VITO, critically reviewed by an external and independent expert from Denkstatt and Third Party Reports and EPDs are created and published on the TEPPFA website. The process reflects a European sector approach for EPDs.

4. Overview of the LCAs and EPDs for plastic pipe system applications

- Sewage and drainage applications (non-pressure):
  - PVC-U solid wall sewer pipe system [12]
  - PVC-U multilayer (foamed core) sewer pipe system [13]
  - PVC-U multilayer (core of foam and recyclates) sewer pipe system [14]
  - PP structured (twin) wall sewer pipe system [15]
  - PP solid wall sewer pipe system [20]**
  - PP structured wall multilayer sewer pipe system [20]**
- Water and gas distribution applications (under pressure):
  - PE water pipe system [8]
  - PVC – U water pipe system [9]
  - PVC – O, MRS 31,5 MPa, water pipe system [10]
  - PVC – O, MRS 45 MPa, water pipe system [11]
  - PE gas pipe system [19]**
  - PE water pipe system installed by directional drilling technology **
- Soil and waste applications in the building (non-pressure):
  - PP pipe system [6]
  - PVC-U pipe system [7]
  - PP low noise pipe system [18]**
  - PVC-U low noise pipe system [18]**
- Plumbing, hot & cold applications in the building (pressure):
  - PEX solid wall pipe system [16]
  - Polymer, aluminium, polymer multilayer pipe system [17]
  - PP-R pipe system [21]
  - PB-1 pipe system**
- Rain gutter applications:
  - PVC-U rain gutter system**

** In preparation

5. Some results for plastic pipe systems

5.1. Sewage and drainage applications

The functional unit of the sewer pipe systems that have been studied has been defined as: “the below ground gravity transportation of sewage over a distance of 100 m by a typical public European plastic pipe system and its alternative concrete pipe system from the entrance of a public sewer system to the entrance of the waste water treatment plant, over their complete reference service life of 100 years, calculated per year”.

PVC-U solid wall sewer pipe system
The environmental impacts of the PVC-U solid wall sewer pipe system is mainly caused by the product stage (raw materials) and the construction process stage (excavation of the). When comparing the PVC-U solid wall sewer pipe system with a concrete sewer pipe system fulfilling the same functional unit, we can conclude that for most environmental impact categories the contribution of the concrete pipe system is relatively lower, although the difference is not significant. Only for global warming of the PVC-U solid wall sewer pipe system has a lower contribution (see Figure 1).

PVC-U multilayer (foamed core) sewer pipe system
The technical possibilities of the plastic pipe systems provide excellent tools to fit these systems to many different requirements. A new product in which a reasonable amount of plastic is replaced by air reduces the environmental impacts dramatically in most environmental categories. When considering a multilayer sewer pipe system instead of a solid wall sewer pipe system, the environmental impacts are reduced significantly. At the same time the environmental impacts of a

PVC multilayer foam core pipe system results in a lower contribution in comparison to the environmental impact of a concrete pipe system and this is valid for all environmental impact categories considered. Figure 2 presents the comparison for global warming.

PVC-U multilayer (core of foam and recyclates) sewer pipe system

In this type of PVC-U multilayer pipe system the virgin PVC material in the core of the pipe wall is replaced partly by foamed virgin PVC and recycled PVC. When considering this multilayer sewer pipe system instead of a solid wall sewer pipe system, the environmental impacts are reduced significantly. At the same time the environmental impacts of this multilayer pipe system with a core of foamed PVC and PVC recyclates results in a lower contribution in comparison to the environmental impact of a concrete pipe and this is valid for all environmental impact categories considered. The use of recyclates further reduces the CO2 equivalent. Figure 3 presents the comparison for global warming.

Figure 1: Comparative environmental profiles: PVC-U solid wall versus concrete sewer pipe systems

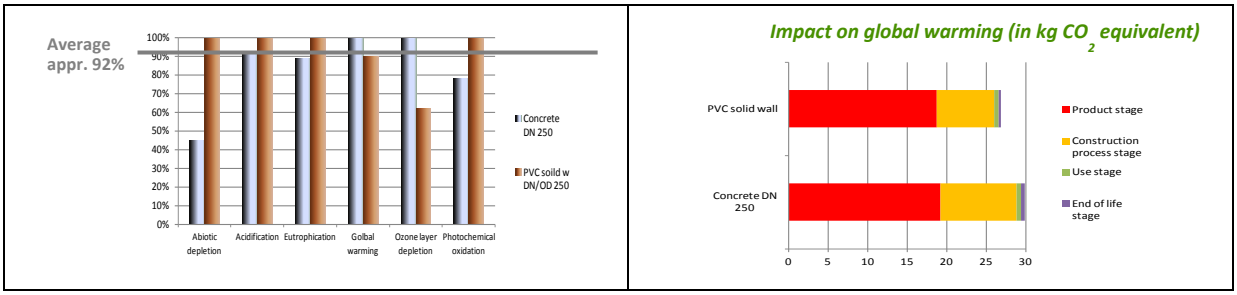

Figure 2: Comparative environmental profiles: PVC-U multilayer (foamed core) versus concrete sewer pipe systems

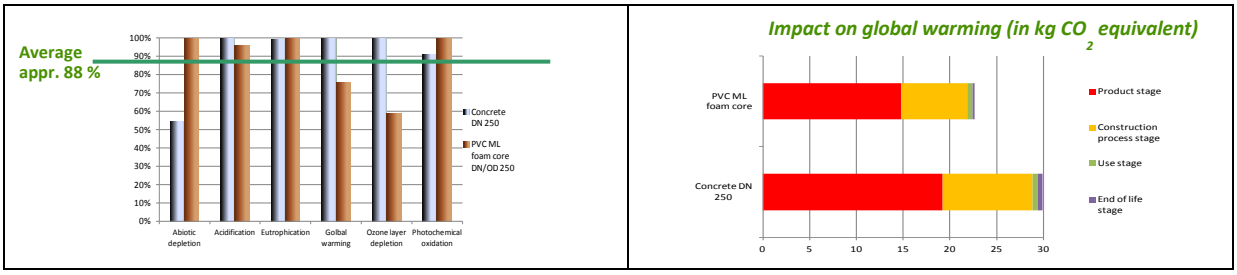

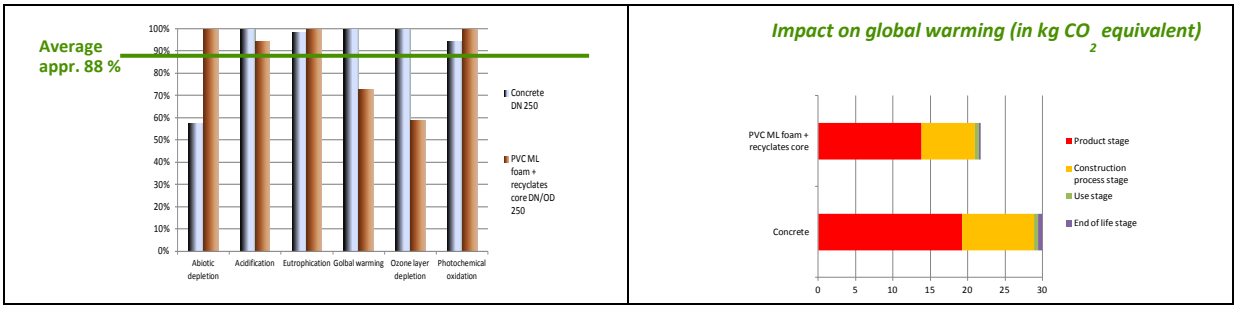

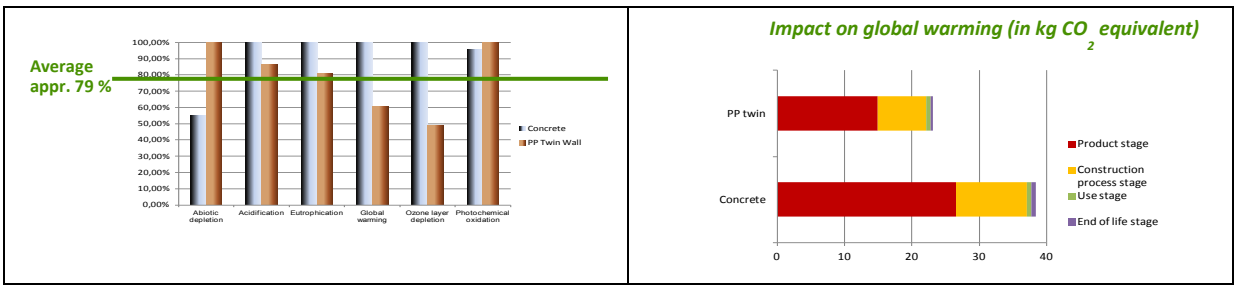

Figure 3: Comparative environmental profiles: PVC-U multilayer (core of foam and recyclates) versus concrete sewer pipe systems

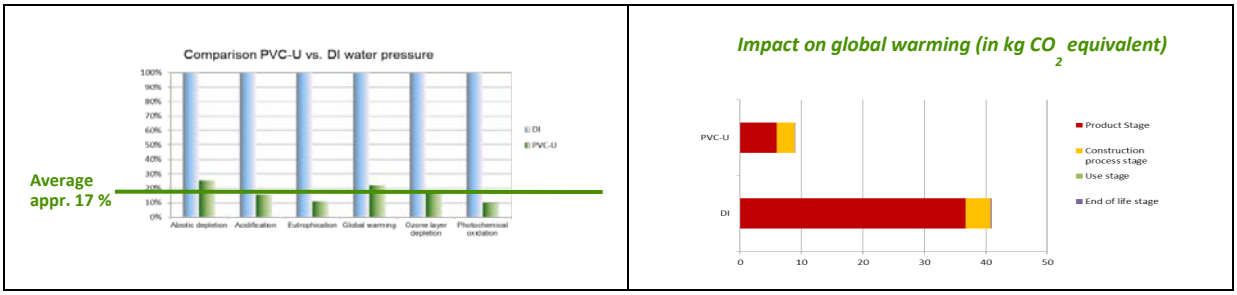
PP structured (twin) wall sewer pipe system

In this LCA study DN/ID 300 PP and DN 300 mm concrete piping systems are compared. When considering a PP sewer pipe system with a structured (twin) wall in comparison to a concrete sewer piping system this results in a relatively lower contribution for all environmental impact categories considered. The excellent environmental behaviour of PP twin wall sewer piping system is again an evidence on the innovative nature of plastics. Figure 4 presents the environmental comparison.

Figure 4: Comparative environmental profiles: PP structured twin wall versus concrete sewer pipe systems



5.2. Water and gas distribution applications

The functional unit of the water and gas distribution pipe systems that have been studied has been defined as: “the below ground transportation of gas/drinking water, over a distance of 100 m (from the exit of the water plant to the water meter of the building), by a typical public European plastic pipe gas/water distribution system and its alternative ductile iron pipe system over their complete reference service life of 100 years, calculated per year.”

PVC-U water pipe system

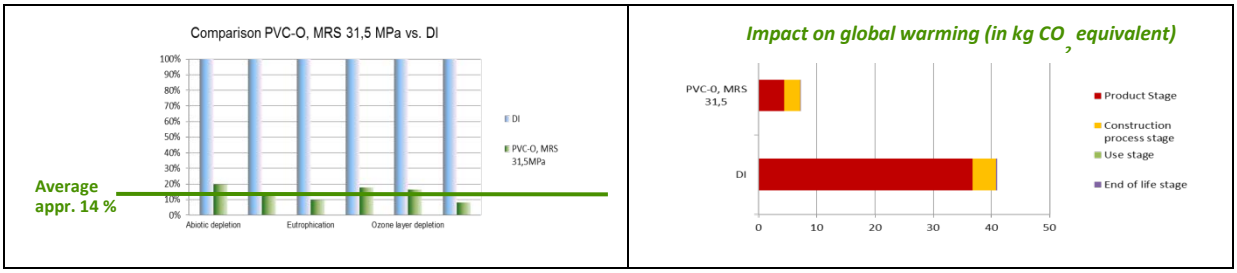
The environmental profiles of the PVC-U water pressure pipe system is mainly caused the raw materials (PVC) during the product stage and by the construction process stage (mainly due to excavation operations at the trench). When considering all environmental impact categories of the LCA, we can conclude that the environmental impact of the PVC-U water distribution pipe system is significantly lower than the ductile iron pipe system that is fulfilling the same function (see Figure 5).

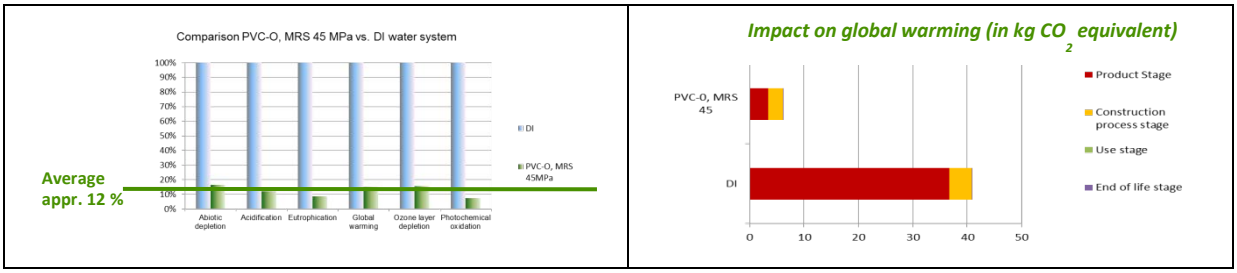
Figure 5: Comparative environmental profiles: PVC-U versus ductile iron water pipe systems

PVC-O water pipe systems (bi-oriented)

Two PVC-O bi-oriented water pipe systems have been assessed: the PVC-O 31,5 MPa pressure and the PVC-O 45 MPa pressure pipe system for water distribution. Both environmental profiles are dominated by the product stage (raw materials production) and by the construction process stage (excavation operations at the trench). When considering all environmental impact categories of the LCA, we can conclude that the environmental impact of both PVC-O water distribution pipe systems is significantly lower than the ductile iron pipe system that is fulfilling the same function (see Figure 6 and Figure 7).

Figure 6: Comparative environmental profiles: PVC-O (31,5 MPa) versus ductile iron water pipe systems





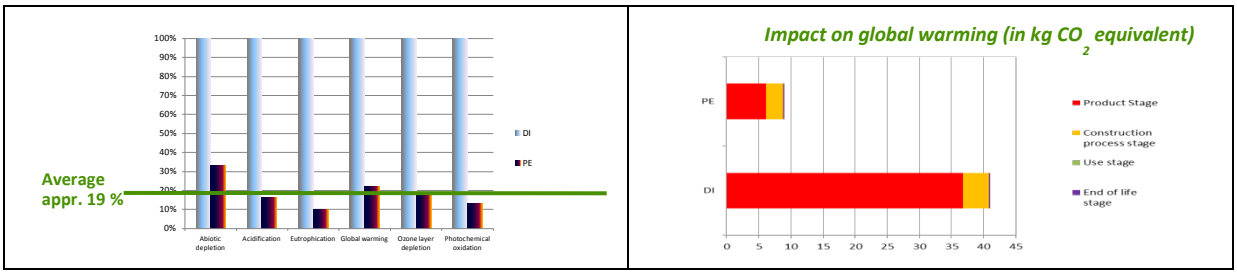


Figure 7: Comparative environmental profiles: PVC-O (45 MPa) versus ductile iron water pipe systems

PE water pipe system

The environmental profiles of the PE water pressure pipe system is mainly caused the raw materials (PE) during the product stage and by the construction process stage (mainly due to excavation operations at the trench). When considering all environmental impact categories of the LCA, we can conclude that the environmental impact of the PE water distribution pipe system is significantly lower than the ductile iron pipe system that is fulfilling the same function (see Figure 8).

Figure 8: Comparative environmental profiles: PE versus ductile iron water pipe systems

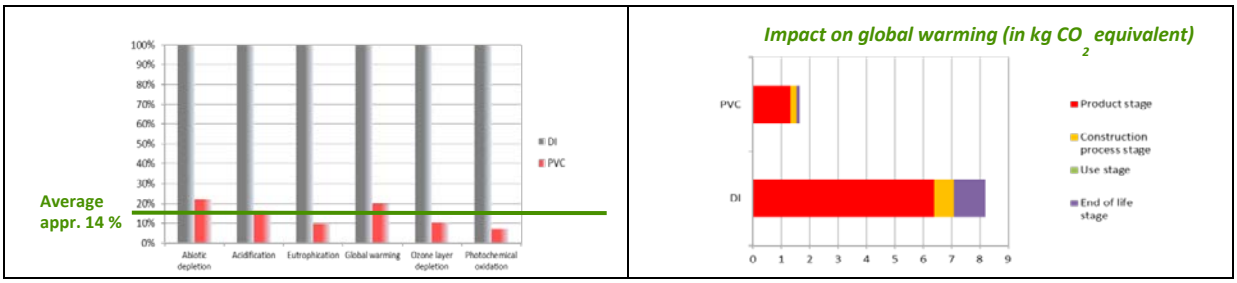
5.3. Soil and waste applications in the building

The functional unit of the soil and waste pipe systems that have been studied has been defined as: “the yearly impact of different soil and waste gravity drainage systems’ installation into a typical European 100 m² apartment, incorporating a bathroom, separate WC, kitchen and washroom, considering the reference service life of the pipe systems to be aligned with the 50 year of reference service life of the apartment”.

Plastic soil and waste pipe system

The environmental profile of the PVC-U and PP soil and waste pipe systems is mainly determined by the product stage and more specifically by the production of the different pipe system components. When considering the environmental impact of a PVC-U and the PP soil and waste pipe systems compared to a ductile iron soil and waste piping system it results in a significantly lower contribution for all the environmental impact categories considered (see Figure 9 and Figure 10).

Figure 9: Comparative environmental profiles: PVC-U versus ductile iron soil and waste pipe systems



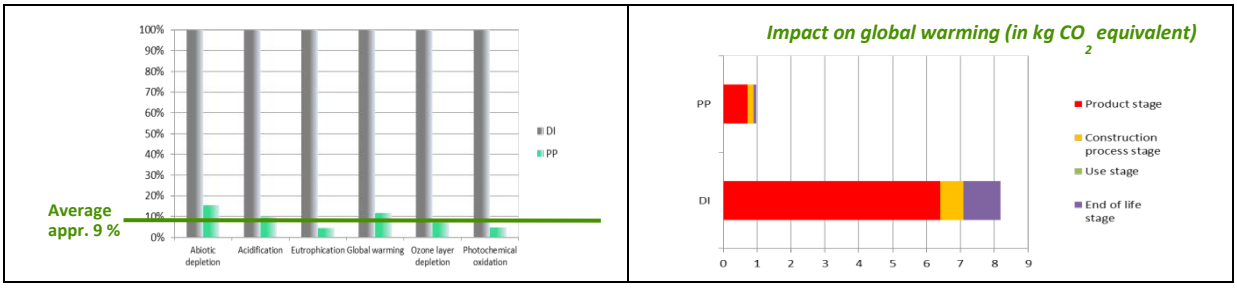


Figure 10: Comparative environmental profiles: PP versus ductile iron soil and waste pipe systems

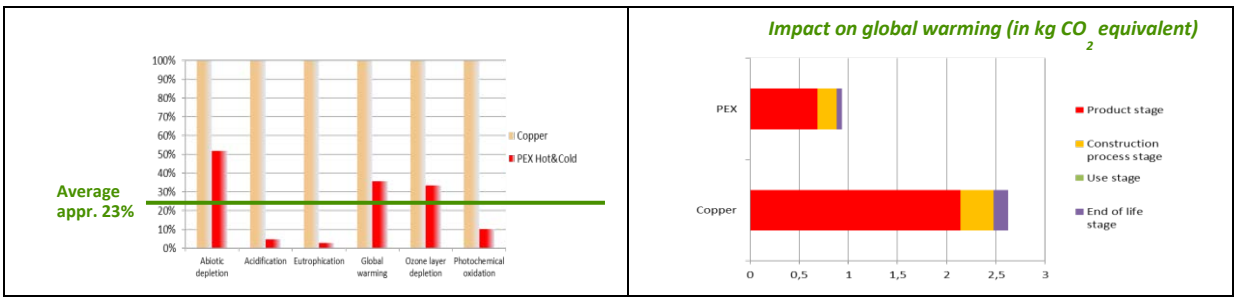
5.4. Plumbing, hot & cold applications in the building

The functional unit of the hot and cold pipe systems that have been studied has been defined as: “the pressure supply and transport of hot and cold drinking water, from the entrance of a well-defined apartment to the tap, by means of a hot and cold drinking water pipe systems’ installation, supplying a 100 m² apartment, incorporating a bathroom, separate WC, kitchen and washroom, considering the reference service life of the pipe systems to be aligned with the 50 year reference service life of the apartment. The environmental profiles are calculated per year.”

Plastic pipe systems for hot and cold

The environmental profile of the PEX solid wall and the polymer – aluminium – polymer multilayer pipe systems for hot and cold water in the building is mainly determined by the product stage and more specifically by the production of the different pipe system components. When considering the environmental impact of the plastic pipe systems for hot and cold water compared to a copper hot and cold pipe system it results in a significantly lower contribution for all the environmental impact categories considered (see Figure 11 and Figure 12).

Figure 11: Comparative environmental profiles: PEX solid wall versus copper hot and cold pipe systems



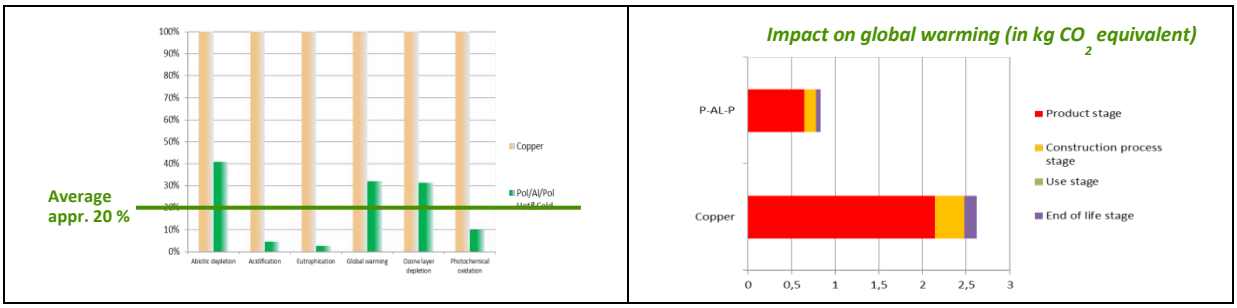


Figure 12: Comparative environmental profiles: Polymer/Al/polymer versus copper hot and cold pipe systems

6. Conclusions

The development of EPDs allows a comprehensive insight in the environmental impact of plastic pipe systems over their entire life cycle.

The results of the LCAs indicate that the impact of plastic pipe systems on the environment is relatively lower compared to the environmental footprint of main non-plastic piping materials.

The contribution of plastic pipe systems to global warming (CO2 footprint) is for all plastic piping systems that have been studied lower in comparison of pipe systems made out of competing materials for the pipes.

TEPPFA is committed to develop new EPDs for other types of plastic pipes and fittings.

TEPPFA members are committed to further reduce the environmental impact of plastic pipe systems.

Short Summary

The Bavarian Center for Applied Energy Research (ZAE Bayern) is currently raising the new R&D building “Energy Efficiency Center” [1] (EEC) within a public funded research project. The EEC, which will be finished by June 2013, includes offices, laboratories as well as an Info-centre which is open to the public and informs the visitors about the implemented innovative systems and current R&D activities within the funding scheme “Research for Energy Optimized Buildings”.
The overall aim of this project is to demonstrate the compatibility of energy efficiency, user requirements and appealing architecture. The EEC aims to be a technology reference and along with the strong interaction of research, demonstration and dissemination at one place it is supposed to accelerate innovation processes in the field of energy optimized buildings.
Since the EEC is a partial lightweight building with a translucent building envelope and high internal heat gains, an integral, sustainable concept for cooling is required. For this, several new technologies are combined. To minimize energy consumption and to ensure thermal comfort for the employees a highly innovative building automation system will regulate and control the interaction of the single systems.
The centrepieces of the cooling concept are two fire fighting cold water tanks with a volume of 100 m³ each, which are connected to the buildings cooling circuits. While one tank as a backup is cooled by a conventional compression cooler, the second tank is connected to the ZAE-developed “Passive Infrared Night Cooling” (PINC). PINC is an open rainwater circuit using natural re-cooling via infrared heat radiation exchange with the cold night sky on a special area of the roof. It is therefore a highly efficient, energy saving cooling method. The cold water is used for the cooling units in the laboratories as well as for the regeneration of the implemented PCM cooling ceilings in the offices. The PCM cooling ceilings are a new development which improves the thermal connection of the PCM to the room air as well as to the cooling circuit. At daytime the PCM is cooling the room passively while melting. When outside air is too cold or too hot for natural ventilation of the building, tempered air is supplied by a Liquid-Desiccant Cooling System (L-DCS) which uses a concentrated hygroscopic salt solution for dehumidification and evaporative cooler for cooling.
After its completion the building will undergo a comprehensive long-term monitoring and optimization phase.

Keywords: PCM; energy storage; cooling concept; energy efficiency; L-DCS

1. Introduction

Current approaches in reducing CO_2 emissions as part of international and national climate protection policies are based on people's consciousness about the increasing threat of the greenhouse effect. Likewise, ecological and economical consequences, as well as the constantly augmenting costs of fossil fuels have promoted these current policies to significantly reduce CO_2 emissions. In view of plans to increase the energy efficiency by 20% until 2020, turning old buildings into energy efficient ones as well as establishing high standards for energy efficiency of new buildings has become notably important in Germany. Suitable insulation of buildings alone for example may reduce heating demand by 50% while it significantly improves thermal comfort inside buildings. Besides that, with growing insights in the field of energy research several new technologies were developed in the past years which promise more energy efficiency in buildings. Anyhow, in the building sector innovations often take many years until being accepted on the market. This means that a great potential of energy savings is still unused.

Based on these facts the main target of the new R&D building for the Bavarian Center for Applied Energy Research (ZAE Bayern) is to combine cutting edge energy efficient technologies, to optimize their interaction, to identify synergy effects and to accelerate their introduction to the market by demonstration. These ambitious goals are promoted by gathering the know-how of the involved research partners from science and industry and by exchanging experience and ideas. In order to save energy and to provide sustainability and comfort, the main goal is rather to find a reasonable approach to optimize the building’s technology and its innovative envelope than to construct a model for a zero-energy building [1].

Due to the innovative, resource saving lightweight construction of the EEC including a membrane rooftop as well as the highly insulated lightweight facades, the EEC will show a highly dynamic thermal behavior. Because of high internal heat gains from measurement setups, electronic devices, solar gains and occupants high requirements especially for cooling have to be met. As the aim is to minimize the conventional cooling power backup in order to achieve high efficiency, new approaches with innovative technologies and building materials are required to meet the demand. In this paper an overview of the innovative technologies integrated into the EEC and the cooling concept using several energy storage technologies will be presented.

2. Energy Efficiency Center (EEC)

The Energy Efficiency Center (EEC), illustrated in *Figure 1*, is currently under construction and expected to be finished in June 2013. The overall aim of the design of the EEC is to create a reference building which implements innovative techniques, serves demonstrational purposes, and is used for research and development in the field of energy optimized buildings. Hence, the project not only involves integral planning, but also setting up and putting an innovative building into operation. The new research building involves innovative, energy efficient materials, components, and systems, all of which are to demonstrate their applicability for both old and new buildings. The EEC is designed to be easily extendable and is equally devoted to energy efficiency and aesthetically architectural design [2].

Figure 1: Perspective view of the EEC (© Lang Hugger Rampp GmbH).

The EEC includes offices, laboratories and a technical center as well as the corresponding infrastructure for the research activities of the ZAE Bayern in Würzburg. Furthermore, a seminar room, a conference room and a public Information Center are part of the room concept. In the Information Center, the development results of the EnOB-program (Research for Energy Optimized Buildings), funded by the Federal Ministry of Economics and Technology (BMWi), will be presented and explained.
The two-storied building is characterized by a light-weight construction in combination with a highly transparent building envelope with large glass surfaces. It is covered by a translucent roof membrane which serves as weather protection and plays an important role in light and climate management of the building as it creates an intermediate climate zone which acts as a preconditioned heat-insulating layer in the cold season and can be ventilated in summer to prevent overheating. Underneath the roof membrane there is an insulating layer which is carried out partly opaque, partly translucent using highly insulating aerogel modules in order to facilitate optimal daylight conditions for the offices underneath.
The lightweight facades are triple glazed with applied low-e coatings and insulated with vacuum insulation panels in the opaque sections.

Due to its partly translucent roof construction and the large fraction of glass façade the EEC in some parts achieve almost 100% daylight autonomy and no artificial lighting is needed most of the time. A side effect of the partly translucent building envelope is an increased solar heat input. As the outer shell of the building as well as the interior construction is lightweight because of flexibility requirements and resource saving aspects, little heat storage capacity is available to buffer temperature fluctuation. As a result, frequent changes between heating and cooling demand would occur in spring and fall, and elevated temperatures would likely occur in summer. To avoid room climates outside the comfort range without integrating too large conventional cooling power reserves, a combination of several thermal energy storage (TES) technologies is implemented to meet the cooling demand in an energy efficient way. The storage technologies are:

- room integrated phase change materials (PCM) to add additional thermal mass to the building (PCM in wallboards and PCM in cooling ceilings),
- a liquid desiccant cooling system (L-DCS) with a concentrated salt solution as energy storage to supply cool or preheated dehumidified air to the building,
- Passive Infrared Night Cooling (PINC) to provide the cold for appliance cooling and PCM regeneration stored in one of the cold water storages.

These storage technologies will be presented below.

3. Applied TES technologies

The cooling concept of the EEC is based on the integration and interrelation of four different innovative thermal energy storage systems. The implemented passive systems include the integration of PCM in building materials and the ZAE-developed passive infrared night cooling with cold water (PINC), while the active systems include an open cycle liquid desiccant cooling system (L-DCS) as well as an individually optimized cooling ceiling with PCM.

3.1 Passive Infrared Night Cooling (PINC)

The centerpieces of the cooling concept are two fire-fighting cold water tanks with a volume of 100 m³ each, which are connected to the building's cooling circuits via heat exchangers. Whereas one tank is cooled by a conventional compression cooler, the second tank is connected to the ZAE-developed "Passive Infrared Night Cooling" (PINC). A scheme of this system, which is successfully in operation at the existing building of the ZAE Bayern since 2000, can be found in *Figure 2*.

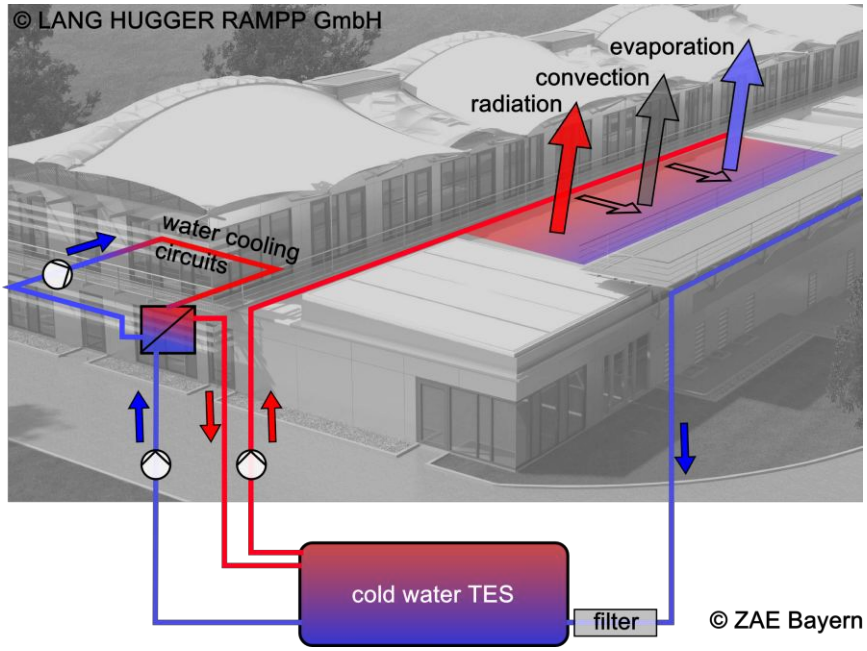

Figure 2: The cooling load is connected to the TES by means of a heat exchanger. The water in the TES is re-cooled on the rooftop, mainly during night time. The cooling effect is caused by infra-red heat radiation exchange as well as convection and evaporation.

PINC is a highly efficient, energy saving cooling method. Cold water is extracted from the bottom of the tank, pumped through a heat exchanger within the building to extract heat from the building, and the resultant warm water is fed back into the tank underneath the surface of the water. This process leads to a pronounced stratification inside the tank with temperature gradients of approx. 1 K/m. In order to re-cool the cold water TES, the stored warm water is pumped up to the roof at night and sprinkled over the sheet metal roof of the building where it runs freely and is cooled down chiefly by the heat radiation exchange with the cold night sky but also by evaporation and convection. The cooled water is fed back into the bottom of the tank. Electrical energy is only used for pumping the rainwater onto the roof. High coefficients of performance (>20) can thus be achieved [3].
As PINC is an open system, water evaporates and the loss has to be compensated which is automatically achieved by additionally collecting rain water from the roof.

3.2 Liquid Desiccant Cooling System (L-DCS)

Apart from the PINC storage system an open cycle liquid desiccant cooling system (L-DCS) is

installed in the EEC. Such a system can reduce ventilation cooling loads of buildings, which often amount to more than 50% of the total cooling load, very efficiently [2]. A scheme of the system as well as an overview of the cooling concept is shown in *Figure 3*. Outside air is dehumidified in an absorber by a concentrated hygroscopic salt solution (lithiumchloride) and subsequently cooled in an air cooler. The conditioned air is then provided to the building. The warmed-up air returning from the building is used in indirect evaporative coolers to produce cooling water by evaporating water from wetted heat exchanger surfaces. The cooling water cools subsequently the supply air cooler and the absorber. The dehumidification process of the outside air is driven by a flow of concentrated salt solution. The solution is diluted in the dehumidification process and has to be regenerated. In a regenerator the solution is re-concentrated by evaporating water at temperatures of 70°C to 80°C with the district heating net acting as heat source. The system of concentrated and diluted salt solution stores driving energy for this process very efficiently. The salt solution can be used as energy storage and transport medium. In winter the heat exchangers installed in the absorber and evaporative coolers can act as a heat recovery system. The open cycle liquid desiccant cooling system (L-DCS) was developed under participation of ZAE Bayern in a BMWi-funded project [4].

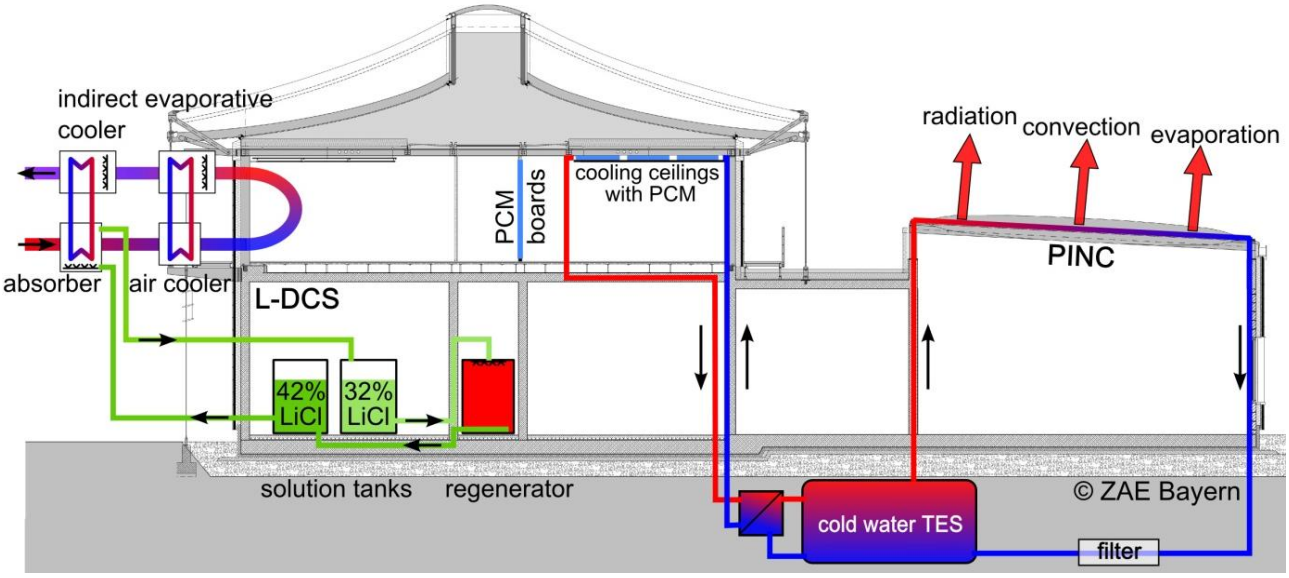

Figure 3: Overview of the implemented innovative TES systems and their interaction. The L-DCS dehumidifies and cools or preheats outside air for additional room temperature regulation. During this process the salt solution dilutes and has to be regenerated.

3.3 PCM in wallboards and cooling ceilings

During the last 15 years, ZAE Bayern has collected extensive experience in the field of Phase change materials (PCM) in buildings in several public funded projects (e.g. [5], [6]). PCM undergo a reversible phase change between the solid and the liquid state in a material specific temperature range. By the phase change PCM are able to store a large amount of heat in a narrow temperature range as all absorbed heat is required to break up the bonds of the crystal lattice. As this happens at a constant temperature level the process is called latent heat storage (*Figure 4*). Therefore the implementation of room-integrated PCM has a temperature stabilization effect and allows the buffering of temperature peaks without the need of energy consuming conventional cooling systems. If the (encapsulated) PCM is completely in its liquid state heat can only be stored as sensible heat and no temperature stabilization effect takes place. Hence, the PCM is regenerated at night to restore its high heat storage capacity. Since the stored heat is again released during the solidification process of the PCM, ways to remove this excess heat from the building has to be considered.

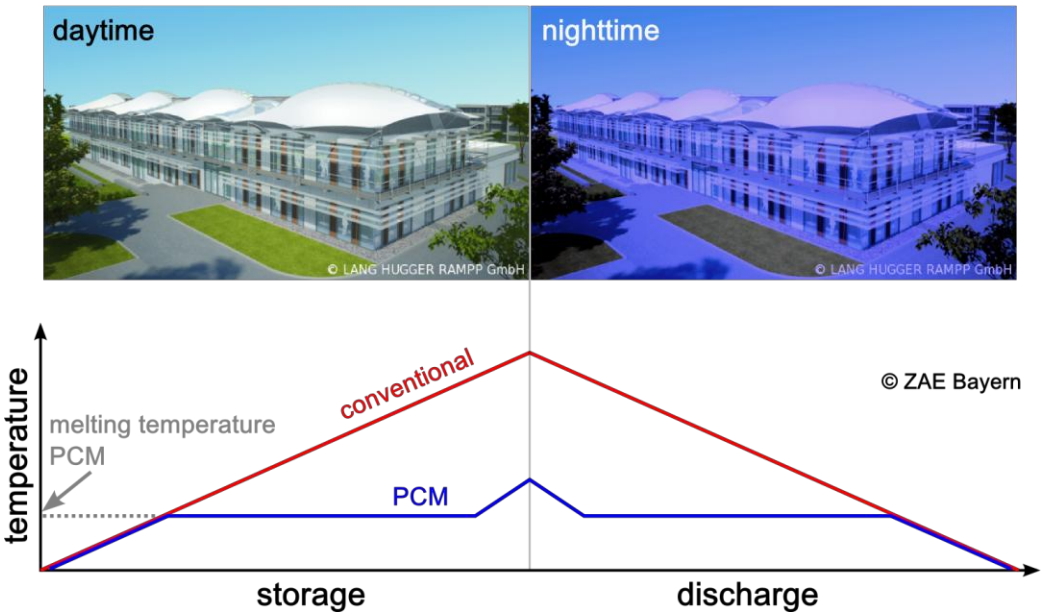

Figure 4: Conventional (sensible) and latent heat storage.

In the EEC, phase change materials melting around 23°C will be incorporated in building wallboards as well as in the cooling ceilings. Experiences show that especially PCM in building materials like wallboards are reacting quite slow to temperature fluctuations of the room air due to low heat transfer coefficients to the room air in the case of free convection. This is problematic during the charging process (passive cooling in daytime) as well as for regeneration of the PCM. In the EEC, natural ventilation will take place during nighttime. If needed, a ventilation system can provide forced convection to overcome the problem of low heat transfer coefficients leading to an acceleration of the charging and discharging process.
The cooling ceilings are individually optimized to reduce the thermal resistances between the PCM and the room air as well as between the PCM and the water cooling circuit. If needed, the stored heat will be removed during nighttime via a cooling water circuit connected to the firefighting water tank which is in turn connected to the PINC system. With the PCM in the ceilings and wallboards and in combination with the supply air of the L-DCS as well as an effective shading regulation no active cooling is needed most of the year. Further optimization of the system is planned during the construction and the operational phase in order to make this application ready for the market.

4. Cooling concept – Integration of TES technologies on EEC

One of the most interesting aspects of the building cooling concept is the integration of both passive and active thermal energy storage systems (see *Figure 3*).

The cold water from PINC is used for the cooling units in the laboratories as well as for the regeneration of the implemented PCM cooling ceilings in the offices. Space cooling in the entrance area, info center and conference rooms is achieved by cold water that is supplied to the heating / cooling floors. Additionally, the equipment in the laboratories is cooled directly by a separate cold water circuit, which is likewise connected to the cold water PINC storage. When the outside air is too cold or too hot for natural ventilation of the building, tempered air is supplied by the Liquid-Desiccant Cooling System (L-DCS).

In daytime, office-cooling at large extend is realized by the PCM incorporated in building materials and the PCM cooling ceilings in passive mode. If the outside air temperature is above 22°C the open cycle L-DCS can support the cooling via cold air supply. Since the PCM melts while absorbing heat, it is of great importance to ensure its regeneration overnight and hence ensure high system efficiency the following day. Specifically, the re-cooling of the PCM at night is required to take full advantage of its latent heat storage capacity. The PCM in the wallboards is regenerated either by natural night ventilation or by forced convection using the ventilation system to enhance

the heat transfer coefficient. The regeneration of the PCM applied to the cooling ceilings can be passively achieved by natural night ventilation or actively by incorporating cold water from the cold water TES. To guarantee the regeneration of the PCM (freezing at about 21°C) overnight, cold water with a temperature between 16°C and 18°C is required to ensure the needed cooling power. This was validated exemplary with a thermal building simulation (ESP-r [7]) for the south-west oriented office (see *Figure 5*) using the test reference year weather data set for Würzburg, Germany, with extreme summer conditions (TRY-Region 13 [8]). The simulation period extends from day 172 to 177 of the year, corresponding to June 21 to June 26. A 14 day forerun was used to initialize the thermal starting condition of the room. In the simulation the room was equipped with 180 kg PCM on a surface of 12.4 m² mounted on the cooling ceiling with an active area of 21 m². The simulated PCM has an assigned specific heat capacity of 72 kJ/kgK in the melting range between 22°C and 24°C. For regeneration of the PCM active cooling with 18°C forerun temperature is applied to the ceiling between 9 pm to 6 am with a volume flow of 316 dm³/h (only weekdays). As it can be seen in *Figure 5* the PCM can be completely regenerated with this cooling strategy. The needed forerun temperatures can be delivered by cold stored in the cold water storage connected to the PINC system and no conventionally generated cooling power is needed most of the time.

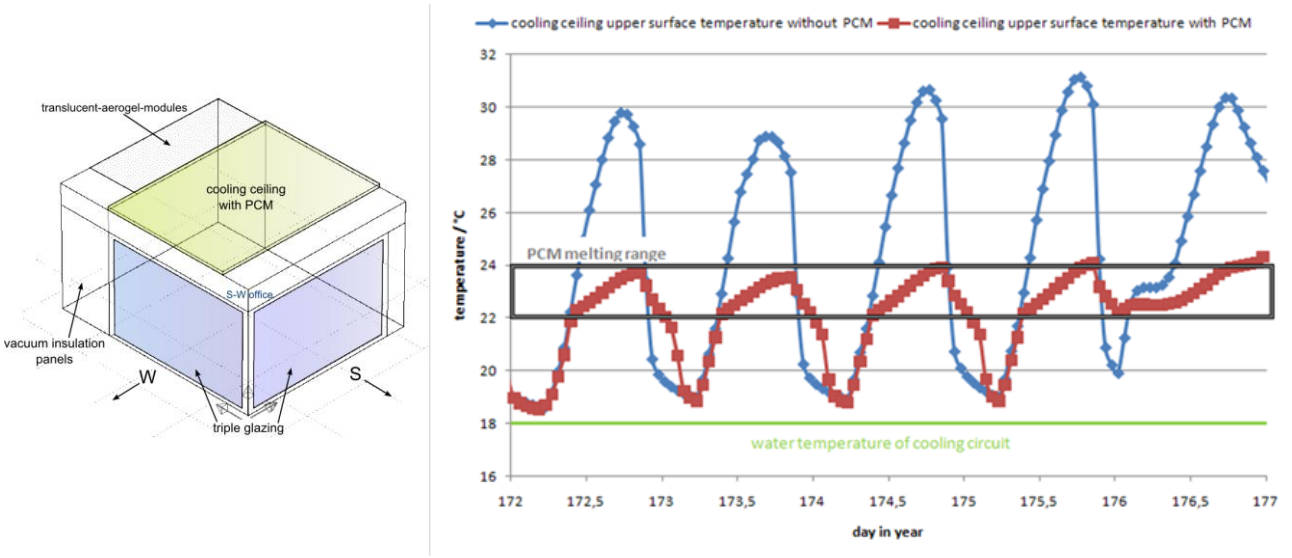

Figure 5: Simulation model used in the ESP-r simulations and temperatures of the upper side of the cooling ceiling without PCM (blue line) and with PCM (red line). The red line corresponds to the PCM-temperature.

The activation of the cooling ceiling may also enhance the regeneration of the PCM-wallboards and therefore leads to a better system performance.
Hence, it is evident that the interrelation of the PCM and PINC systems is important for the overall performance of the cooling concept. The principal aim is to use passive means in order to cover a large fraction of the building cooling loads and consequently use the active L-DCS system when the passive TES systems are not sufficient. During long periods of hot weather the cooling ceilings can also be activated in daytime to meet the comfort requirements. However, to minimize the need of active cooling, the building automation system uses a local weather forecast for a predictive room tempering and a demand-based PCM regeneration by controlling the shading, the night ventilation and the active PCM regeneration.
As there is a differentiation in the energy demand of the various building areas depending on the use of the respective space and the number of occupants, it is important for example to achieve different cooling scenarios for laboratories and offices or conference rooms; constant boundary conditions should be achieved in some laboratories given that constant cooling is often required for some measurement setups connected to the cooling circuit while in offices and seminar rooms there are more fluctuating cooling loads. Therefore, in order to adapt to individual demands and needs, every room has its own intelligent controller to achieve optimal results. Furthermore, energy

inefficient operations such as cooling at a sunny day with open blinds are displayed to the user in the control device and can simply be adjusted on demand by pressing just one button. This generates a user awareness of an energy efficient behavior promoting a positive effect on the overall building performance.
In addition to this building management system, a so called “high level controller” will be available for research purposes. The high level controller interacts with the building management system and allows fast and flexible implementation of control solutions by using the high-performance programming language of Matlab®. Based on a short time weather forecast the “high level controller” decides on the thermal energy storage strategy ("load" or "unload"). The “high level controller" predicts and regulates in real time the optimal control of all thermal storage elements of the building:

- Accessible thermal mass of the building (e.g. by blinds control or passive night ventilation),
- Charge condition of the PCM ceilings,
- Controlling of the Passive Infrared Night Cooling (PINC),
- (Thermal) charge condition of the two cold water TES,
- Charge condition of the solar collector hot water tank.

5. Monitoring

Many developments of the ZAE Bayern in the building sector are demonstrated in buildings, which are distributed over the entire Federal territory. Therefore it is a concern of the ZAE Bayern to bundle several of these newly developed technologies in the EEC and to demonstrate their performance, effective interaction and generated synergy effects in an integral building concept. Since the ZAE Bayern is involved in the development of these technologies, it is an opportunity for optimization und further development of the various innovative systems applied in the building.

Already in the planning and construction phase of the EEC, the monitoring concept as well as the necessary hardware was determined together with the involved project planners in order to create the prerequisite of the intensive monitoring of the building. The second phase of the monitoring concept includes the intensive monitoring of the building where a number of tasks will be fulfilled. Initially, the building energy consumption will be recorded in order to determine the energy consumption characteristics, including the differentiation in various energy consumption data such as auxiliary power for pumps, air support and light. Furthermore, a detailed analysis of all the technical equipment and especially the innovative systems will be performed in order to optimize their operation. After the 2-year intensive monitoring and detailed analysis on energy consumption and user satisfaction, as well as further monitoring on the function and performance of the various systems, the long-term monitoring of the building is being processed. The long-term monitoring lasts at least 3 years and has three objectives; the analysis of the building operation over an extended period, the assurance of a continuous data collection and its delivery to the central database and the possibility of a continuous operation, monitoring and optimization of the various systems.

A significant advantage of the local monitoring and evaluation process is the possibility to directly influence the regulation and performance of single components in a short term. Single components can be removed, modified or changed and then remounted by the scientists. Thereby, an ongoing research and development of the innovative systems can be carried out very efficiently. Also, for selection of the innovative components, neither compromises nor suboptimal solutions have to be taken into account.

6. Discussion / Conclusion

For the first time, the thermal energy storage systems “PCM”, “PINC” and “L-DCS” are combined in one building in order to improve energy efficiency and to use and analyze synergy effects. In cooperation with the building automation system the thermal energy storage systems have an enormous potential to make the use of thermal energy equipment more effective. Subsequently, large scale energy substitutions are reachable which is important from an economic as well as sustainability perspective. Many types of energy storage play an important role in energy

conservation. Thermal storage in a building may be decisive for the reduction of cooling loads and temperature increases, but also the achievement of indoor thermal comfort requirements. In the Energy Efficiency Center the positive effects of energy storage technologies will be proved, the systems and the interaction among themselves will be optimized and verified through a long term monitoring. Therefore this project creates a high attention and has the potential to accelerate the innovation processes in the field of energy optimized buildings.

Short Summary

The recast of the European directive on energy performance of buildings in May 2010 (EPBD, 2010) tightened and added some requirements for new and existing buildings. All member states have to implement national plans to enforce the amount of nearly zero-energy buildings (NZEB) and till 2020 all new buildings have to fulfil this standard [1]. Because of long renovation cycle even existing buildings shall be transformed into nearly zero energy buildings, if major renovation measures are applied.

In the project “B02 enVELOP C - Multifunctional Cover in Refurbishment of Facades and Buildings” a prefabricated renovation system with passive and active modules shall be developed and demonstrated on existing buildings constructed in 1970. Based on an existing passive cardboard insulation system with timber framing, additional active modules with integrated photovoltaic shall be implemented. The photovoltaic cells are integrated into the glass cover of the ventilated façade. A special experimental set-up, developed at the University of Applied Sciences Technikum Wien, should investigate the impact on the natural convective air flow as well as the effect on the insulation properties of the panel.

Keywords: passive house; refurbishment; prefabricated building elements; building integrated renewable energy systems

1. Introduction

The refurbishment of the existing building stock offers high potential for energy savings and contributes a big part to reach the defined climate and energy policy goals for 2020. In Austria the current rate for thermal refurbishment is around 1% [2]. The ambitious goal of the Austrian Climate Strategy of 5% is far away in the medium term [3]. The reasons are quite diverse and relate financial issues, technical requirements, legal regulations and much more.

According to article 9 of the EPBD every member state shall propose measures to increase the number of buildings and encourage best practice transformation of existing buildings into nearly zero-energy buildings [1]. The Austrian implementation of the EPBD is defined in the OIB- Richtlinie 6 [4] supplemented by several standards. The nearly zero-energy building is defined in ÖN-8110-1 depending on the surface to volume ratio. Figure 1 illustrates the current building code and the suggestion of the national plan for 2020, separated for new buildings and retrofit [5]. The horizontal axis is assigned to the surface to volume ratio and the vertical axis to the space heating

demand. As large-volume buildings have a low S/V ratio they are found on the left hand side of figure 1 and single family houses with a high S/V ratio are on the right hand side. Also the standards for low energy house, nearly zero-energy building and passive house are highlighted.

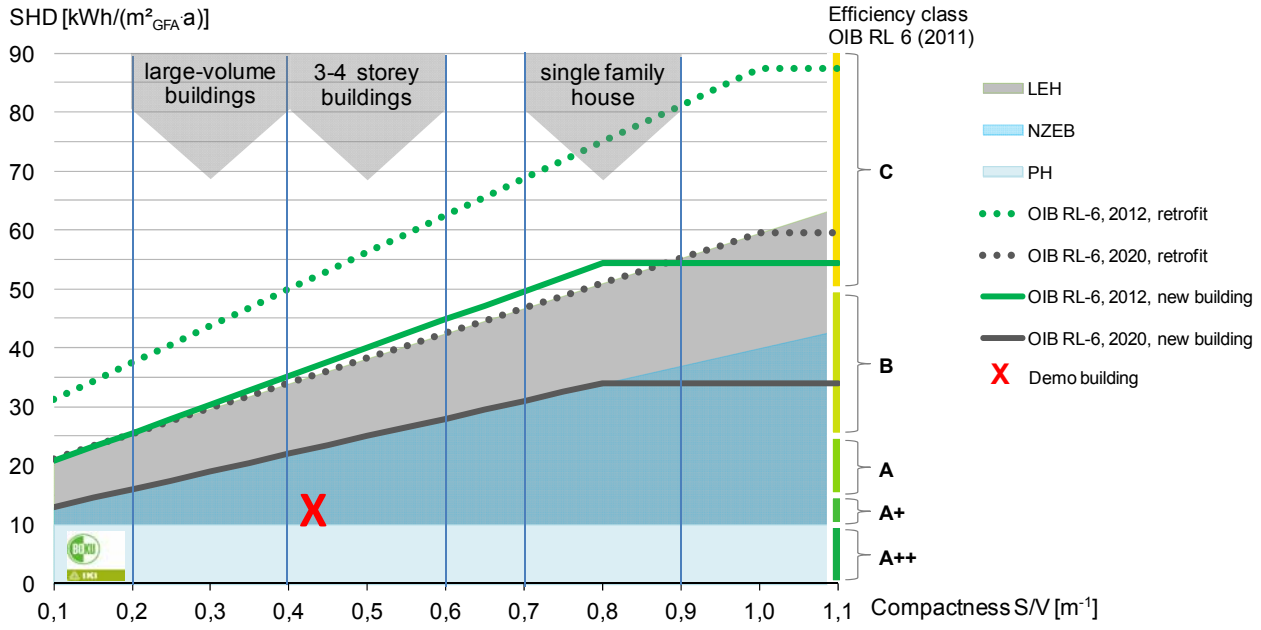

Fig 1: Austrian implementation of the EPBD and national plan till 2020 (SHD: space heating demand, LEH: low energy house, NZEB: nearly zero energy building, PH: passive house) [source: own diagram]

The selected building to be refurbished is a four storey building with a S/V ratio of 0,43 as marked with a red cross in figure 1. The building was constructed in 1970 and has 33 dwelling units for social housing as well as 2 business premises. Because of the hillside situation the basement is separated in dwellings and business premises in the southern half and cellar compartments in the northern half. The current space heating demand (SHD) is about 110 kWh/m^2_{GFA} and shall be reduced to 13 kWh/m^2_{GFA}. All dwellings are inhabited and the refurbishment measures are undertaken during complete inhabitation. To reduce the strain for tenants no floor plan modifications within the dwellings are done. The intervention is basically limited to replace windows and install a decentralised ventilation system. Following constructional measures shall be done:

- **Basement and cellar ceiling:** The southern part of the basement with dwellings and business premises cannot be insulated at the floor slab, as they are inhabited. In the northern part with the cellar compartments the cellar ceiling will be insulated with 8 cm insulation panel as the ceiling height is very low.
- **Exterior walls:** The exterior walls on the south side should be insulated with a novel developed façade system (see chapter 2). The prefabricated façade is based on an existing passive cardboard insulation system with timber framing. In addition active modules with integrated photovoltaic cells shall be implemented. Furthermore the decentralised ventilation system is integrated in the prefabricated panels. On the remaining exterior walls a thermal insulation composite system with 24 cm of EPS F Plus shall be applied.

  The balconies and loggias shall be glazed. Because of their arrangement it is not possible to separate them thermally. The glazing improves their usability as the noise pollution of the street in front is quite high.
- **Top floor ceiling and roof:** The top floor ceiling shall be insulated with 40 cm of insulation and the existing roof cover will be novated. The attic will not be extended.

- **Windows:** All windows will be replaced with triple glazed wood-aluminium windows. The U-value of the new passive house windows is U_w = 0,80 W/(m²K). The windows on the south side will be implemented with integrated sun blinds to protect against overheating in summer season.
- **Thermal bridges:** To reduce thermal bridges the insulation of the exterior walls will be applied below the ground in the area of the unheated cellar. The connection between attic, roof and wall is considered in detail. The window frames will be overlapped with insulation.

2. Façade system

Usual refurbishment actions are based on thermal insulation composite systems on the façade. Beside the southern part a thermal insulation composite system will be applied on the walls of this demonstration building also, because of financial issues. On the southern wall the prefabricated façade described in this chapter will be applied. The system is based on a cardboard insulation panel with timber framing and is distributed by GAP-Solution GmbH. Figure 2 shows the schematic of the panel. The cardboard panel is 29 mm thick and protected by a float glass pane against rain, vermin and other environmental exposures. The special comb structure absorbs solar radiation and heats on the inner wall side. The heat process is dependent on the angle of solar radiation. In winter, when the angle is low, the sunlight gets deep into the comb and heats the underlying wall. The resulting warm zone in the wall reduces the transmission heat loses near zero. In summer, when the angel is high, the sunlight doesn't get into to comb and the heat effect is marginal. The radiation is partly reflected and the combs shade each other. Further information on the cardboard comb panel is found in the technical description, see [6].

Within the project "B02 enVELOP" the gap-solutions system was further developed [7]. In the float glass pane photovoltaic cells were integrated partly. Figure 3 illustrates the integrated PV cells on the first prototype. Because of the dynamic characteristics of the cardboard comb panel the effects of the photovoltaic cells on the thermal behaviour and the rear ventilation of the panel have to be investigated in detail.

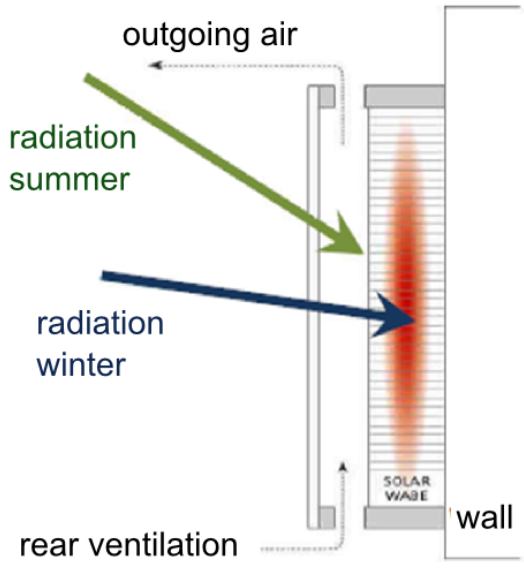

Fig 2: Schematic and function of the gap-solution insulation panel, [6]

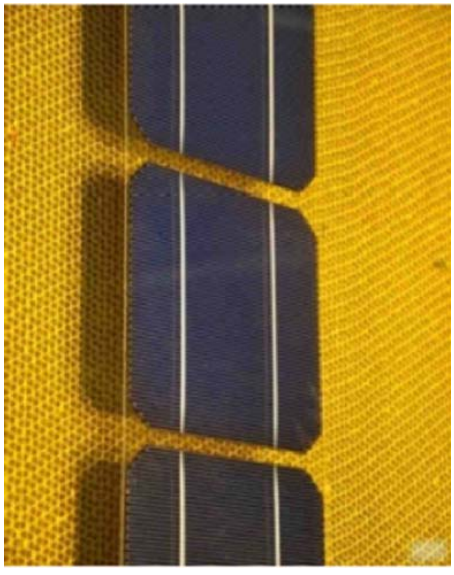

Fig 3: Further development with integrated photovoltaic cells into the glass cover, [8]

3. Experimental set-up

The integrated PV cells provide shading on the façade panel partly. Hence the natural convection flow of the rear ventilation is affected. In addition the solar radiation input is reduced and the warming effect in the combs is influenced.

The goal of the experimental investigations was to identify an appropriate layout for the photovoltaic cells to minimize the effect on the functionality of the façade panel. Furthermore the soiling of the inner glass surface should be assessed as the deposit of aerosols and dust is mainly depending on the convection flow.

The investigations of the effects of PV cell integration were carried out in the laboratories of the University of Applied Sciences Technikum Wien. For this purpose a special experimental set-up was developed. The set-up is based on test facilities of thermal heat panes and was extended for specific measurements.

3.1 Object of investigation

The standard production size of the cardboard comb panel is 1,0 x 1,5 m. The outside dimension of the experimental element was 1,0 x 1,0 m resulting in an aperture area of 0,93 m². The lateral faces were made of acrylic glass to get a visual view inside the rear ventilation layer. The experimental panel was assembled according the actual situation on building sites including cover strips. The underlying wall mounting with insulation and existing wall was not considered.

3.2 Test station

The test station was arranged indoor in the laboratories of Technikum Wien. An artificial light source consisting of six metal halide lamps, each 1.000 W connection power, was used to irradiate the façade panel. A cross-flow radiator fan was used to simulate exterior wind conditions on the glass surface. Below the test panel a reservoir with aerosol-mist was mounted, which could be filled without any pressure. With the reservoir it was possible to visualise the convection flow throughout the entire width of the panel. The panel was equipped with several sensors and measurement devices:

- **Inlet and outlet temperature:** For the measurement commercial PT100 sensing devices were used and calibrated according to DIN EN 60751 [9]. Inlet and outlet temperature were measured with two structurally identical sensing devices each. The results were averaged for interpretation.
- **Temperature in the rear ventilation layer:** The distribution of the temperature in the rear ventilation layer was taken point wise on eleven measurement points. The sensing devices were TESTO thermal flow velocity probes (robust hot bulb). The measured values were logged with the measuring instrument TESTO 480.
- **Velocity of the convection flow:** Similarly the velocity of the convection flow was taken point wise at the same measurement points with TESTO thermal flow velocity probes.
- **Temperature of the outside glass surface:** The temperature on the surface of the glass was taken on the same measurement points and logged with TESTO 435.
- **Thermal flow:** The thermal flow through the panel was measured with two heat flow plates of the company Alhorn and logged with the software LabView.

3.3 General requirements

In Vienna the solar radiation on a vertical and south oriented façade is 811 W/m² at maximum. For the experimental investigations a middling radiation of 508 W/m² was chosen. To align the light sources of the sun simulator to a homogenous distribution of the radiation was a difficult task. Across the entire aperture area the radiation field differed about 13 % and across the defined measurement area about 9%. Figure 4 shows the distribution of the solar radiation on the aperture area of the façade panel. The distribution of solar radiation intensity is according manufacturer certifications similar to the standard spectrum Global AM 1.5 defined in ISO 9845 [10].

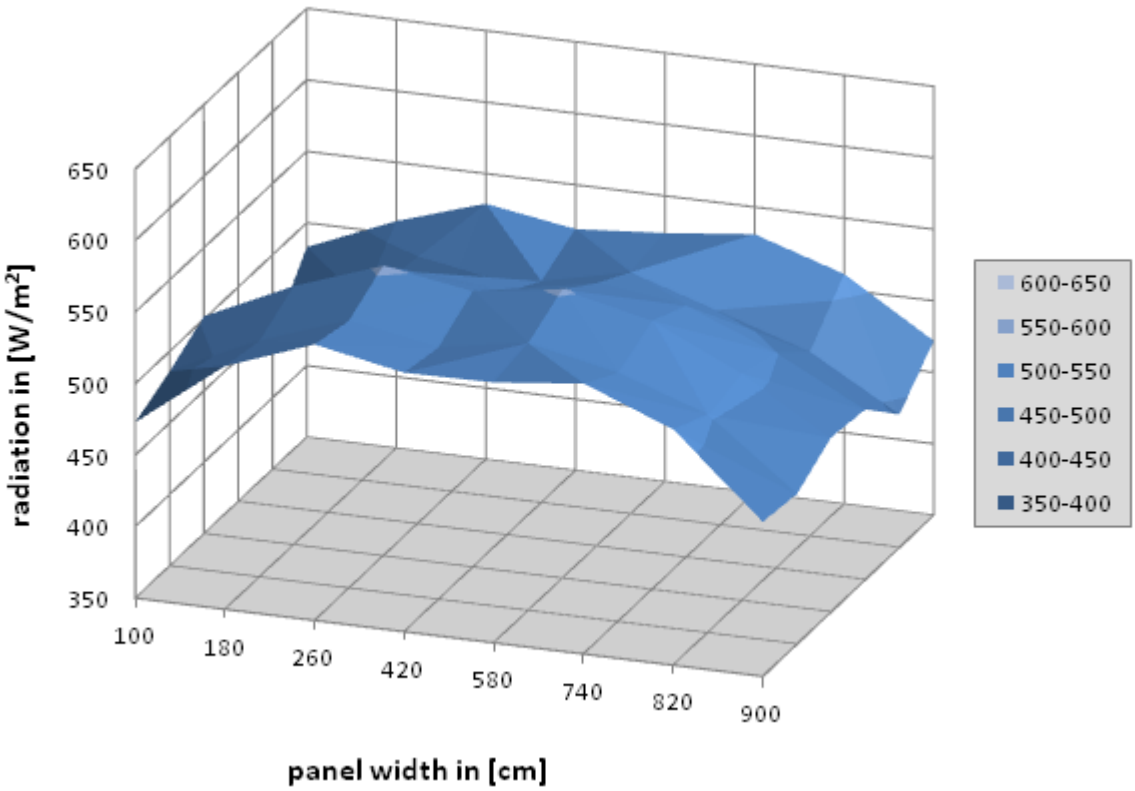

Fig 4: Distribution of the solar radiation on the aperture area of the façade panel, [8]

4. Experimental procedure and results

The main goal was to identify an appropriate layout for the integrated PV cells. Consequently the standard panel has to be investigated at first to define a reference for comparison. The photo-voltaic cells are commercial mono crystalline cells with a dimension of 15 x 15 cm and an electric output of 4,08 W_{PEAK}. For the experimental set-up the integrated PV cells were not connected to each other and have been in a no-load condition. Thus no electrical energy was produced. Four different PV cell layouts were investigated:

- **PV variant 1:** Two columns of vertical aligned PV cells in the middle width of the panel. Each column consisted of six PV cells.
- **PV variant 2:** Two columns of vertical aligned PV cells in the middle width of the panel with a spacing of 20 cm in between. Each column consisted of six PV cells.
- **PV variant 3:** Two rows of horizontal aligned PV cells in the middle height of the panel with a spacing of 20 cm in between. Each row consisted of six PV cells.
- **PV variant 4:** Three rows of horizontal aligned PV cells in the middle height of the panel. Each row consisted of six PV cells.

To generate valid comparisons all measurements were taken in steady state condition, which was achieved after a warm-up period of around 3 hours. The steady state condition was defined by two parameters:

1. the alteration of inlet and outlet temperature was below ± 0,5 °K and
2. the alteration of the thermal flow was below ± 2 W/m².

Each variant was surveyed three times.

4.1 Results on temperatures

In the steady state condition the average inlet temperature was about 24,6 °C for the reference panel. With a middling radiation of 508 W/m² the average outlet temperature was about 44,6 °C. Thus the air was warmed by 20 °K in the panel. The thermal flow through the reference panel is about 96 W/m². In figure 5 the measurement results for the temperature in the rear ventilation layer of the façade panel are illustrated for the reference panel and selected variants with different PV cell layout. PV variant 1 represents the vertical alignment as the results of PV variant 2 are quite similar. PV variant 3 represents the horizontal alignment as the results of PV variant 4 are quite similar. In both variants 1 + 3 the aperture area was shaded by about 30 % and the air was warmed by 17 °K in average. The thermal flow through the panel was reduced across the panel by about 16 % and directly behind the opaque PV cell by about 50 %.

The graphs in figure 5 show an unsymmetrical pattern and a small bias of about 0,5 to 1 °K. A reason for this bias is the laterally arranged cross-flow radiator fan. In addition an outdoor measurement with the same experimental set-up was conducted and resulted in a small bias also, because of outdoor wind conditions.

A first conclusion could be drawn on the measurements about the temperatures: A vertical alignment of the PV cells has a bigger effect as a horizontal alignment. The resulting temperature pattern of PV variant 3 is similar to the reference variant, but the shading of the PV cells causes lower temperatures. The temperature pattern of PV variant 1 differs a lot compared to the reference panel and leads to a very inhomogeneous temperature profile over the panel width.

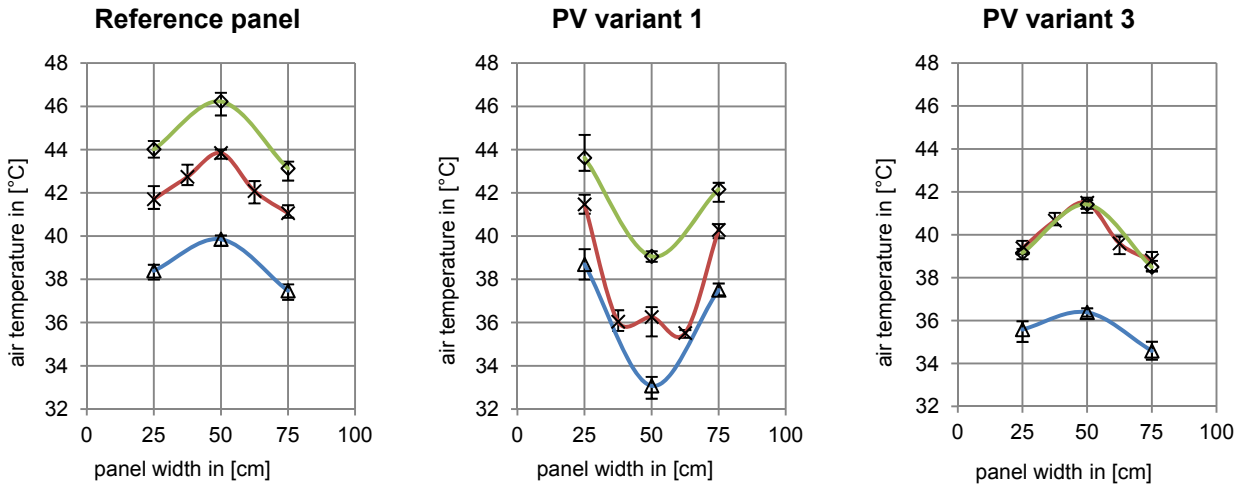

Fig 5: Measurement results for the temperature in the rear ventilation layer of the façade panel for the reference panel and selected variants with different PV cell layout, [8]

4.2 Results on convection flow velocity

The measurement results on the convection flow velocity show similar patterns as the temperatures. The average convection flow velocity of the reference panel is about 0,16 m/s and the emerging volumetric flow is 16,6 m³/h. The highest convection flow was measured in the middle of the panel. Also the small bias and unsymmetrical profile could be explained by the influence of the laterally arranged cross-flow radiator fan.

In PV variant 1 the convection flow behind the vertical aligned PV cells breaks down significantly and leads to a very inhomogeneous profile across the panel width. The average convection flow velocity of PV variant 1 is about 0,13 m/s and the emerging volumetric flow is 13 m³/h. PV variant 3 shows lower alterations and the average convection flow velocity is about 10 % lower compared to the reference panel.

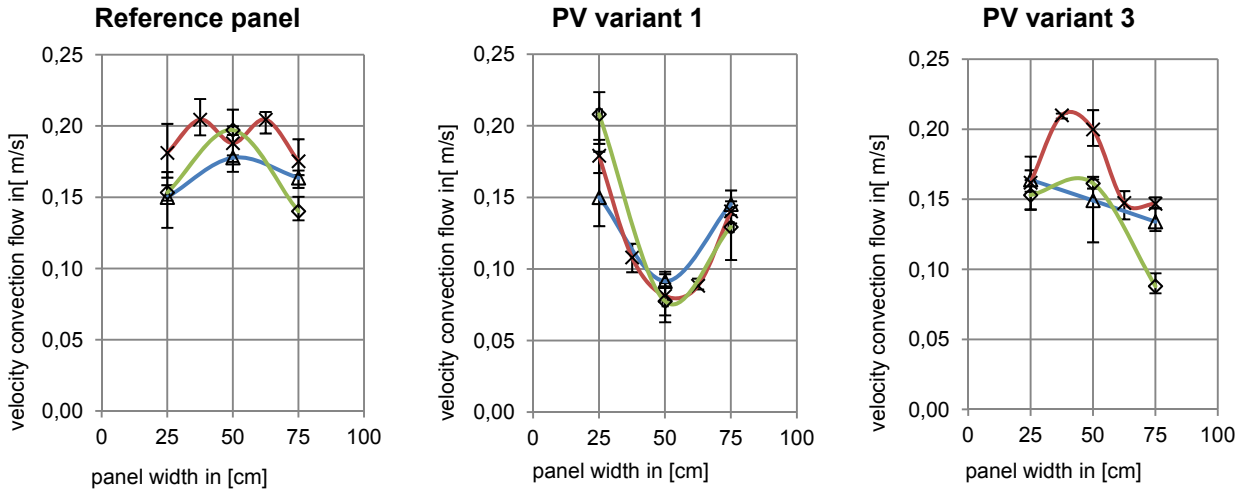

Fig 6: Measurement results for the convection flow velocity in the rear ventilation layer of the façade panel for the reference panel and selected variants with different PV cell layout, [8]

5. Conclusions and outlook

The outdoor measurements under exterior conditions (natural radiation, wind, temperature, etc.) confirm the experimental set-up. The integration of PV cells into the glass cover influences the temperature profile and natural convection flow in the rear ventilation layer to some extend. The lowest influence was observed in PV variant 3. Based on the experimental results the PV cell layout on the façade of the demonstration object should be aligned in horizontal patterns and the density should not exceed one third of the aperture area.

It seems feasibly to recommend an additional investigation and apply semi-transparent PV cells. Thus the shading is lower and the effects on temperature, natural convection and thermal flow through the panel could be reduced further.

For the demonstration object a dynamic building simulation will be carried out. Hereby the focus is on thermal comfort in summer time. The adaption possibilities to climate change issues should be analysed using the climate scenarios and the weather data set of the summer season 2003. The results of the measurements are used to fine tune the previous CFD (Computational Fluid Dynamic) simulation and support the development of a TRNSYS type for building simulation.

Jakob Bonomo, Cree GmbH, Austria, jakob.bonomo@creebyrhomberg.com

Short Summary

More than 50% of the world's population today lives in cities with more than 1 million inhabitants - and the trend is increasing. 40% of today's energy, CO2 and resource consumption and 40% of waste production are accounted by the global construction industry. In the past, urban architecture has been based predominantly on conventionally produced prototypes with long, complex and resource-intensive construction work. A situation which the Cree GmbH, a subsidiary of the Austrian Rhomberg Group, intends to change with a hybrid construction system for multi-story buildings with up to 100 m height and 30 stories. The project is based predominantly on a renewable raw material - wood.

The goal of the project LifeCycle Tower was to develop a flexible, prefabricated, construction system as a new, independent product, which meets all technical and economical requirements of modern real estate markets. Additional emphasis was placed on the systematically improved resource- and energy efficiency. An integrated planning process was applied to the entire project. This means that representatives of all areas of knowledge (architecture, static, facility management, building technology, etc.) had worked jointly through the essential tasks in their entirety. Another central element was carrying out theoretical simulations, which were checked and confirmed with real trials (e. g. fire tests).

The result of the Project is a flexible “new to the world product”:
- for timber based multi-story buildings up to 100 m and 30 stories
- for multiple uses such as office, apartment and/or hotel
- with a positive energy balance
- with an unmatched ecological footprint
- which is prefabricated and independent from manufacturers or geographical locations

Now, the theoretical development became reality. A prototype, LCT ONE, with eight stories was built in Dornbirn, Austria.

Impact on business & ecological environment
- up to 90% improved CO2 - balance
- 50% improved resource efficiency
- Construction times cut by half
- Regional value added by local production possible
- Flexible usage and conversion of building

Keywords: Cree, life cycle tower, sustainability, hybrid timber, high-rise building, lct one, wood, resources, construction, large volume

1. Global challenge for the building industry

Processes of cultural, ecological and economic change observed around the world are leading to an altered frame of reference for and different demands on the building industry.

1.1 Urban growth

The urbanization of the world presents an enormous challenge to the future of mankind. Even today, 50% of the world's population lives in cities of more than a million inhabitants. Experts believe that this could rise to 75% within 30 years. Over the same period the world's population is expected to rise by 78 million people per year – roughly the population of Germany (United Nations 2008).

The countries that profit from an economic upswing strive to transform their cities into better places to live.

Buildings will have to reach greater heights to keep pace with the rising requirement for space. Accordingly the future activity of the global building industry will become concentrated in urban areas and on the construction of multi-story buildings.

1.2 Scarce resources

If present-day methods of using the world’s resources were maintained, then 2.5 planets would be required to satisfy the future demand for resources. For Europe in particular, where 90% of all raw materials have to be imported, guaranteeing the fulfilment of that need for resources will be an essential precondition for prosperity and social harmony.

Construction worldwide is responsible for around 40% of today's consumption of resources and energy as well as 40% of global CO_2 emissions (United Nations Environment Programme 2009). It is clear that efficient use of resources and energy, and a reduction in CO_2 emissions will be considerable factors in successfully addressing these issues. One of the consequences will be an increase in the statutory provisions and targets relating to energy and resource efficiency applicable in many countries.

1.3 Conventional construction

Up to now, urban development has been based mainly on conventionally built prototypes of complex construction. This entails high construction costs, long erection times and elevated design and construction risks.

Systematization and industrialization of the building production process, such as emerged decades ago in the automotive industry, has so far not been seen in the construction industry.

2. Integrated research – high-rise buildings in wood

The changing global construction scene was the trigger that spawned a research project over several years. An international interdisciplinary team of experts led by Cree GmbH has developed a new type of **wood-hybrid construction system for buildings up to 100 m high** (30 stories). The special feature of the research process was the integrated interplay of knowledge leaders from all the professions in the building industry, such as architecture, structural engineering, building physics, building services, process management, marketing etc.

Three main objectives were pursued:

2.1 Large-volume building

As a result of the global trend towards urbanisation, efforts were made to develop a solution for use in an urban context. The objective was the development of a multi-story building solution capable of reaching up to 30 stories or 100 m in height (Cree GmbH 2010).

2.2 Resource efficiency

The shortage of resources and the associated rising prices of raw materials turn the intelligent use of material goods into an enormous competitive advantage for the building industry. Therefore timber, a renewable and local resource, was chosen as the basis for the development of the new building system. Its reduced "ecological backpack" is only half that of conventional buildings (Manstein C & Reisinger H 2010). Most products we create from the resources of the earth contain far more material by virtue of their extraction, transport and processing than their self-weight alone would suggest. According to the renowned chemist and environmental researcher Prof. Friedrich Schmidt-Bleek all goods have an ecological backpack. To produce a kilogram of steel takes on average 8 kg of mineral ore and fossil fuels, a kilo of copper 348 kg, while a kilo of aluminium "actually" weighs 37 kg. Wood has an ecological rucksack of 1.2 kg. Moreover, wood as a material has the potential to improve the CO_2 balance by 90% (Braune A & Benter M 2010) and reduce the weight of the building by 50 % (Cree GmbH 2010).

2.3 System building

A further objective of the research was to develop a standardised universally usable modular system containing a significant proportion of building technical services (heating, cooling, ventilation,). The individual elements should, as in the automotive industry, be capable of being prefabricated in a factory and modular to the extent required by the client. The concept of serial off-site production was intended to ensure economies of scale, consistently high quality and rapid erection of the building on site.

The **first research project "8+"** investigated the technical feasibility of buildings in wood construction. The results showed that it was technically feasible (from a structural engineering point of view) to erect buildings 80 m or more in height. The research did not consider the commercial marketability or the likelihood of obtaining statutory construction approval of the final concept. It was therefore not possible to construct a building based on principles of the "8+" research project.

The **second "LifeCycle Tower" research project** extended the findings of the "8+" project and developed a new building system modified to suit the requirements of the modern real estate market. Industrial prefabrication and special consideration of fire safety in the design led to the new product becoming ready for the market.

From research project to built property: with the "**LCT ONE"** the developed concept was transformed into reality in the form of an eight-story demonstration building.

3. The LifeCycle Tower – innovative building system for urban, sustainable architecture

3.1 Architecture

The system can be divided into three main components: core, hybrid slab and façade columns.

3.1.1 Access core

For the LifeCycle Tower research project, a rectangular core was adopted as the basic structure to ensure that the nodes in the stiffening components would be as few and as simple as possible and compatibility maintained with every available facade system. The core is erected in two sections,

each 32 m high, in order to maximize stiffness and ductility while being economically competitive with conventional building systems. The reduction to two horizontal interfaces secures not only structural and economic benefits; it also permits a high degree of prefabrication and shortens the construction time. The central core for this project was selected primarily for its structural properties; however this arrangement also has disadvantages when it comes to efficient use of floor area, as incorporating the second escape route inevitably results in a less favourable rentable space ratio. In general, individual stories and their technical services can be accessed via one or several centralized or decentralized be used. The options are available depending on regional building regulations for tall access cores. The cores serve as the stiffening element of the building. While wood is the optimal choice as a material for the access cores, concrete and other non-combustible building materials can also buildings.

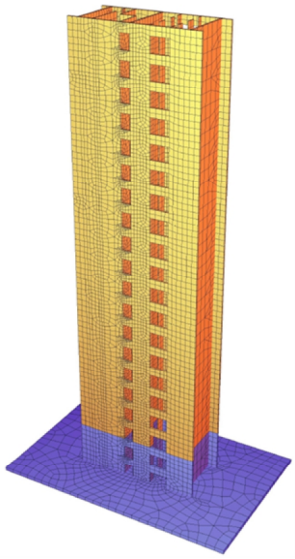

Fig.1: Core

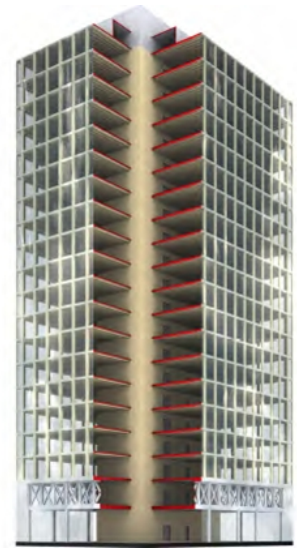

Fig. 2: Shell & Core

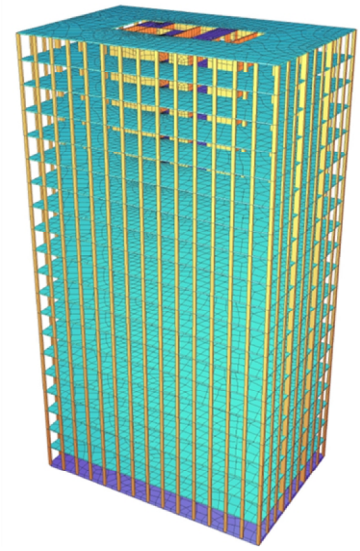

Fig.3: Shell & Core

3.1.2 Hybrid slab

A wood-concrete composite rib construction was chosen for the slab. This fulfils several functions: First, it enables the floor plan to be arranged freely thanks to its long span (<9.45 m) and secondly it guarantees the separation of the stories in the building from each other, as required by fire protection regulations. The space between the ribs allows the building services to be installed within the thickness of the slab. The system also increases the resistance to the spread of fire at the deck soffit. Suspended ceilings are not envisaged. The wood should be left visible for the room users to enjoy, as at the facade supports.

Fig.4: Hybrid slabs

3.1.3 Facade columns

Double columns, designed to provide the required fire resistance, transfer the facade forces directly to the slab, avoiding transverse compressive stresses, and then directly into the column pair

below. The pull out or lateral forces, between the double columns and the hybrid slabs, are prevented from separating by strong, but simple, mortise and tenon joints. Wooden frames link several pairs of columns into one unit that can be installed together with the façade. The combined installation of primary and secondary facade elements allows site work to progress more quickly compared with conventional systems as this is a completely dry method in which no curing times are involved.

Fig.5: Loadbearing system

3.2 Modular construction

Prefabricated construction elements with consistent, standard solutions reduce the need for one-off designs. Construction details have already been incorporated and the components only have to be put together on site. Subsequent work involving non-prefabricated components, such as separate fire protection cladding, is kept to a minimum. The elemental approach avoids the need to construct complex details on site, which is difficult to ensure is done properly in such environments.

Fig.6: Construction phases

3.3 Energy design

A clever, highly energy-efficient building services concept was developed for the LifeCycle Tower, which can be built to low-energy, passive house or plus-energy standard. The qualities of the respective location are utilized optimally for the building. Priority is given to the use of renewable energy sources in the energy planning of the building, sources such as geothermal energy, for example, that can be used for both heating and cooling the building. The distribution and delivery system is adjusted to the respective system temperatures. Combined heating-cooling ceiling elements have been developed for space heating and cooling.

The lighting, a comfort ventilation system as well as smoke detectors and sprinklers are all integrated between the ceiling elements. Other possible elements focusing on the use of regenerative energy include solar thermal systems for hot water, regenerative fuel plants where high water temperatures are required and photovoltaic systems integrated in the facade. Despite sun protection

measures, the demands on room temperatures in summer (comfort criteria and workplace guidelines) make the use of passive cooling ceilings to cool the building inevitable. However, the higher energy expense that this involves can be reduced by an intelligent control concept (exterior shading controls, automatic night cooling, occupancy sensors) and correct user behaviour.

3.4 Fire safety

Fire protection is an important aspect in obtaining approval to construct multi-story buildings. In the last 20 years, modern timber construction has experienced enormous growth both in terms of technology and in economic efficiency, which is also reflected in the continuous amendments to the statutory regulations. Significant differences within national and regional statutory regulations continue to mean that generally applicable statements about the likelihood of construction approval being granted for multi-story buildings cannot be made, all the more so because approval is very dependent on the proposed building use (hotel, office, residential).

A detailed analysis of the possibilities offered by timber construction and consideration of the risk of the spread of fire posed by the combustibility of wood led to the development of a certified fire protection concept. A number of large-scale fire tests have been carried out in Europe for the floor slab elements of the building system. These tests show the technology is able to withstand up to a two hour fire test. Based on the results of these tests, the components have been optimized leading to a reduction in the amount of concrete used, and the granting of the required REI 120 certificate.

4. Commercial considerations

Construction costs for a system-built LifeCycle Tower are fully comparable with those of a conventionally constructed building. A comparative analysis for the two building types found that the additional initial investment cost for the LifeCycle Tower was only 2%. The objective of the further research is to achieve cost leadership in the area of resource & energy-efficient large-volume buildings.

4.1 Industrial series production

Industrial prefabrication of standardized components will exploit the economic advantages of scale and learning curve effects. Factory quality assurance will also lead to minimisation of errors and consistently high quality of construction on site.

4.2 Supply chain management

Cree is not a manufacturer. The independence of contractors and subcontractors means that the best bids out of the local market suppliers can be accepted for production and erection. Capacity bottlenecks or overproduction can be evened out by flexible integration of the producing firms.

4.3 Life cycle-oriented design

The cost of erecting a building is responsible for only 20% of the total cost of the building over its entire life cycle. The concept of the LifeCycle Tower incorporated extensive considerations of cost-effective use, reuse and demolition of the building. One of the consequences of this is the absence of loadbearing partition walls in the structural frame, which allows room sizes to be freely varied in the future. A high energy standard ensures low operating costs and the wood can be used for energy generation following the cascading use principle at the end of the building's life cycle.

5. Implementation concept

5.1 Formation of Cree GmbH

A dedicated company with a present staff of 15 was set up in 2010 to further develop and market the findings of the research. The partners are Rhomberg Holding GmbH, Signa Holding and RIMO Privatstiftung. The development of the LifeCycle Tower and Cree has been met with acclaim and interest from all over the world, presented at international conferences and cited as a pioneering project in innovative timber construction by leading experts.

5.2 Proof of concept

5.2.1 Eight-story prototype LCT ONE

The design conclusions drawn from the research project were implemented in an eight-story (27 m) demonstration building built in Dornbirn, Austria. Based on this prototype, the advantages of the building concept (including resource and energy efficiency, up to 90% improved CO2 balance, 50% shorter construction time, series production) are reported on a public stage. The project serves as an exemplary model for modern sustainable building and point the way ahead for the future development of this sector of the construction industry.

Fig.7: LCT ONE outside

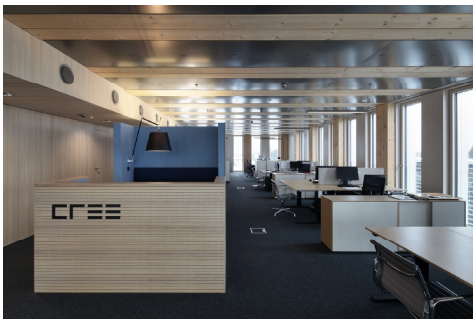

Fig.8: Cree office

Fig.9: LCT ONE at night

5.2.2 First customer project IZM (Illwerke Center Montafon)

The first commissioned project is a large building (120 m) with about 10.000 m² floor area being built in Vandans, Austria. The technical and economic advantages of the proposed LifeCycle Tower wood-hybrid building system were decisive in the commissioning. Verifiable compliance with the fire safety requirements and the ecological advantages of the system were further important factors in the acceptance of the tender by the client.

Fig.10: IZM building phase

Fig.11: IZM

5.3 International marketing

The building system in its finally developed form will be marketed internationally using LCT ONE and IZM as reference projects. Potential target markets will be analysed in parallel with the international positioning of the Cree brand.

5.4 Country-specific construction approval

The engineering feasibility of the tower based on its current stage of development can be confirmed. Construction approval of actual projects still has to be obtained from the competent authorities in each future location. A strategy of sequentially increasing the maximum permissible building height will be adopted to ensure future construction approval. Cumulative experience (construction approvals, fire safety concepts, certifications, testing,) grows with every completed project and serves as the basis of discussions for obtaining approval of the next higher building class.

6. Conclusions

The concept offers enormous opportunities – for the local timber construction industry as well as housing component manufacturers, contractors and suppliers. The uniqueness of using wood as a visible and sensual construction material for high-rise buildings will lead to new modern perception of nature's building material.

In terms of its export potential, the LifeCycle Tower provides an opportunity for local skills to develop international connections and to strengthen the economy and research locations. It allows small and medium enterprises (SMEs) to benefit, above all those which in isolation are considered not to possess the necessary prerequisites for strategic internationalisation. The implementation and international marketing of the developed modular system opens the way for SMEs to international know-how transfer and real export opportunities.

Wood as local renewable construction material will become increasingly important: it secures regional or national independence interms of raw material supplies and protects against high prices.The propagation of the LifeCycle Tower concept in regions in which timber is of high importance therefore strengthens their economies and independence.

Short Summary

Awareness that the use of green building materials towards long-term sustainable development includes addressing environmental, performance and economic issues in an integrated way is promoting synergies in waste recycling between different industries. In this regard, the ultimate goal is to turn a polluting waste of one industry into a product with added-value for another industry. Within this scope, this paper addresses the reuse of an oil refining industry waste – the spent fluid catalytic cracking catalysts – in the concrete repair mortars composition.

Keywords: Oil-cracking catalyst; Concrete repair mortars; Waste recycling; Green building materials

1. Introduction

The market demand for concrete repair materials has grown considerably due to: (*i*) deterioration and distress of concrete structures as the age of existing infrastructures is increasing, (*ii*) the understanding that sustainable construction practices includes the ability to extend the structures longevity in order to both continue using embodied energy of construction materials and to reduce demolition wastes, and (*iii*) the need to fulfill mandatory regulations.

Moreover, since cement production is a natural resources, an energy as well as a carbon intensive process, repair practices - particularly using green products - reinforce the aforementioned environmental impact mitigation. In this regard, the production of cement based materials, including concrete repair mortars, with partial replacement of cement with other lower carbon material with cementitious properties has been recognized as a lever for greener products manufacture [1]. In addition, if the surrogate material is an industrial by-product – being recycled in the cement based materials composition – there is also a concomitant decrease in landfill disposal of wastes as well as an increase in profits by adding value to a waste.

In order to improve the yield of more valuable products obtained from crude oil, refineries use currently approximately 500000 metric tons/year of an aluminosilicate catalyst in their fluid catalytic cracking (FCC) units, of which 20% are used in European refineries [2]. When the catalysts no longer exhibit the required catalyst activity must be replaced becoming a waste (wFCC catalyst). Currently, most of the wFCC catalysts generate are disposal of in landfills the environmentally least preferred option.

Although, the exact chemical-mineralogical composition of wFCC catalysts depends on the manufacturer and specific process is going to be used in, their most active phase is the zeolite-Y. This zeolite is an aluminosilicate with a three-dimensional crystalline structure consisting of tunnels

and cages, which produces a high (internal and external) surface area. Previous studies have shown that when wFCC catalyst is incorporated in cement based materials can undergo a pozzolanic reaction with calcium hydroxide ($Ca(OH)_2$) – liberated during cement hydration – producing additional strength-providing reaction products i.e., calcium silicates hydrate (C-S-H) and calcium aluminates hydrate (C-A-H) [3, 4, 5, 6]. The formation of these cementitious products will contribute to the matrix microstructure densification leading to an improvement of both mechanical properties and durability [7, 8, 9] of wFCC catalyst containing cement based materials.

Within this scope, this paper presents results of a study aiming to assess the viability to produce concrete repair mortars incorporating wFCC catalyst. Experimental work was carried out following the test methods prescribed in EN 1504-3 standard since it provides the specifications for structural and non-structural repair products of concrete structures.

2. Experimental program

The raw materials used were: commercial Portland cement type CEM I 42,5R (according to EN 197-1 standard); wFCC catalyst originated in a portuguese refinery plant (PETROGAL S.A. company); sand (according to EN 196-1 standard) and SIKAPlast 898 superplasticizer (SP).

The chemical analysis of wFCC catalyst was performed by X-ray fluorescence spectrometry using a *PANalytical* model *Axios* equipment (Table 1). The loss on ignition and chloride content were evaluated following EN 196-2 and EN 196-21 standards, respectively. The specific gravity of wFCC catalyst was determined by helium pycnometry using an AccuPyc 1330 instrument from Micromeritics and the specific surface areas were determined by nitrogen adsorption at 77 K using a Micromeritics ASAP 2000 apparatus. The bulk chemical composition and physical properties of the wFCC catalyst listed in Table 1 show that the wFCC catalyst present a high content of SiO_2 and Al_2O_3 (representing approximately 92% w/w) typical of the pozzolanic materials and that the catalyst exhibits an extremely high specific surface area.

Table 1: Bulk chemical composition of and physical proportion of wFCC catalyst [10].

Characterization	wFCC catalyst
Chemical composition (% w/w)	
SiO_2	39.59
Al_2O_3	52.81
Fe_2O_3	0.55
CaO	0.09
MgO	0.19
SO_3	0.23
K_2O	0.04
Na_2O	0.68
Ti_2O_3	0.82
P_2O_5	0.06
Cl^-	0.01
Loss by ignition	1.49
TOTAL	**99.56**
Physical properties	
Specific gravity (g/cm^3)	2.71
Specific surface area (m^2/g)	150.07

Repair mortars were prepared using water (w), sand (s), binder (b) and superplasticizer (SP), in a weight ratio (w/s/b/SP) of 0.5/3/1/0.005, respectively. Binders used were plain cement (used as reference) and blended cements formulated by partially replacing cement with wFCC catalyst in the range of 5 to 15% w/w. Notation adopted for the repair mortars is summarised in Table 2.

Table 2: Notation adopted for repair mortars and correspondent binder mixture proportion.

Notation	Binder mixture proportions (% w/w)	
	Cement 42.5 R	wFCC catalyst
C100	100	0
wFCC5	95	5
wFCC10	90	10
wFCC15	85	15

Mortars mixing procedure was performed in accordance with EN 196-1 standard excepted the previous mixture of the superplasticizer in the water. Consistency of fresh mortars was evaluated, immediately after mortars mixing, by flow table test, as prescribed in ASTM C 1437-07. After the flow test, mortars were placed in 40x40x160 mm prismatic steel moulds and cured so that flexural and compressive strengths were able to be assessed at 2, 7 and 28 days of curing ages in accordance with EN 196-1 standard. The flexural strength results are the average of three tests and the compression strength results are the average of six compression tests.

The static modulus of elasticity in compression of mortars was determined following test method 2 described in EN 13412 standard. Testing specimens were prepared using the same prismatic moulds filled with the same mixtures used as in the case of mechanical strengths evaluation and water cured for 28 days. The principle of the test consist in measuring the change in the specimen strain when loaded to produce a stress between 0,5 N/mm^2 and on-third of compressive strength of the specimen measured previously. The modulus of elasticity results are the average of the values obtained with three specimens for each repair mortar composition.

The tendency of repair mortars to imbibe water by capillary action was evaluated as prescribed in EN 13057 standard. In brief, the procedure consists in preparing three cylinder mortar specimens (∅100 × 25 mm) for each of the same mixtures tested to evaluate mechanical strengths. The specimens were water cured for a period of 28 days and thereafter dryed in an oven at 40 ºC until reached a constant mass (defined as a weight change of not greater than 0.2% in 2 hours). The measurements of water capillary absorption were carried out exposing one of cylindrical faces of each specimen to water. During the experiment, the depth of imersion of tested specimens face is 2 mm. The water ingress was calculated by measuring the increase in the mass of a specimen at various testing periods such after 12 min, 30 min, 1 hour, 2 hours, 4 hours and 24 hours from its first contact with water. The amount of water absorbed (kg) was normalized with respect to the cross sectional area of the specimens exposed to water (m^2).

3. Results and discussion

Table 3 presents the consistency results assessed through spread values of the repair mortars, incorporating 0, 5, 10 and 15% w/w of wFCC catalyst, on the flow table. The results show that by increasing the waste FCC catalyst content there is a reduction in the mortars workability. This trend, attributable to the significant water retention by the wFCC catalyst due to its huge specific surface area with affinity for water, has been reported before [10].

Table 3: Spread values on flow table test (mm) of repair mortars with 0, 5, 10 and 15 % (w/w) of cement replacement with wFCC catalyst.

Mortar	Spread values (mm)
C100	223
wFCC5	218
wFCC10	207
wFCC15	188

Fig. 1 and Fig. 2 show, respectively, the flexural and compressive strengths of the repair mortars with 0, 5, 10 and 15% w/w of cement replacement with wFCC catalyst for different curing ages. The results of Fig. 1 show that flexural strengths of wFCC catalyst blended cement mortars are typically lower than those of plain cement mortar at same curing age. However, with a delay in the strength development of 7 and 28 curing days, respectively, for 5 and 10% w/w of cement replacement with wFCC catalyst, the difference between flexural strengths of blended cement mortars and the flexural strength of reference mortar becomes negligible.

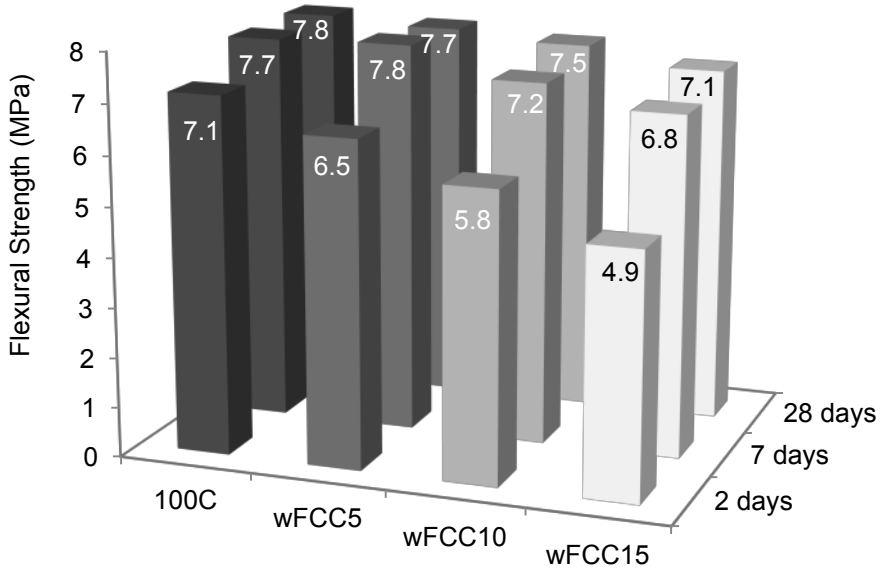

Fig. 1: Flexural strength of repair mortars with 0, 5, 10 and 15 % (w/w) of cement replacement with wFCC catalyst for 2, 7 and 28 days of curing age.

The results present in Fig. 2 show that on the 7th curing day the blended cement repair mortars containing up to 10% w/w of wFCC catalyst already exhibit compressive strength slightly higher than that of the reference mortar. The incorporation of 15 % w/w of wFCC catalyst delays the compressive strength development but from 28 days of curing age the strength is similar to that of plain cement mortar. The improvement in mechanical strengths of the cement repair mortars is likely to be due to the exceptional pozzolanic activity of the wFCC catalyst under study [10].

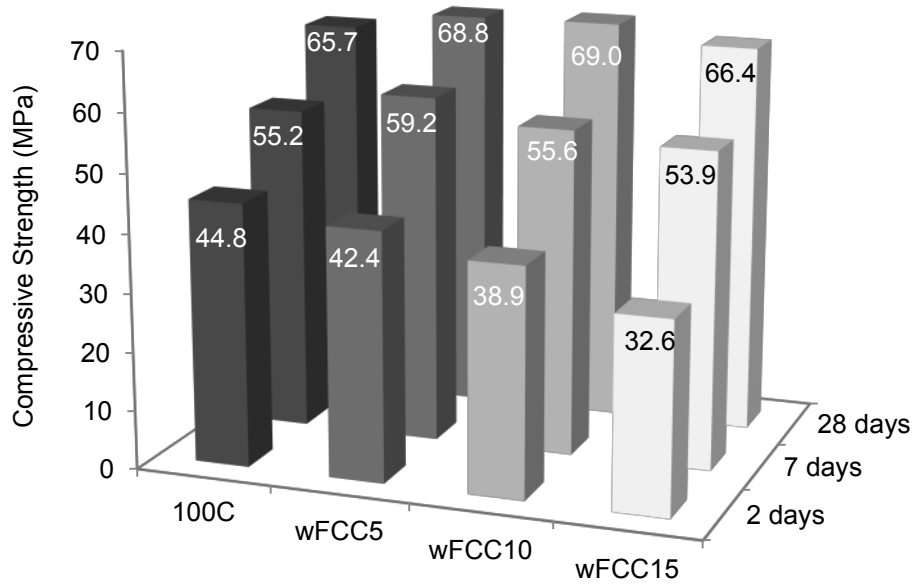

Fig. 2: Compressive strength of repair mortars with 0, 5, 10 and 15 % (w/w) of cement replacement with wFCC catalyst for 2, 7 and 28 days of curing.

Table 4 lists the values of modulus of elasticity in compression of the repair mortars at 28 days of curing age. Cement replacement with up to 10% of wFCC catalyst do not significantly affect the modulus of elasticity in relation to the reference cement mortar. However, increasing incorporation level of wFCC catalyst in the repair mortars composition tends to decrease the modulus of elasticity and, consequently, lower their stiffness.

Table 4: Modulus of elasticity in compression (E) of repair mortars with 0, 5, 10 and 15 % (w/w) of cement replacement with wFCC catalyst.

Mortar	E (GPa)
C100	36.3
wFCC5	36.9
wFCC10	35.9
wFCC15	24.2

Fig. 3 plots the water intake by capillary action on repair mortars against the square root of the time of immersion. The slope of the linear fit of these experimental results, for each mortar composition, provides the capillary absorption coefficient, S (kg/m^2.h$^{0.5}$). All the repair mortars incorporating wFCC catalyst exhibited lower water absorption than the reference plain cement mortar. Moreover, increasing the wFCC content in the mortars composition leads to a reduction in capillary water absorption coefficients i.e., increases the water penetration resistence. These results are in good agreement with previous studies [11] reporting a remarkably lower water absortion in cement based materials incorporating pozzolans than in plain cement based materials. The higher water penetration resistence in pozzolan containing cement based materials – namely in these repair mortars incorporating wFCC catalyst – may be explained as an effect of the pozzolanic activity because the additional forms of C-S-H and C-A-H produced lead both to a reduction in the capillary pores size as well as a decrease in pores interconenctivity [11].

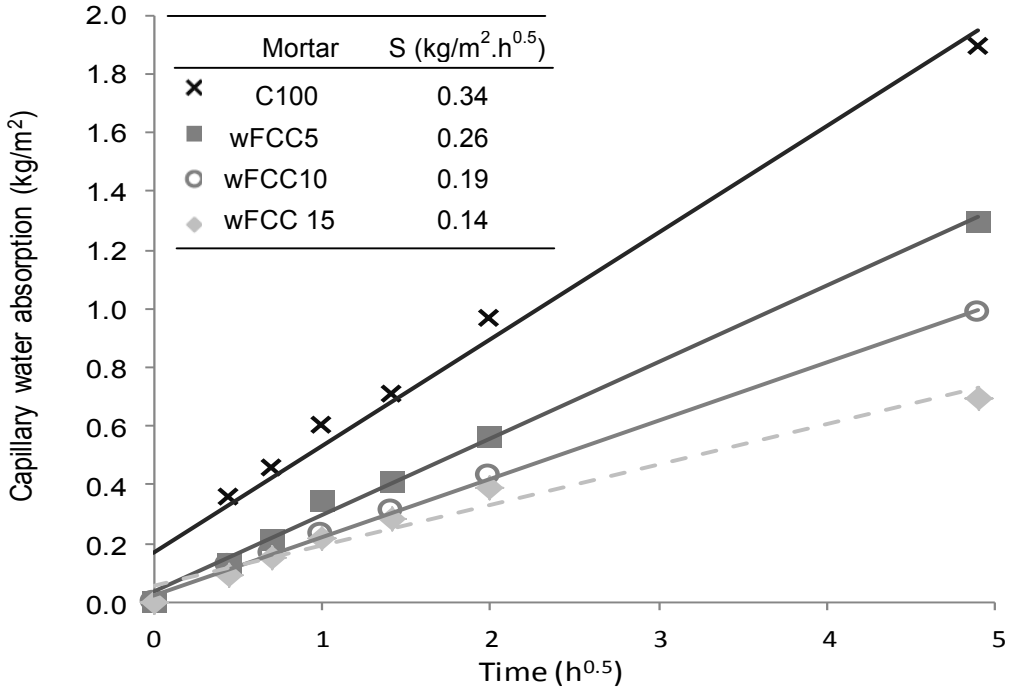

Fig. 3: Water absorption by cappilary action of repair mortars with 0, 5, 10 and 15 % (w/w) of cement replacement with wFCC catalyst.

4. Conclusions

This study aims at contributing to developing concrete repair mortars reusing a waste generated by the oil refining industry. This industrial ecology promotes synergies that are able to generate significant environmental and economical dividends for both the oil and construction materials industries as they become more technologically advanced.

Table 5 presents both:

- the requirements for the properties assessed in the present study towards each of the classes (R1 – R2 Non-Structural; R3 – R4 Structural) of concrete repair mortars as defined by the EN 1504-3 standard;
- a systematization of key experimental results obtained for repair mortars incorporating up to 15% of wFCC catalyst.

It can, therefore, be deduced that mortars with wFCC catalyst incorporation up to 15% w/w complies with the assessed specifications of all classes of concrete repair products set out in EN 1504-3 standard.

Table 5 – Experimental results and requirements laid down in EN 1504-3 standard for classes R1 to R4 of concrete repair mortars.

	EN 1504-3 standard requirements				Experimental results		
	R4	R3	R2	R1	wFCC5	wFCC10	wFCC15
Compressive strength, 28 days (MPa)	≥ 45	≥ 25	≥ 15	≥ 10	70.5	71.4	69.2
Elastic Modulus (GPa)	≥ 20	≥ 15	NR	NR	36.9	35.9	34.1
Capillary absorption coefficient (kg/(m^{2}h$^{0.5}$))	≤ 0.5	≤ 0.5	≤ 0.5	NR	0.26	0.19	0.14

Legend: NR – No requirement.

It should also be taken also in consideration that wFCC catalysts are classifed as non-hazardous solid waste which means that they do not pose a substantial present or potential hazard to human health or the environment [2, 12]. Actually, previous studies on heavy metals leaching from wFCC catalysts containing materials showed that they comply with environmental requirements [13, 14]. Moreoves it is not also antecipated these catalysts to have a negative effect neither on indoor air quality nor on ecotoxicity for soil.

Therefore, major findings in this investigation reveal that there is a large potential to use waste FCC catalyst as a constituent in repair mortars producing novel materials with adequate performance and durability and, concomitantly, making a significant contribution for "greener" construction materials.

Short Summary

For years polymer foams have posed an excellent „warm shell“ for buildings. Generally the foam is used for external wall insulation and is not employed for additional functions. Yet forming a sandwich from rigid laminates and a quite shear resistant polymer foam core, results in extraordinary stiff elements that provide not only thermal insulation, but form a load carrying structure. The sustainability of the sandwich structure can be raised by combining materials from renewable resources. The sandwich system currently developed in cooperation with our partner from industries C3 House Technologies consists of phenolic foams of varying density and natural fibre reinforced laminates. A phenolic resin matrix provides on the one hand sufficient fire resistance for the entire sandwich itself, and on the other hand a high performance thermal insulation. The material system may be employed for compact construction methods. One may also rely on local resources for the laminates by the selection of fibres and their ratio of mixture in the natural-fibre-fleeces. Additionaly by manipulating the ratio of the various fibres in the fleece one can design the mechanical properties according to use. Depending on the pressing technology, the fibre-resin-ratio and the kind of fleece the elastic modulus of the laminates can be adjusted in a wide range to fit the particular application like external or internal walls.

Keywords: sandwich; biocomposite; lignin; biofoam; bioeconomy; phenolic resin; lignosandwich

1. Introduction

Man has always sought materials to implement his ideas and to meet his requirements. The development of construction engineering is therefore closely linked with the development of construction materials.

Fibre-reinforced plastics were first used in their own right as a class of construction material in the construction industry in the middle of the 20th century. They made it possible to construct plane load-bearing structures and lightweight sandwich structures, dream-like structures with thin walls spanning wide stretches and floral or crystal structures, providing us with a novel type of housing and protection from the environment.

Fibre-reinforced plastics are a multifaceted class of construction materials as the most diverse types of fibres as well as thousands of combinations of plastics together provide high-performance materials. Plastics are currently undergoing a period of transition. Oil is no longer the sole means of producing plastics: natural products are undergoing chemical processes and are being offered as bioplastics. Natural fibres are now fulfilling other roles apart from their traditional use as textile fabrics in the clothing and carpet industries. The construction system being developed is based on the combination of a new composites, existing findings in the field of lightweight construction using sandwich systems, and sustainable resource and energy saving construction methods that are currently in use.

2. Fibre-reinforced plastics

Fibre-reinforced plastics are composite materials comprising a matrix presenting the embedding material and the reinforcing fibres. The fibres transfer forces across the structure. The fibres used are glass, carbon, aramid and natural fibres. The matrix is usually a thermoset, e.g. unsaturated polyester resin or epoxy resin. The matrix forms the construction component, conducts and transmits the forces arising to the fibres and protects them. Essentially, the matrix in combination with additives determines the following characteristics:

- Resistance to chemicals
- Resistance to ageing
- Fire resistance,
- Impact resistance,
- Electrical properties.

The specific density, thermal conductivity and thermal expansion depend on the proportions of the resin, reactants, fibres and fillers.

As the fibres absorb the forces in the structure and as the resin is the most expensive constituent in a composite material component, there is clearly a need to increase the fibre content and to use layers of minimum thicknesses. This enables material costs to be reduced and the load-bearing structure to be more efficiently utilised. A new load-bearing system, a sandwich, is formed by the high-tensile and shear-resistant bond of the composite material formed as thin covering layers around a core of hard foam. Despite their low mass they can support considerable weights and additionally have an integrated thermal insulation effect. Sandwich components are therefore used as well as a spatial partitioning and separately as a load-bearing wall or roof component. Most of the composite structures constructed to date have therefore employed sandwich construction methods.

3. A brief history of the use of fibre-reinforced materials in the construction industry

Plastics served initially at the end of the 19th century as a replacement for rare and therefore expensive natural products. Thanks to the development of numerous different types of plastics, it was not long before plastics were being used in their own right in many sectors, including the construction industry. The thermoplastics and thermosets developed were used in the chemical industry in high quality products produced following quality assurance procedures to enable these products to compete with traditional materials over the long term. The advantages of plastics for consumer goods lay in their low mass and colourability, as well as in the fact that they made less “noise” and did not rust.

An important factor was the development of different petrochemical based wood glues which played an important role in the manufacture of plywood (glued laminated veneers) for the construction of aircraft and airships. In 1933 a polyester resin resistant to water and chemicals was developed by Carleton Ellis in the USA. Glass fibres had been manufactured industrially since 1935. This was followed in 1942 by the development of the glassfibre reinforced polyester by the US Rubber Company. Glassfibre reinforced plastics (GFRPs) had been used in the USA as early as 1943 in aircraft construction for sandwich components with a balsa wood core.

In the 1940s to the 1970s GFRPs underwent a short but very productive phase for a construction material (Voigt, 2007). The chemists, chemical companies, processors, engineers and architects and artists too created a highly developed construction material with a wide range of applications. They proved that GFRPs with their very wide range of forms could be used not only in the sporting goods industry, in the manufacture of boats, motor vehicles and aircrafts but also in the construction industry as self-supporting/load-bearing materials.

Development work in the 1950s initially concentrated on attempts to bring GFRPs up to a standard comparable with other construction materials and to investigate their possible applications, taking into account the material requirements, such as weather resistance and flammability. In carrying out these developments the aim was to develop high-performance and durable materials, to test them, to introduce guidelines and to produce these materials to a consistently high quality standard.

The demand for GFRPs in the military sphere, for example for radar domes (Sonnefeld, 1954, page 159), led to a rapid development and widespread use of this material. The chemical and plastics-processing industry encouraged architects and civil engineers to develop possible applications for the construction industry. Architects and civil engineers had already become aware of this new promising class of material that could be moulded to any shape. The French Snail Shell (1956) developed by the research group led by Ionel Schein and the Monsanto House (1957) developed by the Massachusetts Institute of Technology (MIT) are the most well known research and presentation structures of this period [Genzel & Voigt, 2005, page 39 – 71],[Monsanto, House of the Future, 1954 – 1964].

Most of the composite structures were built between 1960 to 1972 in the industrialised nations (e.g. Fibreglass House Fig.1). The interest, indeed the enthusiasm of the pioneers in the new construction material, is due to the large number of diverse structures which were regarded throughout the world as innovations and as proof of the productivity of this sector of industry and the construction industry, as well as serving as an example for the restructuring of this sector into a construction industry. The concentration on house building was based on the great need for housing after the Second World War and the preference of the modern age for the single family home.

Fig 1: Fibreglass House 1970, development, design and show house: FG Design Wolfgang Feierbach (Wolfgang Feierbach, fg design, 1968, Photo: IBK Archive).

At least 176 different GFRPs structures were built during this twelve year period, 66 of them actually in smaller series. The buildings ranged from very small modules up to blocks of building of 27,000 m2, constructed from hundreds of identical GFRPs components. Apart from structures made of thermally insulated sandwich elements with hard foam core, light plane load-bearing structures were also built which used a small amount of materials and had a large span, such as shells, tiled slabs and hyperbolic surfaces. Examples of successful, economically and technically mature constructions of canopies, building shells or exhibition buildings include the International Airport at Dubai, Arab Emirates (1971), the Olivetti Training Centre in Haslemere, GB (1971), and the public buildings at Iqualuit and Igloolik, Nunavut, CAN (1971), the construction system fg2000 (Fig. 1), FRG (1968/74), and the Futuro, FIN (1968) [Igloolik Research Center,Nunavut, CAN, 1971].

Industrial construction based on prefabrication of highly specialised building units from consistently high quality, great economy, low labour costs and rapid construction, was illustrated and presented by homes prefabricated from glass fibre reinforced composites.

Generally speaking, there was a marked change within the construction industry in the 1970s. Analyses and examinations were carried out of the state of post-war building. For the first time, public concern was expressed about the state of architecture which was in most cases poor – an architecture which was also described as functionalism imposed on building design by economic constraints. This signalled the end of the optimism of the 1960s which was superseded by the general disillusionment of the 1970s.

The economic change was triggered by the oil embargo imposed by the Organisation of the Petroleum Exporting Countries) (OPEC) in autumn 1973. OPEC deliberately reduced the amount of oil produced by about 5% in order to influence the price of oil for its own advantage. Because of the adverse effects due to the economic situation, the rejection by the public of GFRP structures and overly complicated planning and approval procedures, fewer and fewer GFRP projects were carried out. Despite intensive campaigns to publicise the benefits of these materials, it was not possible to dispel people's prejudices, or to request sufficient time to solve all the technical problems. And yet as early as the 1970s construction methods using glass fibre-reinforced plastics had been in terms of their design, features and durability a fully-fledged competitor of construction methods using traditional construction materials.

In the 1990s construction with composites once again attracted the interest of architects and civil engineers. The aim was for architecture to make interior spaces come alive once again by using organic forms and at the same time to use the new possibilities of digital and virtual designing. The pavilions of the Swiss Expo Expo'02(2002), the Light Sculpture ›D-toren‹ in Doetinchen, Netherlands (2004), Chanel Contemporary Art Container (2008) and The Walbrook, London, Great Britain (2009) illustrate this basic principle of an architecture that strikes a vivid response in the mind of the viewer (ForumSoft, Expo'02 Switzerland 2002).

The further development of digital programmes, of PC-based three-dimensional designing and construction, which enable data to be transmitted directly to robots and CNC milling machines, today makes the construction of industrial buildings into a flexible Just-in-Time production process, especially for technically accomplished architects. This enables greater savings to be made for constructions using fibre-reinforced plastics, even for one-off building projects.

4. Design & architecture

A large amount of the heat and energy produced, and thus the consumption of finite gas and oil reserves, goes into heating buildings. The aim of the European Union therefore is to reduce energy consumption by 20% in 2020 by increasing energy efficiency. This shall be achieved by reducing CO_2 emissions, renewable energy sources and last but not least by reducing energy consumption by the consumer (Energy Efficiency Plan of the European Commission, 2011, page 1).

Two-thirds of the energy consumed by buildings during their service life is for heating and ventilation. Efficient thermal insulation and the airtightness of the building shell would result in great savings. The principle of the passive house has attracted interest throughout the world and has served as a shining example in reducing energy consumption. Most of the extremely low heat requirements of such houses are covered by "passive" sources, such as sunlight or ground heat. The main way energy is reduced in the passive house is by reducing energy losses through transmission and ventilation. This is achieved by effective thermal insulation and the airtightness of the entire building shell and a controlled ventilation of living areas with heat recovery from the outgoing air.

Insulated, airtight structures are constructed of many layers which not only exceed the dimensions of the overall structure (overall wall thicknesses of 50 cm), but also lead to sources of defects like thermal bridges and leakages. A compact design in which the load bearing structure simultaneously ensures the building physics and provides protection against weathering (compact system after Deplazes, 2009, page 80), can be achieved by the use of a sandwich system. There are variations in the width of sandwich systems that have already been developed and tested in timber structures, and in structures using composites, as illustrated above. Building on these experiences current research is directed at developing materials for the challenging sector of energy-saving construction.

In the ongoing research projects at the Fraunhofer IWM in Halle experiences in construction and use of composites are linked with current industrial production standards in construction industry and plastics-processing industry. So innovative combinations of renewable raw materials can be employed for sandwich systems, so called Natural Composite Panels (NCP). These are qualified for applications in architecture and construction industry. Apart from the compact solution of load bearing structure, building physics and protection against weathering described previously, NCPs also offer the advantage of savings in material because of thin walls, high quality thanks to the controlled industrial manufacture of the materials, as well as elements with individual design possibilities, a high degree of prefabrication, weight saving thanks to the lightweight design and thus savings in transport costs, good workability and quick installation. Primarily renewable locally available raw materials are used.

5. Materials

The sandwich system (NCP) currently in development with the industrial partner c3house technologies GmbH comprises a phenolic foam core of varying thickness (60- 120 kg/m^3) and top layers from laminates that are reinforced with natural fibres (Fig. 2).

Fig 2: Components of the sandwich system, sandwich element (source: C3 House Technologies GmbH)

The use of a phenolic system as matrix guarantees on the one hand that the fire classification protection [B s1 d0] for the whole sandwich is achieved. On the other hand the phenolic foam offers very good thermal insulation properties which enable the sandwich system to be used for the compact design. By selecting suitable non-woven fabrics (e.g. flax/hemp/sisal/linen) in a varying ratio, it is possible to use local resources and to systematically set the mechanical properties. Depending on the pressing technique, the proportion of the matrix material, the ”prebinding” (e.g. via the degree of needling) and the type of the non-woven fabrics, one can set the laminates modules of elasticity between 6 - 12 GPa and the tensile strength between 50 – 80 MPa and thus tailor the system for the respective use (e.g. as an exterior wall or internal element).

A further advantage is seen in a low thermal expansion α of the upper layers by temperatures between – 40℃ to 100℃. This ranges from – 40℃ to 30℃ for α = (9e – 006 ± 2e – 006)1/K and even less at α = (3e – 006 ± 2e – 07)1/K in the range of 30 ℃ to 100 ℃. This means that laminates reinforced with natural fibres expand only marginally under thermal load and therefore impose only small additional loads upon the structure.

The materials used in NCPs are specified according to the current international requirements for load bearing structures and building physics and are designed on in teamwork with the manufacturer, load bearing structure designer and architect (Fig. 3), taking into account manufacturing requirements and the structural design.

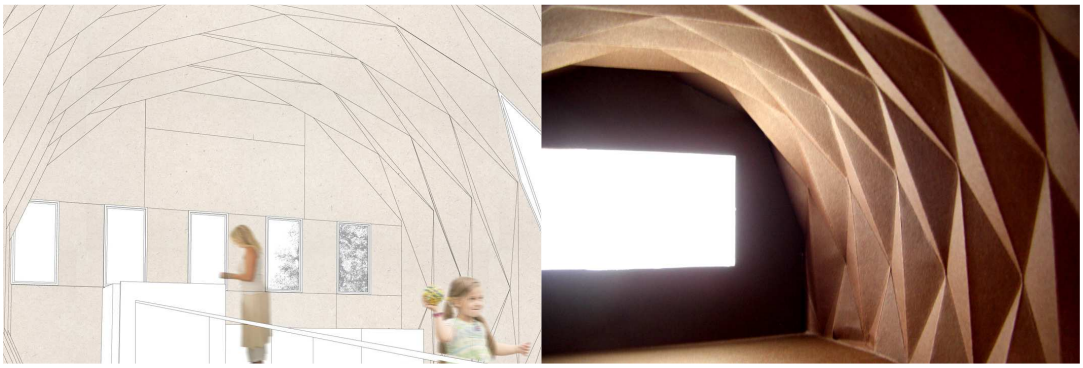

Fig 3: Components of the sandwich system, sandwich element (source: C3 House Technologies GmbH)

Besides the creative flexibility of the NCP construction system, seen on the illustrations, the innovation in structural design is the joining technique – bonding is appropriate for the material involved. Bonding is superior to mechanical joining. Local overloads, that would generally lead to the material being ripped out like in a bolted connection, can not occur. By bonding elements such as windows and doors can easily be integrated.

6. Summary and future prospects

A compact construction method can be implemented by the sandwich system presented which comprises upper layers reinforced by natural fibres and a foam core of phenolic resin. The choice of suitable raw materials and their combination in the sandwich enables the sandwich to be optimally tailored for the respective application. Perspectively, it will be possible to replace part of the petrochemical component (phenolic resin) by lignin as a biobased component, receiving a construction material that consists of 20 – 50% renewable raw materials.

The lignin is produced from beech-wood via the organosolv-process. Then it is chemically integrated into the phenolic resin. The proportion of lignin in the resin can be varied from 5% (P05) to 10% (P10) up to 20% (P20).

This poses an quite prospective idea since using lignin means using natures own synthesis instead of artificial petrochemical processes for resin production and thus reducing the energy needed for resin production. The worldwide availability of lignin is estimated up to about 20 billion tonnes per year - a sufficient raw material base for a prospering lignin based bioeconomy.

This means that up to 80% of the material for the described sandwich elements may be bio-based. In the framework of “LignoSandwich”, a project in the research cluster “Bioeconomy”, the whole value-added chain from the Hardwood to the bio-based sandwich system for constuction (see Fig. 4) is explored.

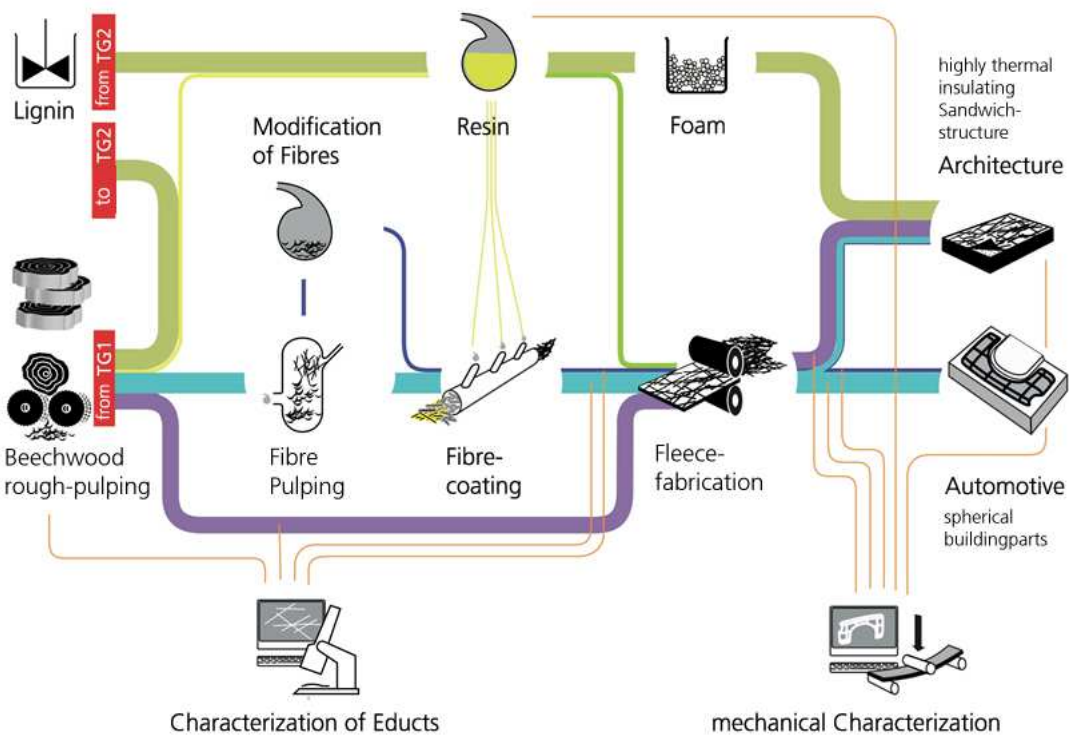

Fig 4: Material flow from beech-wood to a highly thermally insulating bio-sandwich

Short Summary

Many Control Design approaches presuppose the knowledge of a state space description of the system. As in many real and large scale systems the construction of a state space model using analytical equations and rough assumptions is a time consuming process leading most of the times to questionable precision. System simulation software has been developed for several applications over the recent past decades. For this purpose a System Identification approach is proposed in the present paper. The idea of the System Identification from a simulation model using statistical measurements from the simulation output data has been of great interested for optimal control schemes which require accurate and furthermore, agile, simple and practical models to handle. In practice real systems and accurate simulation models, show nonlinear dynamic behavior which concludes to linear approximation-identification models being unsuitable for this purpose. The proposed Multi-Linear State Space Model Identification process is using the idea of mixing signals as weighted contribution factors for the final model behavior. A common Least Square error minimization process is used to minimize the model approximation error.

Keywords: Building, Simulation, SSM, Modeling, System Identification

1. Introduction

In control engineering, the field of system identification uses statistical methods to build mathematical models of dynamical systems from measured data. System identification also includes the optimal design of experiments for efficiently generating informative data for fitting such models as well as model reduction.

It must be noted that a white-box model based on first principles could be also build, e.g. a model for a physical process from the Newton equations. In many cases, though, such models are overly complex and possibly even impossible to obtain in reasonable time due to the complex nature of many systems and processes affecting the central model of interest.

A much more common approach is to start from measurements of the behavior of the system and the external influences (inputs to the system) and try to determine a mathematical relation between them without going into details of what is actually happening inside the system. Therefore a black-box (no prior knowledge for the system is available) system identification process is applicable to any measurable system and can be proven as a very efficient scheme for System State Space Model (SSM) realization.

Large scale non-linear systems are usually described in details by very large and complicated differential equations. These equations in order to be analytically complete usually demand the knowledge or the calculation from empirical graphs or tables, of many parameters. In addition, "necessary" physical simplifications and assumptions that conclude to fitting errors, between the constructed model of the system and the actual system, must be considered in order to make feasible the building process of a reliable model. Thus, control schemes, especially, for large scale systems (e.g. buildings, traffic networks) avoid dealing with state space models.

A common strategy is the use of precise and detailed simulation models to simulate systems. Simulation models require several calculations and much execution power. Many applications require fast simulation results due to their nature, thus even online control algorithms using co-simulation schemes can be proven impractical and not efficient at all. In addition a practical drawback in this strategy, is the mobility and compatibility of such model. Generating a precise enough, State Space Model (SSM) bypassing special and usually expensive simulators served by complicated connection interfaces which have to be incorporated in the system simulation scheme can be the only efficient solution to many practical applications.

This paper copes with the idea of approximating a dynamic SSM of a given, either simulation or real, system by using off line measurement data, using a common input-output system measurement database. The main idea is trying to minimize the approximation error of the state space realization matrices, using a simple and convenient way. The proposed strategy introduces state space subdivision and local linearization according to the current system working point - state. Locally referring but globally representative weight functions decide the contribution of each linear subsystem to the final model total dynamic behavior.

2. Transformations and Approximations

Let us consider a general non-linear system which assumes the following dynamics

$$\dot{\chi} = F(\chi, u, w) \tag{1}$$

where $\chi \in \Re^n, u \in \Re^m, w \in \Re^d$ denote the vectors of system states, control inputs and system disturbances, respectively, F is a nonlinear vector function which is assumed to be continuous.

2.1 Multi-Linear Subsystem Mixing Signals

The problem in large scale non-linear systems is the inherent inability of extracting a linear state space realization group of constant matrices in order to be able to design a convenient control system.

Assume that system function F can be approximated using smooth mixing signals membership functions, so as to have smooth switching between the linear subsystems and even more smooth switching between the linear subsystems respective controllers. Also assume as a first step that all states, control inputs and disturbances of the system can be measured or are given:

$$y = Cx = C\left[\chi, u, w, 1\right]^T \tag{2}$$

where matrix C is known and can be considered $C = I$ without loss of generality. Please note that the feedback vector is augmented using an ace at end, due to a constant term considered for all linear subsystems.

Let $\beta_i, i = 1, \ldots, L$ denote a set of smooth *mixing signals* that satisfy the following properties:

$$\beta_i(y) \in [0,1], \quad \sum_{i=1}^{L} \beta_i(y) = 1, \forall y \tag{3}$$

and, moreover,

$$\sum_{i=1}^{L} I\left(\beta_i(y)\right) \le 2 \tag{4}$$

where $I(\beta_i(y))$ denotes the indicator function $I(\beta_i(y))=1$ if $\beta_i(y)>0$ and $I(\beta_i(y))=0$ if $\beta_i(y)=0$.

The activation functions β_i separate the system augmented state space $x\in\Re^{\dim(x)}$, where $\dim(x)=n+m+d+1$, into L overlapping regions, with each of the activation functions assigned to one of these regions. An activation function $\beta_i(y)$ is active [i.e., $\beta_i(y)>0$] whenever y ($y=x$ since $C=I$ is assumed) belongs to the respective region $\beta_i(y)$ has been assigned to. Please note that due to Eq. (4), every time there are maximum 2 activation functions active. We will, moreover, assume that the mixing signals β_i span the whole space y lies on, i.e., we will assume that for each possible y, there exists at least one i such that $I(\beta_i(y))=1$. In order to avoid degenerate cases where two or more mixing signals coincide, we will also assume that $\beta_i(y)\neq\beta_j(y), i\neq j$ holds over a non-negligible subset of $\Re^{\dim(x)}$.

Remark 1: Condition Eq. (4) can be relaxed by requiring – with the exception of at most two mixing signals – all mixing signals take negligible values for each particular y. In such case, the design of mixing signals becomes less complicated by using, e.g. Gaussian functions which show very good fitting properties.

2.2 Multi-Linear State Space Model

Using the above design considerations for the mixing signals β_i we can employ standard function approximation techniques to approximate the system dynamics. Instead of approximating a pure linear model for the specified system, an iterative exploration process decides the number of mixing functions to be used by giving the smallest approximation total error. The idea is to identify many linear subsystems describing the system dynamics in different working areas respectively, where the system behaviour usually changes in a significant manner. At each state the selection of the respective active linear subsystems is decided by the weight factors (mixing functions) and the total system behaviour can be represented analytically by the following equation:

$$\dot{\chi}\approx\sum_{i=1}^{L}S_i\approx\sum_{i=1}^{L}\beta_i(y)\left(\overline{A_i}\chi+\overline{B_i}u+\overline{G_i}w+\overline{F_i}\right) \tag{5}$$

If we group the state space matrices and vectors in one matrix that incorporates them we can write:

$$\dot{\chi}\approx\underbrace{\left([\overline{A}_1\overline{B}_1\overline{G}_1\overline{F}_1][\overline{A}_2\overline{B}_2\overline{G}_2\overline{F}_2]\ldots[\overline{A}_L\overline{B}_L\overline{G}_L\overline{F}_L]\right)}_{=:\Theta}\underbrace{\begin{pmatrix}\beta_1(y)\begin{bmatrix}\chi\\u\\w\\1\end{bmatrix}\\\beta_2(y)\begin{bmatrix}\chi\\u\\w\\1\end{bmatrix}\\\ldots\\\beta_L(y)\begin{bmatrix}\chi\\u\\w\\1\end{bmatrix}\end{pmatrix}}_{=:\Lambda}, \tag{6}$$

and replacing the derivative by the difference quotient the compact form of the equation reads:

$$\frac{\chi_{[new]}-\chi_{[old]}}{\Delta t}=\dot{\chi}\approx\Theta\Lambda \tag{7}$$

2.3 Discrete Time Analysis

To simplify even more Eq. (7) we can use discrete time analysis and assume that the Δt -time step of the generated or measured data is significantly smaller than the time constant values, referring to the dynamics of the system. This assumption is reasonable in large building systems where the time constants have values (depending on the construction) up to 100 hours, compared to the data time step (usually few minutes). Thus alternatively Eq. (7) can then be written as (consider Δt = 1):

$$\chi_{[next]} \approx \chi_{[old]} + \Theta\Lambda \quad . \tag{8}$$

3. Approximation Error Minimization Analysis

After the problem formulation, the main problem is the approximation – calculate Θ matrix which contains all the state space realization constant matrices for every linear approximation member subsystem S_i as described above. In order to form the Least Square problem the following calculations are presented. From Eq. (8) we have:

$$\Lambda^T\Theta^T \approx (\chi_{[z+1]} - \chi_{[z]})^T \quad . \tag{9}$$

The above equation has the general form of the Least Square problem $QX = B$ which is used to minimize the approximation error of X vector. Consider:

$$Q = \Lambda^T,\ X = \Theta^T, B = (\chi_{[next]} - \chi_{[old]})^T \quad . \tag{10}$$

Matrix Λ and tall vectors $\chi_{[next]}, \chi_{[old]}$ include simulation output data or measurement data of the system to be identified. The values of β_i functions (normalised Gaussian functions) are formed using for each data time step the whole or part (C matrix depends on the specific application) of feedback vector y. The kernel functions used in this proposed application are normalised scalar Gaussian functions using the norm of y vector to decide the maximum two active subsets at each given state – working point of the system.

This vector is formed to decide the membership magnitude of the respective linear subsystem. Each row of Θ matrix is approximated using Least Square method with Λ vector and the respective $j-th$ state variable vector $(\chi^{(j)}_{[next]} - \chi^{(j)}_{[old]})$.

In conclusion the problem becomes a regression approximation problem in which we want to minimize the approximation error e using the Least Squares method. The optimization problem becomes:

$$\min \quad T = \sum_{j=1}^{n}\sum_{z=1}^{\mathcal{N}} e_{zj}^2 \tag{13}$$

where $\mathcal{N}$ is the total sample number of the training data set, n is the number of state variables and e_{zj} is the approximation error defined by

$$e_{zj} = (\chi_{[z+1]} - \chi_{[z]})^{(j)} - \Theta^{(j)}_{row}\Lambda_{[z]} \tag{14}$$

where $z = 1, 2, ..., \mathcal{N}$ and $j = 1, 2, ..., n$.

4. Building Model and Zoning Procedure

To test the developed system identification algorithm we use a validated building model generated with TRNSYS [1]. This model has been developed during the project PEBBLE (for details see http://www.pebble-fp7.eu/).

4.1 Center for Sustainable Building (ZUB)

The ZUB building, built in 2001, located at the campus of the University of Kassel, Germany is an exemplary low-energy building. The ZUB has three floors, a basement and an atrium in contact with a nearby building. It is occupied by researchers in the field of building physics, equipped with a significant number of sensors, and used for experimental investigations in the field of energy optimization and building technologies.

The overall volume of the heavy-weight construction is 6882 m³, the net heated floor area is 1332 m^2 and the main floor space is 892 m² [2]. Floor height is close to 4 m and the annual heat demand is between that of a low-energy building and a passive house, approximately 30 kWh/m² or 5.3 kWh/m³; electricity consumption based on the heated net floor area is approximately 20 kWh/m^2 a. More details about the ZUB and its energy concept are given in [3, 2].

Fig. 1a shows the ZUB building model, designed using Google SketchUp, with shading groups in purple. Since the building is equipped with Thermally Activated Building Systems (TABS): independent radiant floors, and radiant ceiling systems in each room, each physical room was defined as a separate thermal zone. In total 26 zones are required to model the whole building. The atrium at the back of the building consists of three thermal (convective) air-nodes, – one per floor, – combined to a single (radiative) zone, for more details on the model and the simplification see [4, 5].

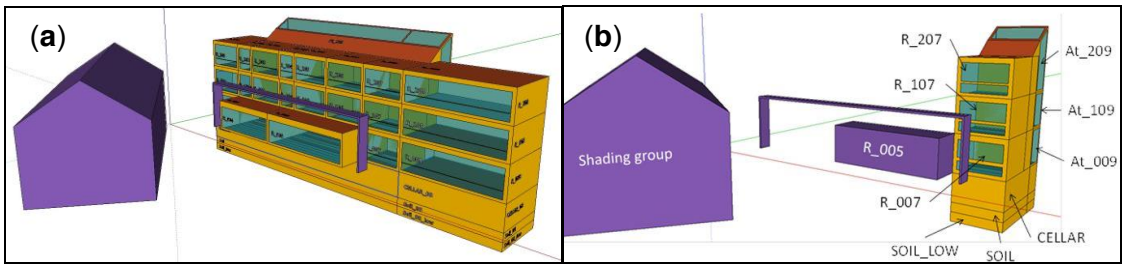

Fig. 1: building model for the ZUB (a) and reduced building model (Tower); designed in Google SketchUp.

For testing the proposed system identification procedure a reduced model the so called Tower is used. This Tower is essentially a cut-out of the building that preserves all relevant characteristics from the whole model, compare Fig. 1b. The implementation approach of SysID, uses TRNSYS simulation output data for system identification. Used weather data are for 2003.

Another major discussion topic of building simulation and control schemes is the zoning procedure. Zoning is defined by simple but often not clear principles. A thermal zone is defined as an individual space or group of neighbouring indoor spaces that is expected to have quite similar thermal loads and behaviour. Zones are defined in thermal building simulation to reduce the number of independent HVAC subsystems. The zone room demarcation in the subject building is done under this simple principle. The three zones due to their orientation and corner position, subject to the whole construction, are expected to have different thermal behaviour depended on unpredictable outdoor environment thermal loads.

A common concept in system identification schemes is the excitation persistency of the system so as the input signal should be such as to excite all the modes of the plant to be identified to assure the convergence of the parameters to their true values. For this reason a simulation schedule is

followed in the building simulations in order to generate proper data for the identification scheme: Every six hours (that is every 24th time step) random control actions were generated and applied to the system to ensure all system dynamics are excited fairly (Fig. 2).

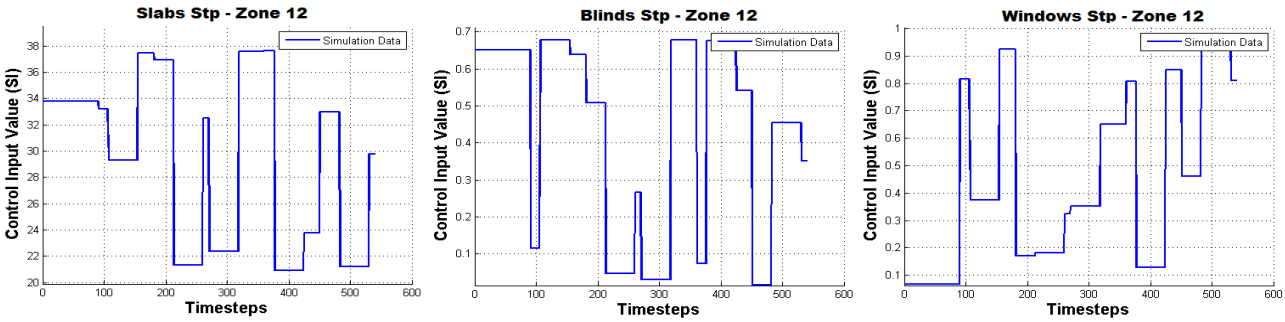

Fig. 2: Simulation random system excitation control signals

5. Parameterization and Identification Results

5.1 Discussion of State-Control-Disturbance Variables

Deciding the proper state and control variables that provide satisfying results with less data complexity and data size is discussed in the present section. In our approach these variables were defined and grouped as:

- Indoor mean air temperature and indoor humidity ratio (consider each zone as a single simulation node – uniform mean temperature and humidity ratio for the whole volume of each zone) were used as state variables (χ vector) because these are the main two physical variables deciding the user comfort level (Fanger [6]).
- Schedule ventilation for openings (windows-doors), schedule for blinds, HVAC temperature set points were considered as the controllable signals for the building model (u vector).
- Outdoor humidity ratio, outdoor temperature, wind speed, wind direction, total solar radiation and office occupancy schedule were considered as uncertain disturbances (w vector).

5.2 Identification Results

Simulation and identification results are depicted below. The simulation data used for the identification process (Training) were chosen during winter period and specifically during the first week of the year i.e. 4th – 12th January 2003 (Fig. 3). The simulation data were divided into two data groups the one used for the model training process (70% of total data) and the other one to validate the identified model with unknown validation data (30% of total data). The sampling frequency was set in the simulation model equal to 15 minutes.
The model was validated using different state resetting frequency (f). In the model integration process three different time horizon scenarios were tested as follows:

- Every validation period time step simulation data were used to integrate the model only to the next time step state variable values (f = 1 step – 15 min).
- Every 25 validation period time steps simulation data were used to integrate the model to the next time step state variable values (f = 25 steps – 6 hours).
- Every 96 validation period time steps simulation data were used to integrate the model to the next time step state variable values (f = 96 steps – 24 hours).

Please note that due to lack of space the results included in the present paper refer only to one thermal zone of the building (Zone R_107). Please also note that the first day of every simulation is used as settling time so as the building reaches a reasonable state – working point.

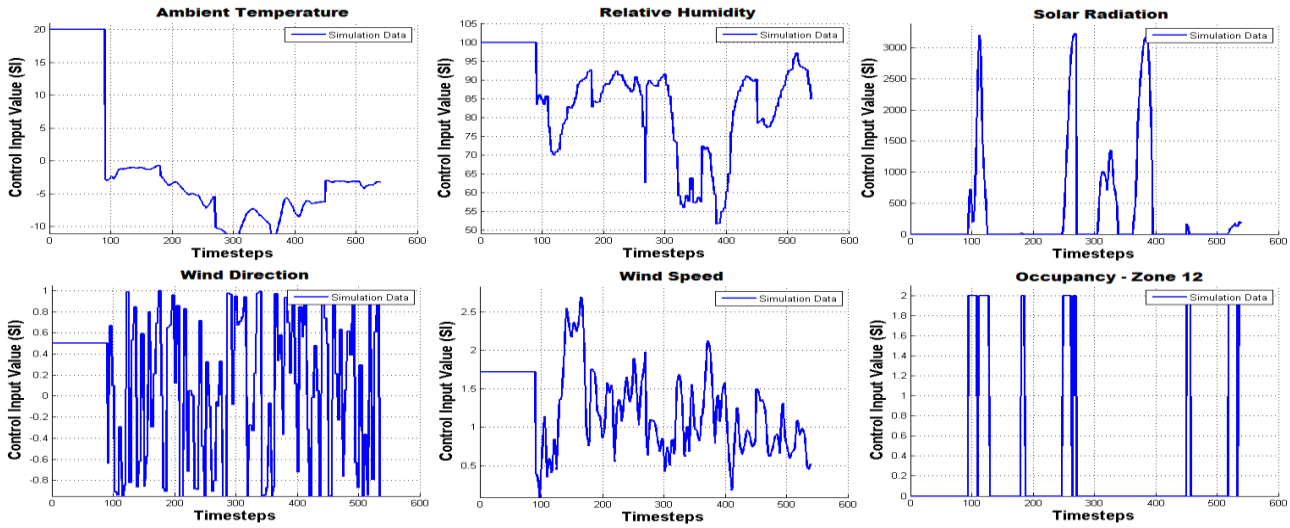

Fig. 3: Simulation Weather Data during the training period which is the first week in January

The summary for the identified model is incorporated in Table 1 below. The respective transients for the validation period are shown in Fig. 4. Note that the blue curves refer to the building simulation results and the green ones to the identified model simulation.

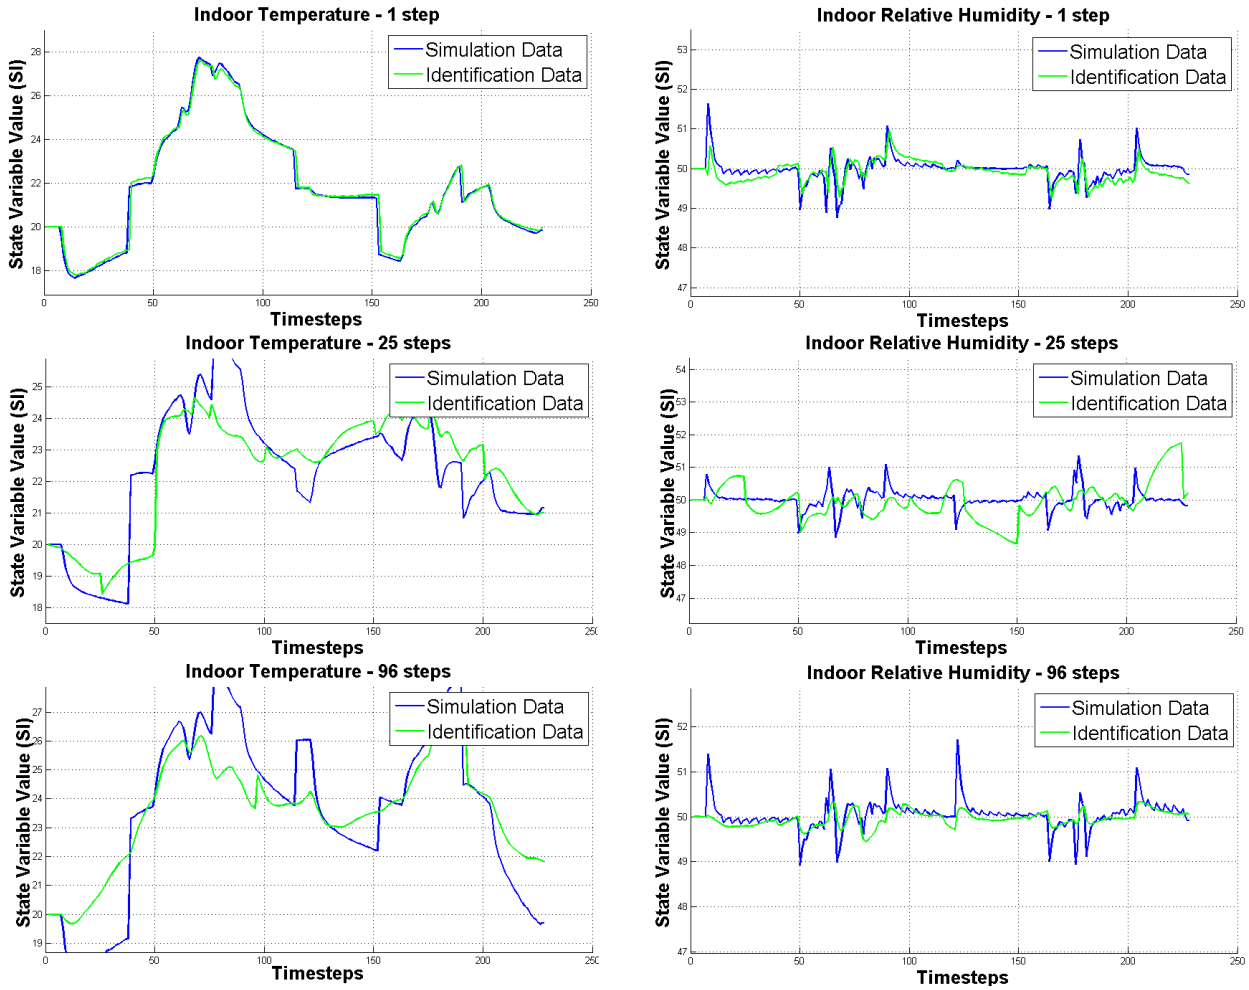

Fig. 4: ID results for indoor temperature in °C (first column) and relative humidity in % (second column) with different state resetting frequency f (different prediction horizon for each row)

Table 1: Identified model summary of results, for three different state resetting frequencies (different prediction horizons)

Steps (1 Step = 0.25 h)	*Prediction Horizon 1*	*Prediction Horizon 25 (6.25 h)*	*Prediction Horizon 96 (24 h)*
Number of mixing functions	2	3	2
Training Period Error (%)	0.9	4.7	6.6
Validation Period Error (%)	1.1	4.5	14.7

6. Conclusion

A system identification approach was proposed in this paper. The identification of a multi-linear state space model which is viable to describe the thermal dynamics of an office building for the near future – based on (simulation) training data from the past – was successfully demonstrated. In this paper simulation data from a validated TRNSYS model of an office building were used for demonstration, but practically these data may stem from measurement data of a real building. Real building data, describing usual operation of the building, however, might not lead to sufficient excitation, which is needed to obtain a "good" model. The idea of mixing signals as weighted factors for the linear sub-models to form the multi-linear state space model proved to work very well if the current state is updated frequently. As the update frequency is increased the modeling error increases significantly for the training period, but especially for the validation period.

klasterdundjer@yahoo.com

Short Summary

The Construction Cluster „DUNDJER“ participates together with number of distinguished research and development organizations in EU, in the 7th FP European project entitled STOREPET (FP7-SME-2011-2, Proposal 286730). STOREPET is a project which goal is develop an innovative thermal and acoustic insulation solution based on phase change materials in building sector. StorePET will be especially designed for lightweight and low thermal mass building envelope structures, as well as for any other residential/commercial/governmental new or refurbishing building projects, with extra insulation and heat storage capacities needs. With a project budget of € 2.4 million, it has been estimated that the new product will produce new streams of revenue worth € 170 million in the materials and energy savings worth above € 300 million. The research is at a moment in progress. One of closing meetings, with presentation of final research results will take place in Niš, Serbia, in the year 2013. The Construction Cluster „DUNDJER“ will have all rights and royalties, including regional production and merchendise.

Key words: building materials, thermal insulation, acoustic insulation, light building constructions, energy efficiency, sustainable building.

1. INTRODUCTION

New building strategies addressing climate change effects and reduction of heating/cooling energy are two fundamental issues at EU level. Figures as the 35,000 excess deaths attributed to the last heat wave in the continent in 2003, or 10% of the world’s energy being used just for heating of buildings support European citizen’s concerns and new EU legislation. New national and communitarian stringent directives, together with the economic slump of the construction sector (showing two digit shrinkage rates) have set extremely high challenges to the already weakened companies in the construction sector, especially the SMEs. A market need and a new opportunity for them is researching competitive solutions for thermal and acoustic insulation of light-weighted constructions, a broadly recognized market driver for the next decade. Lightweight constructions represent an economical alternative to traditional buildings, one of whose main drawbacks is the very high energy load needed to keep internal comfort conditions, as they are unable to curb rapid swings of temperature. When compared to heavier weight materials buildings, it’s estimated that to maintain a thermally comfortable temperature range of 18-24°C, low weight materials use between 2 and 3 times the heating and cooling energy needed by a heavy weight material construction.

2. PROJECT DESCRIPTION

The project concept is based upon the fact that outdoor/indoor heat exchanges (which play a significant part of lightweight buildings cooling and heating loads) can be potentially controlled by a new fibre insulation that possesses a thermally active heat storage capacity. During the day, when temperature rises, the peak loads can be largely absorbed by a PCM-enhanced fiber insulation layer, only to be slowly discharged back to the environment later (during the night time, when outside temperature drops), without affecting the interior building energy balance, as it is aided by the presence of an standard low heat transfer fiber insulation layer. This approach will provide a much slower response of the building envelope to daily temperature fluctuations, helping maintaining inside temperature in a comfortable range and thus avoiding the need for extra energy consumptions to accomplish it. Effective levels of indoor comfort will be also guaranteed by the well known fiber materials excellence, when it comes to reduce airborne noise transmission and its superior performance upon controlling the sound resonance in construction cavities.

3. ENVIRONMENTAL CONTEXT

Currently buildings account for 40% of the world‘s energy and almost half of the today‘s Green House gas emissions. This means that buildings contribute more greenhouse gases than traffic, which is estimated at 31%, and industry, estimated at 28%. When we breakdown and analyze buildings‘ energy consumption, the most worrying aspect is that most of this energy used for heating, cooling or ventilation is needlessly wasted or resulting of poor insulation and all the recent projections claims that this consumption will rise considerably on the next years to come. Under this scope, the last Intergovernmental Panel on Climate Change (IPCC) recommendations has stated that worldwide governments, businesses and individuals must aggressively start to reduce energy use in new and existing buildings, in order to reduce the planet‘s energy-related carbon footprint by 77% (against the predicted 2050 baseline), and stabilize CO_2 levels to reach the level called by IPCC. To reach this objective it‘s estimated that global building sector needs to cut energy consumption in buildings 60% by 2050, in order to meet the global climate change targets.

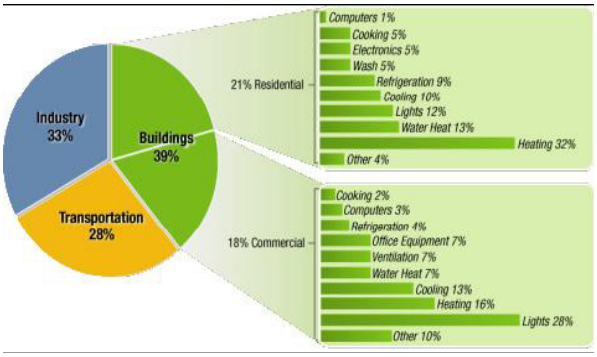

Fig. 1. : Distribution of world energy consumption

With such high levels of energy consumption clouded by severe climate change estimations, the European Community (EC) has triggered a significant number of regulatory and legislative actions. In March 2007, the European Council set clear goals for a reduction of 20% by 2020 in the total energy consumption (below 2005 levels), with a 20% contribution of renewable energies to total energy use and a 20% reduction of greenhouse gas emissions with respect to 1990 figures. In this context, the building sector must assume very ambitious objectives on energy consumption cuts of around 165 Mtoe (millions of tons of oil equivalent) and contribute with 50 Mtoe from renewable energies by 2020. To underline the magnitude of the task, these figures are equivalent to the total joint energy consumption of Spain, Portugal, Greece and Ireland in 2004.
In May of 2010, the new *Energy Performance of Buildings (EPB)* Directive was finally adopted as Directive 2010/31/EU. It calls for improved national regulations upon new and renovated houses energy efficiency, with very ambitious standards and mandatory goals. It also includes a framework for national requirements, related with **heating/cooling** and ventilation systems. In July 2012, the

new directive shall be implemented, though many elements including the regulation of building systems will only be fully enforced by July 2013. By the end of 2020, new buildings in the EU must consume “nearly zero” energy.
With a current stock of around 160 million buildings in the EU, the latest EPB Directive also tack the retrofit of existing buildings, including historic ones towards an effective action against climate change. As for the new buildings, universal trends now show a movement towards lightweight and modular timber or steel constructions (with less site wastes involved and lower embedded energy materials), with global demand for prefabricated housing and elements growing at 3.4 % per year, for a market valued at €51 billion in 2004 for complete buildings alone.

4. THE CONSTRUCTION SECTOR CONTEXT

The construction sector is the one that has suffered most the yet present downturn, partly related to several significant construction bubbles, but also hardly affected by the financial institutions‘ credit crisis.
In particular, focusing on the segment of lightweight prefabricated housing of the building industry, consisting of wood or light steel frame (LSF) and panelized pre-cut structures is expected to show in the next decade the largest growth in terms of novel solutions and production worldwide. Within this segment one of the most important subjects related with building‘s energy efficiency is the use of appropriate insulation materials, both for warm and cold climates (air conditioning is no longer considered an energy-efficient alternative as it accounts for almost 15% of the total energy consumed in Europe). Boosted by present and provisional needs, worldwide consumption of insulation materials is projected to expand 3.8% per year through 2012.. Maintaining the last decade trend, foamed plastic insulation will continue to account for the largest portion of total demand through 2012. Economic expansion in the developing countries of Asia will raise the demand, preferably for foamed plastic, both in building construction and in the production of household appliances. Fiberglass insulation is expected to expand its presence outside of North America (mainly Europe, Asia and all the BRIC - Brazil, Russia, India, and China), while mineral wool will see its share of the market shrink due to the competition of glass wool. Other fiber alternative materials mostly made from recycled materials, like nonwoven technical insulations, will continue to be niche products if they don‘t endorse and push forward their performance.
The increasing demand for energy-saving technologies has contributed to a renewed research for thermal materials that can actively control heat flux environment variations - Phase Change Materials (PCM). The global PCM market is expected to grow from $300.8 million in 2009 to $1,488.1 million in 2015, at an estimated CAGR of 31.7% from 2010 to 2015. The paraffin-based PCM market commands the largest share of the overall PCM market in terms of value, while salt hydrate-based PCMs lead the market in terms of volume. Building and construction currently forms its largest application market, due to the globally increasing demands for indoor temperature control.
European companies in the increasingly knowledge-intensive construction sector need to react quickly to this situation and develop more protectable innovative solutions to remain innovative. In particular, the requirement of higher energy efficiency for buildings has been identified as the primary driver for the construction materials industry. StorePET will provide this EU sector and particularly to the SMEs an excellent knowledge-based competitive tool to ease the recovery and face the near future challenges of our Construction Sector.

5. THE TECHNICAL PROBLEM

Lightweight constructions represent an economical alternative to traditional buildings, one of whose main drawbacks is the very high energy load needed to keep internal comfort conditions, as they are unable to curb rapid swings of temperature. When compared to heavier weight materials buildings, it‘s estimated that to maintain a thermally comfortable temperature range of 18-24°C, low weight materials use between 2 and 3 times the heating and cooling energy needed by a heavy weight material construction.

When comparing the two types of constructions, studies have showed the heavyweight construction could suppress more easily the effects of possible climate change scenario, by maintaining a lower internal temperature than the lightweight construction for most of the time period, with peak temperatures up to 4.5°C cooler. Other studies have revealed that the difference between the peak external and internal temperatures can reach 8º C, when comparing both structures and that a peak temperature delay up to 6 hours can be observed, these delay and amplitude being a complex function of the wall thermal conductivity, the specific heat and several local temperature gradients around wall surfaces. The reason for this huge difference lies on the different thermal mass presented by the two types of constructions. In the case of dwellings for instance, the heat storage and thermal mass properties can vary significantly from 55kJ/m2K for a lightweight timber frame construction to 500kJ/m2K for a solid masonry construction. Thus, thermal mass can be hugely helpful to maintain indoor thermal comfort. Lightweight buildings have a “quick thermal response” and will heat up and cool down over a shorter period than heavyweight building that have a “slow response” (see Fig. 2).

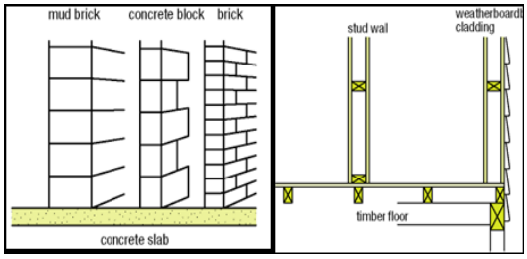

Fig. 2. Materials with high (left) and low (right) thermal mass capacity

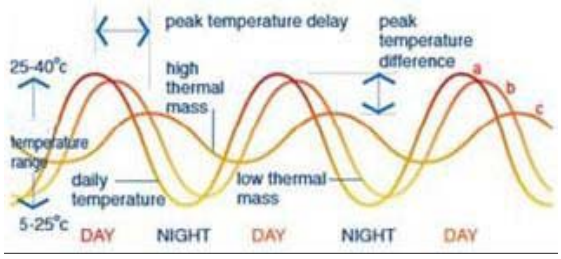

Fig 3. Daily temperature range fluctuations

Thermal mass is most effective in places and in seasons with large daily temperature fluctuations above and below the balance point temperature -BPT- of the building (BPT is the outdoor temperature below which heating will be required in the building because internal heat gains are less than heat loss through envelope and ventilation). In such cases substantially energy is saved by avoiding a significant portion of heat flux being transferred through the envelop backward and forward. Often, the benefits are greatest during summer and fall, when fluctuations above and below the comfort temperature occur. Nevertheless, the same concept can theoretically be used to moderate heat flux under either extreme cold conditions or extreme warm conditions, where outer temperature ranges are well above or below the comfort temperature.

When outdoor temperatures are at their high peak in warm climates, the inside of the building remains cool because the heat penetration through the mass is delayed. If the heat that is stored during the day hours could be evacuated selectively to the exterior at night, the effect of the thermal mass would be very similar to a high performance insulator.

In cold climates requiring intensive heating, thermal mass can be used to effectively collect and store solar gains and to store internal excess heat during the day and selectively release it back inwards. Buildings using electric heating/cooling can simultaneously use off-peak hours enjoying cheaper supply tariffs as daily storing phase. The result will be a substantial net reduction in energy consumption and additional bill cuts due to cheaper electricity.

New European states‘ regulations are more and more concerned about energy efficiency of existent and future buildings and finally looking at **thermal capacity** as a key element for it. For instance, the new UK‘s Building Regulations, recently implemented on the 1st October 2010 refers that thermal capacity of all the internal and external construction elements must play a decisive role on this goal, and used to reduce the heating and cooling demands of a building. Onwards, it will not be enough to consider only the overall heat transfer coefficient (U-Value) of the building elements (level of insulation), but also their related effective thermal capacity per unit area - Thermal Mass Parameter (TMP).

Generally, highly insulated structures cannot efficiently substitute a lack of thermal mass. Thermal mass stores and re-radiates heat, while insulation stops heat flowing into or out of the building. A high thermal mass material is not generally a good thermal insulator and the best insulation material has almost no thermal mass. Thus, in harsh hot climate conditions, the only way to

maintain a comfortable temperature inside a lightweight building on a summer day without installing active air conditioning is to somehow increase its thermal mass. You can do it in traditionally manner with heavy building materials, or by introducing latent heat storage materials in its construction.
Up to now the only solution it's to combine different materials separately for maximum performance. While it is reasonably easy for the heavyweight masonry sector to do this, the quest for thermal mass by lightweight construction builders (that rely almost exclusively upon insulation), it's still seen as a battle that needs urgently to be won in order to stay competitive for the years to come. Although there have been a great deal of resources invested on research (mainly on the US), worldwide construction market is still waiting for economical products that can effectively combine the best of the two worlds (thermal insulation and thermal storage properties), without forgetting the noise insulation ability on a **single, affordable and easy to work product**.
The goal of this project is the development of a new thermally enhanced fiber insulation product solution with the help of phase change materials (PCMs). PCMs are substances with high heat of fusion (high latent heat storage) which, by melting and solidifying at a certain temperature, are **capable of storing and releasing large amounts of energy**. Heat is absorbed or released when the material changes from solid to liquid and vice versa. PCMs are been used for several years as thermal mass components in buildings with some degree of effectiveness upon building energy performance. Today, there are many commercial PCM products available in the market, either in the form of a single material, or in the form of integrated products placed on the interior surfaces of walls, ceilings or floors (such as PCM integrated gypsum wallboards, concrete, plasters, etc). These products are generally used to reduce indoor space day/night temperature swings, due mainly to diurnal solar gains through glazing, by storing autonomously the heat during the day and release it back during the night, providing an extra heat source to keep the inside comfort. To understand the extent of PCM technology upon energy saving possibilities, studies have found that an area of approx. 120 m² using an enhanced plaster with a microencapsulated (thin polymer container) paraffin wax PCM (with a maximum heat storage of 110 J/g), could match up about 40,000 kJ, corresponding to more or less than 11 kWh. This energy consumption is equivalent to the cooling performance of an air-conditioning unit with an input power rating of 4 kW, used at full capacity for 1 hour a day. For a predicted PCM working process for five hours a day during 10 weeks of significant hot weather a year, that would have the same effect as using air conditioning unit for 300 hours, which corresponds to an average saving of 228 €/year, considering the initial equipment investment.
However, none of today's building materials incorporating PCMs in a stand-alone product are designed either to perform as heat flux blockers through the building envelope (external walls and roofs), or as a noise insulator. **The StorePET project intends to overcome this market gap** and act differently from any other PCM available product, **using PCMs fiber incorporation technology to excel the extra advantage of the conventional fiber insulation work**, regarding the large temperature fluctuations that take place in residential attics or at the exterior wall surfaces of lightweight building structures.

6. THE PROJECT CONCEPT

The project concept is based upon the fact that outdoor/indoor heat exchanges (which play a significant role in lightweight buildings cooling and heating loads) can be potentially controlled by a new fiber insulation that possesses a thermally active heat storage capacity. During the day, when temperature rises, the peak loads can be largely absorbed by a PCM-enhanced fiber insulation layer, only to be slowly discharged back to the environment later (during the night time, when outside temperature drops), without affecting the interior building energy balance, as it is aided by the presence of an standard low heat transfer fiber insulation layer. This approach will provide much slower response of the building envelope to daily temperature fluctuations, helping maintaining inside temperature in a comfortable range and thus avoiding the need for extra energy consumptions to accomplish it. Effective levels of indoor comfort will be also guaranteed by the well known fiber materials excellence, when it comes to reduce airborne noise transmission and its superior performance upon controlling the sound resonance in construction cavities.

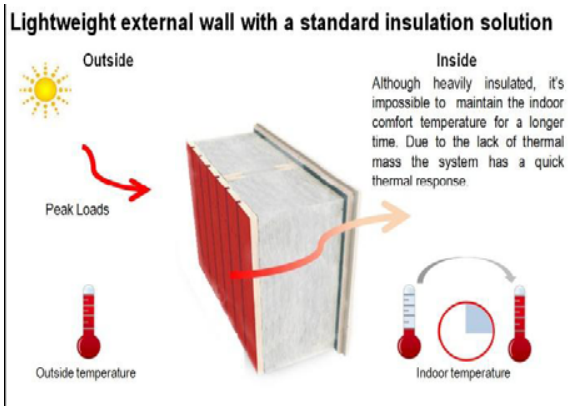

Fig. 4. Standard external insulation solution

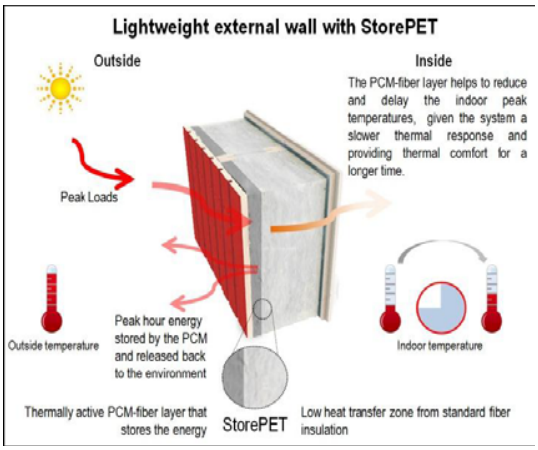

Fig. 5. External insulation with StorePET

From the point of view of energy efficiency design, the added value of the PCMs is its extra ability (on top of the thermal resistance) to reduce energy consumption in the building. The Fig.5. shows how StorePET solution would significantly reduce inside temperature fluctuation and therefore the needed heating/cooling load to keep temperature constant, in a scenario of high fluctuation of outside temperature.

The same conceptual solution when applied to extreme hot or cold temperatures would need different products (PCMs' fusion points, relative concentration and distribution along the matt cross section would be different to avoid external heat than to recover internal heat), and installation layouts (matt allocation, ventilation systems) would as well differ. Maybe the most notable difference is the convenience of an additional ventilation system to take full advantage of the thermal inertia provided by the PCMs.

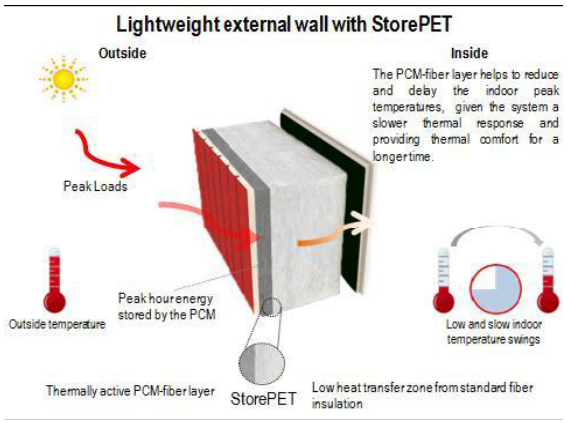

Fig. 6. Extreme high temperatures

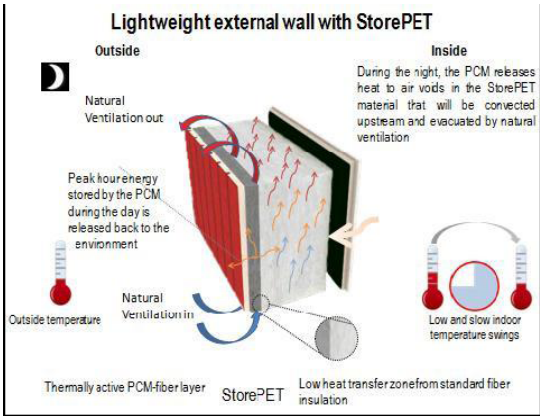

Fig. 7. StorePET with additional ventilation

The above figures (Fig. 6 and Fig. 7) intends to illustrate a scenario of extreme high temperatures. During the day, the PCM acts as a thermal barrier and only a fraction of heat reaches the inside, while the rest is stored in the PCM bat. When temperatures go down in the night (but yet above the comfort temperature), the bat warms up surrounding air. If properly ventilated, natural convection pushes warm air up and then out to the outside, refrigerating the PCM and avoiding storage heat to penetrate the building. An appropriate structure of the bat enabling air mobility in the plane of the facade and restricting the perpendicular direction will favor lateral convection for homogeneous refrigeration and vertical convection for evacuation. The design and manufacture of such a structure through a multilayered approach and other alternatives will be a relevant task of the non-woven panel research.

Although more suitable for warmer climates, while tailoring its composition with different phase change temperature materials and different installation layouts, StorePET will be able to respond to a broad range climate patterns. This will give it a unique and unmatchable versatility amongst other building insulation products. Out of each design temperature season, the product will just act like a normal fiber insulation material, keeping all other thermal and acoustic properties intact.

7. THE SCIENTIFIC, ECONOMIC, AND SOCIAL OBJECTIVES OF THE PROJECT

The main goal of the StorePET project is to develop a new nonwoven technical insulation product that integrates phase change materials for heat storage capacity skills. Maintaining the superior levels of thermal and noise insulation commonly recognized for fiber materials, StorePET will be especially designed for lightweight and low thermal mass building envelope structures, as well as for any other residential/commercial/governmental new or refurbishing building projects, with extra insulation and heat storage capacities needs. Although expected to be more effective in places and seasons with large daily temperature fluctuations, where it‘s possible to take full advantage of its performance abilities, this new product can also be used as standard insulation on any type of climates and a secure choice to counteract global warming rising temperatures.
To ensure that the project is a success we have defined clear objectives that are quantified, measurable and focused during the project‘s work package tasks program and continuing accounted on related deliverables reports.

7.1 SCIENTIFIC OBJECTIVES

- Achieve a clear and extensive understanding of the lightweight building systems currently available, their technical needs and most commonly thermal and noise insulation materials used, its relevant standards and building regulations dealing with the latest energy efficiency requirements;
- Clearly define the theoretical principles evolving thermal conductivity and heat storage and transfer behavior of PCM fiber composite materials, as well as the fundamentals ruling its acoustic absorption and insulation;
- Noticeably identify the best technical fiber characteristics and which PCMs materials and are most likely to be used, based on their thermodynamic, chemical and physics properties, production costs, and technological skills aiming the nonwoven PCM-fiber integration and its end using goals.

7.2 TECHNOLOGICAL OBJECTIVES

- Develop the product‘s design and the technology for its making by building a newly prototype line system for PCM-fiber integration and trial product manufacturing;
- Refine StorePET production technology, aiming to combine the best technical properties with the least embodied energy necessary for its production, using the most cost effective raw materials with the highest recycled content possible and least energy consuming production lines;
- Define the active ventilation systems that should accompany the installation of StorePET insulator, in areas of extreme absolute temperature but low fluctuation;
- Develop a software for thermal and acoustic properties evaluation aiming the design of the optimum StorePET product for a type of installation and a set of variables. It will bring an easy-to-use interface for professionals non highly qualified on the use of sophisticated simulation tools, but will relay on finite elements modeling, properties of raw materials, layer zone designs and climate patterns of the most plausible entrance markets.

7.3 PRODUCT TECHNICAL OBJECTIVES

- Achieve on a lab scale using a guarded hot box facility, reductions in heat flow of about 40% with the new PCM-fiber product, when compared on the equal conditions with the same fiber material produced without the PCM content;

- Achieve by field tests potential and significant cooling load reductions during a spring-summer season period. The fulfillment of this objective will be dependable on the location of these tests. For places with large daily temperature fluctuations during the hot season, peak-hour load reductions higher than 20% and cooling-dominated loads reductions up to 40%, shall be expected (representing real energy savings), when compared to regular fiber insulation materials (mineral wool, glass wool, etc.);
- Secure a thermal conductivity K (W/(mK)) not higher than 0,04 and preferably under this value;
- Accomplish a thermal resistance - RSI value (m²K/W) not less than 2,5 for a nominal thickness of 100mm;
- Achieve a noise transmission insulation (Rw) not less than 55dB for StorePET, when placed between a wall partition made of a double drywall panel, with a 6cm cavity space;
- Guarantee all the other technical requirements to meet the national and communitarian building codes and regulations for each proposed entrance market. Special emphasis shall be given upon moisture and fire resistance, this last one with European fire classification stated not less than Class Bs2d0.

7.4 ECONOMIC OBJECTIVES

- Accomplish significant energy savings concerning the reduction of air-conditioning needs related with the walls/roofs heat exchanges, and a controlled and balanced price for this new product, aiming a reasonable payback time for its end users considering the energy saving possibilities (within a maximum of 5 years).

7.5 SOCIETAL OBJECTIVES

- Increase the consumer (building constructors and home-owners) knowledge and acceptance of this new thermally enhanced insulation product;
- Demonstrate the market demand for a new building insulation material like StorePET;
- Protect/increase the employment in related companies, from raw materials and technical non-woven producers, to PCM suppliers, up to the overall building construction market chain;
- Increase citizen‘s level of indoor comfort and reducing health problems related with thermal and acoustic insulation issues;
- Contribute for the reduction of global CO2 emissions by joining the effort to effectively decrease the building sector account for energy usage.

Short Summary

Nowadays most of the buildings cannot respond efficiently to changing needs of users and society due to the way buildings are designed and constructed. Labour-intensive renovation is often necessary; otherwise demolition of the building will follow. In both cases valuable building materials are lost and new raw materials are needed. Partly therefore, the environmental impact of the building sector is significant.
The need for new buildings materials and the production of waste could be minimized by implementing the time dimension in the design phase, in such way a building can change during its life cycle without ever being an end product. Namely by using compatible components and reversible connections, building components can be added and removed to fulfil new requirements. The removed components can be reused later on in a new configuration.

Therefore, in the context of this paper the impediments of implementing dynamic detailing and the dynamic potential of conventional load bearing structures will be explored. It will be examined how a structure constructed by using a conventional building method (masonry, timber skeleton structure, etc.) can pass into various usage scenarios: expansion, reduction, modifications of the skin, etc. This knowledge will be applied to a generic case study.
By doing this, it will become clear which building method can meet the imposed dynamic conditions and which usage scenarios the load bearing structures can fulfil. These results can be extended to other more specific cases.

Keywords: Generic case study; design for disassembly; detailing; load bearing structure; reuse of building components.

1. Introduction

Nowadays most of the buildings cannot respond efficiently to changing needs of users and society due to the way buildings are designed and constructed. Labour-intensive renovation is often necessary; otherwise demolition of the building will follow.
In both cases valuable building materials are lost and new raw materials are needed. Because of this, the building sector is responsible for 50% of the extracted resources [1]; and moreover, for example for Belgium, 30% of all waste is produced by construction and demolishing buildings.
Partly therefore, the environmental impact of the building sector is significant. The main part of construction and demolition waste is indeed recycled, but the recycling process occurs often with a quality descent by mixing different materials [2]. For instance concrete rubble is almost exclusive reused as foundation material for roads and only 5% of the concrete rubble is used again in

concrete applications [3].
The need for new buildings materials and the production of waste could be minimized by implementing the time dimension in the design phase, in such way a building can change during its life cycle without ever being an end product. [4] Namely by using compatible components and reversible connections, building components can be added and removed to fulfil new requirements. The removed components can be reused later on in a new configuration.
The last few decades design strategies and approaches were developed to facilitate change and the reuse of building parts; nevertheless dynamic building is still restricted to a small scale and specific functions, such as temporary / transitional buildings. A frequently cited reason of this restriction is the lack of constructional knowledge.

Therefore, in the context of this paper the dynamic potential of conventional load bearing structures will be explored. Can we use existing building products (perhaps with small adaptations) to build in a more transformable way? Or are there still some specific impediments?
In this paper the research is clearly defined in terms of building layers: only structural components will be taken into account; because this building layer has the biggest environmental cost compared to other building layers (Fig. 1).
If the structure can anticipate changing needs, the structure will last longer and its environmental cost will reduce. If for example, the structure can be removed when there is no demand any more on the initial site for this structure, and it can be reused in another configuration, the cost will diminish too. In a next research phase the building envelope, partitions, etc. can be taking along.

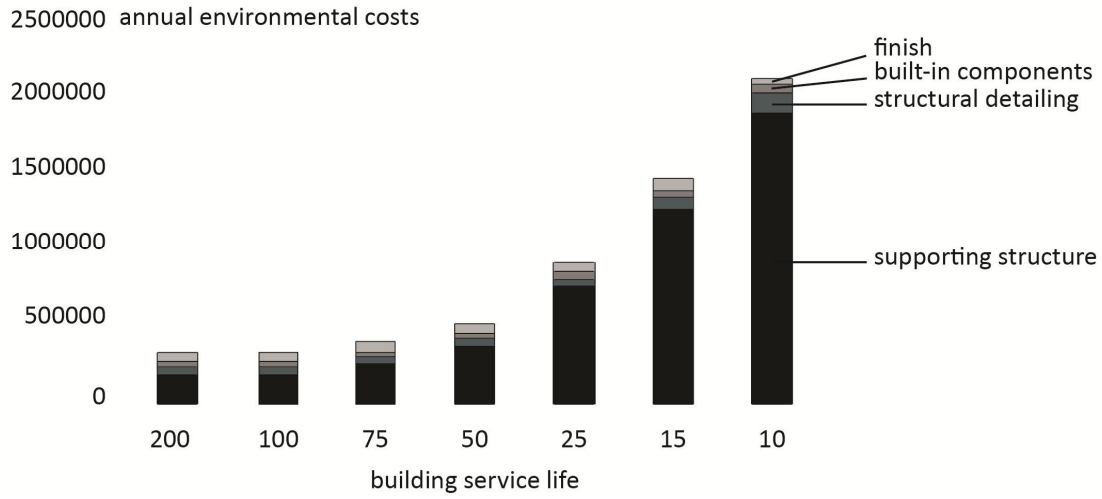

Fig. 1: The environmental load of a building in the case of different building service life scenarios and based on common lifespans of building components. Adapted from [5].

In a previous paper [6] it has been examined how transformable conventional building methods are. There are already adaptable building systems, but they need some adaptations in order to anticipate better changing needs. Those systems will be improved firstly. In a next part it will be explored which scenarios the case should be able to pass into, e.g. expansion and reduction of a basic unit. Finally, those scenarios will be tested on the original and the improved building systems. By doing this, it will become clear which building method can meet the imposed dynamic conditions and which usage scenarios the load bearing structures can fulfil. These results can be extended to other more specific cases.

2. Transformable building systems

2.1 Introduction

Dynamic building systems according to different conventional building methods (masonry, loam structure, etc.) are examined in this section. There will be looked at existing building systems; and if necessary they will be improved.

The characteristics of the components, which will be used to evaluate the transformability are established by literature of Durmisevic [7], Nordby [8], and Paduart [9]; more information can be found in [6].

2.2 Masonry

A large part of the conventional Belgian (new-built) constructions are made of load-bearing masonry with timber beams or concrete floor plates. Most bricks, the components of masonry, are physically suitable to be reused repeatedly. [10] However, when needs change, and therefore renovation or demolition is required, it is difficult to separate the components without damaging them due to the use of cement. The cementitous bricks can be recycled, but this often occurs in an inferior way. It is therefore necessary to examine how bricks can be connected in order to optimize their reuse potential and to respond to changing needs.

A conventional load-bearing masonry has already some good (convertible) properties. For example it is made out of small, light-weight components, namely bricks. This has the advantage that when reusing the components a total different configuration can be made and that the components are easily to handle. Nevertheless, due to the small dimensions, there are a large number of components needed to build for example a wall and by this large number the amount of (dis)assembly sequences on site increases too, which is often a bottleneck for disassembly. [7] Offsite pre-assembly of several building parts provides a possible answer to this problem.
The dimensions of the bricks are standardized according to the method of production, the origin, but the different types of bricks are not mutually compatible. This is unfortunate because compatible bricks could give more architectural flexibility in the reuse phase.
Finally, the influence of a conventional structure on other building layers with different life spans is a major disadvantage. For example the space plan is mainly fixed by the monolithic bearing walls, while according to Brand the space plan changes every 3-30 year and the structure remains sometimes up to 300 years. [11]

SRB-DUP structure (Fig. 2) is an alternative for masonry where building components are unbounded in order to facilitate reuse by using steel plates and bolts. [12] The system consists of a new sort of brick with two holes.
There is another type in the making, namely a smaller variant of Legioblocken®, the Q-bricks (Fig. 3), made of rubble waste. [13] Steel beams transmit the horizontal loads. At the moment, research is going on to use the stones for emergency sheltering. The bricks are held together only by their own weight and can be reused immediately after use. The small, standardized stones could be piled up by one person. Still, the small dimensions cause a large number of components and connections.

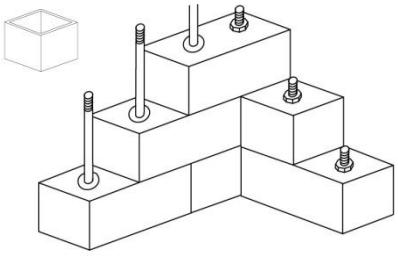

Fig. 2: Existing dynamic alternative for masonry, SRB-DUP structure

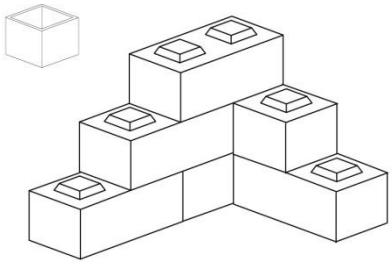

Fig. 3: Dynamic alternative for masonry (in the making), Q-bricks

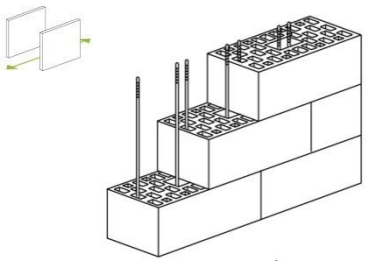

Fig. 4: Improved dynamic alternative for masonry

The influence on the other building layers remains large for both alternatives; and pre-assembly is difficult due to the size of the monolithic entirety. Additionally, for Q-bricks pre-assembly isn't possible due to the way of connecting the bricks.
To propose a possible better alternative there must be worked on the static characteristics of the above mentioned building systems. A boundary condition of the new version is that it should be based on existing products. This ensures an easier application for everyone in the building sector.

The new proposal consists of breeze blocks and steel rods with thread (Fig. 4). The bricks are placed layer by layer over the rods. When an entire wall is built, the stones are tightened with bolts. In this way, a wall can be preassembled. Furthermore, horizontal loads are carried by timber beams. An additional improvement of the SRB-DUP structure could be a single bearing direction. If necessary, small wall elements can be placed to capture forces in the plane of the load-bearing wall, for example, wind loads. This modification reduces the influence of the structure on the other building layers. By making it possible that some parts of the structure can be removed and added independently, this alternative for masonry can be even more easily pre-assembled and adapted.
This proposal should be able to react better on changing needs. Nevertheless, some studies suggest that the environmental costs of using steel bolts will be too high and that historic brickwork with lime mortar could be a better environmental solution with the same salvageability potential. [14] For this reason historic brickwork will be evaluated too in this paper.

2.3 Loam structure

Loam construction is the outsider within stack work. This traditional construction method is rediscovered the last decennia but is still only sporadically used despite of many advantages, e.g. optimal indoor climate and minimal CO_2 emission.
If loam is used as a structural material, a vertical supporting element can be made of loam stones connected with loam mortar (Fig. 5) or of a loam mixture rammed in a formwork (Fig. 6). Those elements can fulfill a supporting function, even up to six storeys high. Horizontal bearing elements can be built out of rammed loam or loam stones sandwiched between wooden lattice beams. [15]
The loam mortar is a reversible connection if moistened. The stones and rammed loam walls can be recycled too if moistened; and they can take a different form. However, there was no evidence found that loam stones may be reused as a new component after use.
The proposed alternative (Fig. 7) is similar to the proposal for masonry; the only difference is the material. The brick itself is comparable to a clay block, proposed in [16] that is optimized in terms of mechanical resistance, weight, economically sensible drying, and thermal capacity. But instead of using loam mortar, bolts and steel rods with thread are used. Horizontal loads are supported by timber beams.

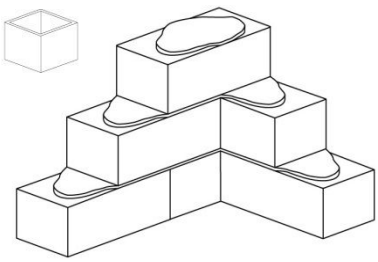

Fig. 5: Loam stones connected with loam mortar

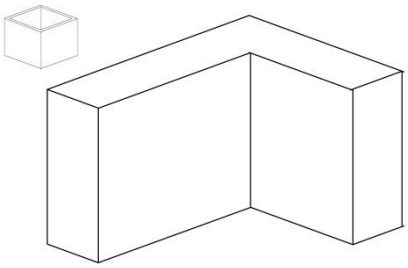

Fig. 6: Monolithic rammed loam wall

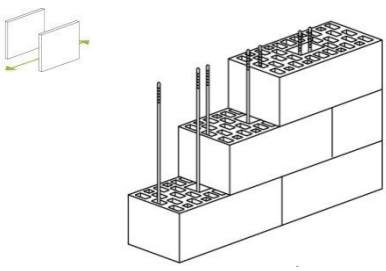

Fig. 7: Dynamic alternative for loam structure

2.4 Massive wood construction

Despite solid wood construction is little used in Western Europe; the opportunities of this construction method are analysed, as it has a great potential reuse without a large footprint.
For example logwork, a traditional solid timber construction, consists of tree trunks, which are cut into equal lengths and stacked without using additions. By lopping the trunks at the ends the different load-bearing walls form a monolithic entirety (Fig. 8). This construction process can be easily executed by two people because the trunks weigh relatively light and are easy to handle. Furthermore, the workforces do not need any special knowledge during the building process.
The components, in this case, the tree trunks, are large, compared to for example components of traditional masonry, which implicate that the number of required components is lower and thus also the number of connections. However, due to the connection method, namely stacking, this building process is difficult to prepare off-site. The connection method is of course completely reversible, so the durable trunks can be reused. The cycle can be simple closed on material level too; since wood can biodegrade safely if no toxic substances were added [17].

A disadvantage of massive timber construction is, as in stack work, that building layers with a different lifetime depend on the structure. For example, openings in the facade should be included in the design of the structure and cannot be made afterwards in a simple way.

A contemporary alternative is Holz100 (Fig. 9). This is a prefabricated building system, which reduces the number of (dis)assembly sequences on site. Wooden planks are joined with dowels into large solid elements; and the different elements are connected to each other on site with nails. Although dowels are a reversible connection, the amount of dowels ensures that the elements are not quite easy to dismantle. Additionally, the Holz100-elements can have all possible dimensions without being based on a generative system, while the trunks used for log work are sawed in more or less standardized dimensions [18]. Finally, one recurring drawback of solid construction is the dependence of building layers with a different lifetime on the structure.
Klimablokken, designed by the architect Berge [19], respond to these disadvantages. He opted for smaller standardized modules that can be concatenated by dowels to major elements (Fig. 10). In this way the blocks can be preassembled, but they can be put together and be taken apart on site too by for example a homebuilder. Timber beams carry the horizontal loads. As the building system can be easily disassembled, the building layers with different lifespans depend less on the structure. The facade could be changed for example, by linking the blocks into another configuration.
As with masonry a single bearing direction of the blocks could be an improvement, wherein the load-bearing walls could be separated into several parts.

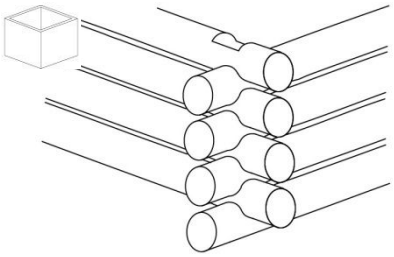

Fig. 8: Traditional building node of massive timber

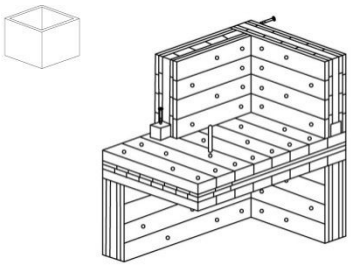

Fig. 9: Existing dynamic alternative for massive timber, Holz100

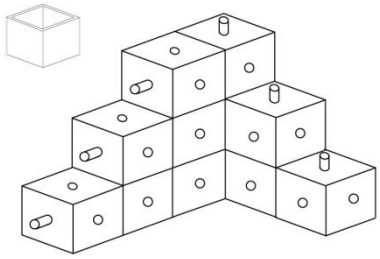

Fig. 10: Existing dynamic alternative for massive timber, Klimablokken

2.5 Skeleton, element and plate structures

Skeleton structures have the advantage that other building layers are little influenced by the structure. For example, the space can be divided and used in freedom, considering only a few columns. Wooden, steel and concrete skeleton structures have this advantage. Moreover, steel can be recycled with the same quality and wood has also the additional benefits mentioned in the preceding section related to the material: a low environmental impact and biodegradable.
Additionally, the components of both building methods can easily be disassembled and reused if the components of the skeleton structure are connected as in Fig. 11 and Fig. 14, namely with bolts. To facilitate disassembly for concrete structures, anchored screws can be used (Fig. 17).

Wooden and concrete components are traditionally not standardized, but rather project dependent. There exist, of course, all ready building systems which have been standardized, such as Lukas Lang® (Fig. 12) and CD20 (Fig. 18). Conventional steel structures are standardized, but the dimensions are not always compatible. Quicon® (Fig. 15) is a possible dynamic alternative for steel skeleton structures.

The components are in all cases larger than brick, which makes the construction process faster, but which will also increase the weight and decrease the ease of handling.

Another wooden building method is timber element construction (Fig. 13). Horizontal laths connected with vertical laths with nails ensure the structural working. As a result, it contains more components than a skeleton structure, but less than a stack work construction. As a result, most

dynamic properties are in between the properties of the two other building methods.
However, if screws are used to connect the vertical and horizontal laths, the elements could be easily disassembled and could give a higher freedom than skeleton structure in the reuse process.
Steel studs are comparable (Fig. 16) to screwed timber element construction.
Another concrete building method is concrete plate structure, but cannot be disassembled in smaller components (Fig. 19).
A single bearing direction of timber element construction, steel studs and concrete plate structure could be an improvement in order to reduce the influence of the structure on the other building layers.

2.6 Conclusions

In this section most conventional building methods were discussed. A summary was given of the mean dynamic properties of existing building systems. Only some small adjustments were suggested in order to anticipate better changing needs. Solid structures have more freedom if they are single bearing, and all conventional structures would improve their reuse potential by standardizing and making their components compatible. By using steel bolts preassemblies can be made of clay and loam bricks; and they can insure an uncoupling into different building elements.
Those proposals should be further elaborated both theoretical and practical. It should be examined whether there is actually an environmental benefit in applying those construction systems in the short and the long term and compared to existing systems.

3. Determination of possible scenarios

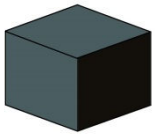

Fig. 20: Volume basic unit

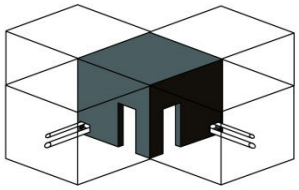

Fig. 21: Horizontal addition to the basic unit

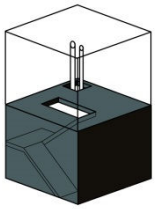

Fig. 22: Vertical addition to the basic unit

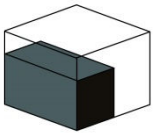

Fig. 23: Reduction

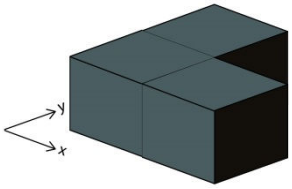

Fig. 24: Joining of two basic units

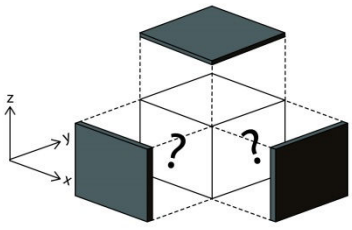

Fig. 25: Modifications of the skin

This section describes some possible usage scenarios for the load bearing structure, on which the abovementioned building systems should be able to anticipate. The scenarios are based on the chapter ‘A manual for flexible housing’ from the book ‘Flexible Housing’ written by Schneider and Till. [20] The included scenarios are the ones where the structure has a major influence on a possible anticipation. For example, if there is need to build an addition on an existing building, accessible from the base unit, there must be enough space in between the structure to build a staircase in order to access the addition. The scenarios were not included if the structure has little effect on a possible anticipation or if there are too many other boundary conditions beside the structure. For instance, a possible anticipation on a change of function (i.e. residential, commercial, office, and retail) depends on many factors, making it little sense to test the scenario on a generic case.

A basic unit consisting of one of the building systems, is the starting point for every scenario. Fig. 20 shows the borders of the structure. The coloured surfaces only indicate the total building volume and do not pass sentence whether it is composed of a skeleton structure or of a solid structure.
The basic unit has unspecified dimensions, because the dimensions depend on the load bearing capacity of the building system and the possible dimensions of the components; it can be considered that the extreme dimensions are approximately 3 by 3 meter.

In the first scenarios, there is a demand for expansion. It examines whether a horizontal and vertical addition is technically possible with the different building systems. (Fig. 21 and Fig. 22) This evaluation considers the connection between the addition and the base unit and doesn’t consider the load-bearing capacity of the base unit, because oversizing the initial structure (foundations included) will make every solution structurally possible.
Additionally, if the addition dependents on the base unit, the addition should be accessible from the base unit; and the services, like water supply, should possibly be extended.

The opposite of addition is a possible scenario too: a reduction in the horizontal and vertical direction of the basic unit (Fig. 23).
Fig. 24 shows how two basic units can potentially transformed into one large space; this scenario is evaluated for the two directions (x- and y-direction).

The following scenarios examine the influence of the structure on the facade (Fig. 25) and on the plan layout (Fig. 26). It is analyzed if the skin can be changed in all directions (x, y and z) without disturbing the structual working; and it must be possible to change the plan layout of the basic unit, whereby the layout is not limited to the boundaries of the building volume in the x- and y-direction.

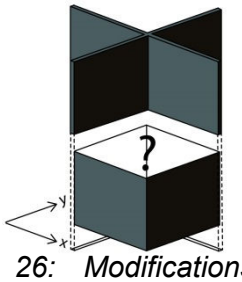

Fig. 26: Modifications of the space plan

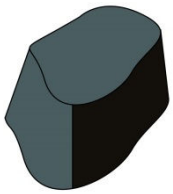

Fig. 27: Dis- and reassembly

The last scenario examines whether the basic unit can be fully disassembled and can be rebuilt in a new configuration () with different dimensions (height, width and length) and a different shape.
Moreover, the possibility of closing the cycle on material level is analysed too. The used materials could be biodegradable or upcyclabe. Upcyclable means that the materials can be recycled with the same quality; and biodegradable means the materials can be given back to nature for biological processes without danger, e.g. no toxic materials.

All other scenarios mentioned in [20] are already contained in another scenario. For example, the extension of the services is included in the scenario where a unit is added.
The described scenarios will be tested in the next section on the different building systems. It will be examined to which extent a particular scenario can occure.

4. Implementing building systems

The different usage scenarios are evaluated for the different building systems in this section. The evaluation is divided in two tables, one for solid structures (Table 1) and another one for other structures (Table 2).

It can be remarked in Table 1 that historic brickwork, Q-bricks, loam stone, rammed loam structure and Holz100 cannot response to various scenarios due to the monolithic volumes of those structures. For instance, a horizontal addition will not easily be accessible nor can services extend. For logwork components it is even impossible to connect a horizontal addition; a second independent structure will be necessary. The other building systems can foresee an access and an extension of the services, because structural elements can be more easily uncoupled.
A vertical addition is easier to implement, especially for the building methods which transfer horizontal loads by beams, because the addition can be accessed and services can extend in between the beams, although the direction of a circulation core is decided beforehand by the beams.
For historic brickwork, Q-bricks, logwork and Klimablokken a vertical reduction can be fulfilled by removing components. For historic brickwork and Klimablokken this is a rather labour intensive process. The SRB-DUP based systems cannot have a vertical reduction, because of the continuous steel rods. As structural elements can be easily uncoupled for SRB-DUP, dynamic loam and Klimablokken, a horizontal reduction can be made for those building methods.
Joining of units is not possible for monolithic building methods nor are changes to the space plan executable. The other single bearing building methods can join units in only one direction, namely the one that isn't supporting the structure; equal for changes to the space plan.
Changes to the skin are comparable too, except the use of beams can facilitate changes to the roof.
Loam stone and rammed loam have reversible connections, but the components will possibly deform during the disassembly process (i.e. humidification of the mortar), so reuse will probably be impossible. The components of the other building methods can be reused. The difference between the reused components lays in the form- and dimensional freedom; namely the smaller the components are the more freedom the new configuration has. Additionally, wooden components can be biodegraded, loam can be upcycled, but backed clay bricks cannot biodegrade or upcycle.
Finally, it can be concluded that the proposed adaptions have indeed a dynamic effect compared to existing dynamic building systems. The modified building systems can give easier access to additions; they can extend services; joining of units and changes in the space plan are now possible in already one direction and reductions and changes to the skin are more easy than before for most adapted systems. Moreover, when reusing the components, they provide more form- and dimensional freedom.

Table 2 contains skeleton, element and plate structures. At first sight it can be observed that those structures can, except for concrete plate construction, anticipate much more usage scenarios than the first mentioned structures. For all skeleton structures horizontal and vertical additions are possible; units can be joined; the building skin can be changed without constraints and space plans can be transformed. Timber element structures and steel studs have the same potential, except the freedom is limited in the load-bearing direction. For example an access through a load-bearing element is less obvious.
CD20 and concrete plate constructions are exceptions. Concrete plate structure and CD20 transfer horizontal loads by solid floor plates, which prevent vertical access, services extensions roof changes. Plates restrain for concrete plate structure horizontal freedom too, for example units cannot be joined perpendicular to the load-bearing walls.
For element structures a horizontal reduction can be fulfilled by removing parts of the structure. All other reductions are difficult, especially compared to some solid structures.
All proposed building systems have reversible connections, so all components can be reused. However, compared to solid structures, the components are bigger, which give less form- and dimensional freedom in the new configuration.
Additionally, steel can be upcycled, but concrete cannot biodegrade or upcycle.
For these structures no major adaptations were suggested, because they are already quite dynamic. Compatible components can improve their reuse potential, but the bad points are less easy to change. For instance, making reductions possible for skeleton structure is not easy to do, but the remark can be made that this scenario will less occur.

5. Conclusions

Existing building products only need some small adaptations in order to anticipate better changing needs. Solid structures can provide more freedom if they are single bearing; and all conventional structures would improve their reuse potential by standardizing and making their components compatible. By using steel bolts preassemblies can be made; and they can insure an uncoupling into different building elements. It can be concluded that the proposed adaptions have indeed a dynamic effect compared to existing dynamic building systems. The modified building systems can give easier access to additions; they can extend services; joining of units and changes in the space plan are now possible in already one direction and reductions and changes to the skin are more easy than before for most adapted systems. Moreover, when reusing the components, they provide more form- and dimensional freedom.
However, with or without adjustments, skeleton structures can pass into most usage scenarios more easily than solid structures. But, compared to solid structures, the components are bigger, which give less form- and dimensional freedom in a new configuration.

In this paper some small adjustments to existing building systems were suggested (e.g. single bearing, compatible and standardized dimensions) in order to anticipate better changing needs. However, those proposals should be further elaborated both theoretical and practical. It should be examined whether there is actually an environmental benefit in applying those construction systems in the short and the long term and compared to existing systems. For instance, some studies suggest that the environmental costs of using steel bolts will be too high. However, maybe for some scenarios and building systems this cost will be lower than the environmental gain. Off course those assumptions have to be evaluated more in detail with the aim to improve the suggested building systems.
In addition, the calculated cost of the systems in the short and the long term should be compared to existing systems too; and prototypes should be made and tested in terms of structural behaviour.
The evaluation of the scenarios can be more detailed in further research; for example the load-bearing capacity can be taken into account in order to know how many vertical additions are possible.
The research was in this paper clearly defined in terms of building layers: only structural components were taken into account. In a next research phase the building envelope, partitions, etc. should be taking along.

Summary

The use of earth as a building material dates back to the beginning of our civilization. In the South of Portugal there is still a large number of buildings with rammed earth walls, but this technology has been falling into disuse since the middle of last century. The earth construction is highly sustainable since earth is a local material and is 100% reusable. The buildings with rammed earth walls have a high thermal inertia which, given the climate characteristics Portugal, improves its thermal behaviour. However, it is desirable that the thermal conductivity of the rammed earth were lower. Environmental concerns related to energy consumption associated with comfort in housing and construction, transportation and application of materials used in construction, has led us to seek new solutions in building typologies on earth.

Considering these aspects and improving the energy efficiency in buildings, this paper presents the results of tests performed in the laboratory on building new solutions on earth.

Geotechnical characterization of the soil used was made and various compositions prepared with the incorporation of expanded clay. The expanded clay was chosen as a thermal insulator made from raw materials available in the regions of Alentejo and Algarve (South of Portugal), which are the regions that are famous for using rammed earth in Portugal.

Compositions were considered soil and expanded clay having the following percentages of expanded clay: 0%, 10%, 15%, 20% and 25%. In order to characterize the different compositions from the point of view of mechanical and thermal performance, cubes were produced with 10 cm edge and assayed in order to calculate its compression resistance and its thermal conductivity. The results showed that the use of this type of building typologies on earth with the incorporation of expanded clay allows to increase your performance by making it possible to adapt this typology needs of today, including the demands of the Portuguese legislation. The results of this research can be applied, with the appropriate adaptations, both in buildings in rammed earth and in buildings in adobe.

Through the testing conducted, the value of the thermal conductivity of the soil sample was obtained and it equals to 1.08 W/m.°C. To a mixture of soil and expanded clay containing 25% expanded clay 2-4, we obtained thermal conductivity of 0.79 W/m.°C.

Keywords: Rammed earth walls, Energy efficiency, Expanded clay aggregate.

1. Introduction

Earth has been used as a construction material ever since the rise of sedentary human civilization based on agriculture. Its qualities are notable, particularly its durability: some existing earth buildings are over 3,000 years old. With the principles of sustainability now established in the mainstream, earth is of great importance as a building material: it is 100% reusable, requires a low level of energy input, is extremely durable, and can be locally sourced, while it does not require any form of industrial processing. Moreover, given its high thermal mass, it offers a high level of thermal inertia for buildings, and thus is particularly suited to climates characterised by large variations in temperature.

In Portugal, earth construction, and in particular building incorporating rammed earth or *taipa* walls is common in the Alentejo and Algarve regions. However, the use of this construction technique has gradually fallen into disuse, especially since the mid-20th century. As masters of the art disappear, we risk losing a fund of specialised knowledge required for selecting soil, determining optimum moisture content and implementing the technique itself: the placement and compression of the earth between wooden formworks.

Portuguese regulations governing the thermal performance of buildings (RCCTE – Regulation of Characteristics of Thermal Behaviour of Buildings*,* the provisions of which are contained in statute law: Decreto-Lei no. 80/2006 [1]) set out requirements regarding limits on the nominal consumption of energy during the cool season that are not easy to comply with when using the rammed earth technique.

The aim of this paper is to provide a contribution towards the improvement of the thermal performance of rammed-earth walls by examining techniques for reducing thermal conductivity. This study involved the use of expanded clay aggregate, which was mixed in different proportions with soil in order to gauge how thermal conductivity could be reduced without decreasing too much the compressive strength of the mixture.

2. Geotechnical and physical characterization

In order to determine the suitability of soil for rammed-earth construction, the physical and geotechnical properties of soil were determined and the soil characterized in accordance with Portuguese standards and LNEC - National Civil Engineering Laboratory specifications, as well as the information contained in the work entitled "*Construção em terra*" (Earth buidlings) [2]. Water content in soil was determined at the collection site, as well as organic matter content, particle size, and liquidity and consistency ranges; the Proctor test was carried out in order to determine optimum water content.

2.1 Geotechnical soil properties

Besides geotechnical and physical tests, Houben and Hubert [3] present a number of traditional tests. A visual assessment of soil colour is made to determine the quantity of organic matter in soil, and the presence of feldspar sand and quartz sand, as well as that of iron oxides in clays. A test of smell enables the identification of the existence of organic matter, for example compost, which promotes a rise in temperature and leads to soil humidification. A touch test determines whether a particular soil is sandy or whether it is a plastic or viscous, in accordance with the amount of clay which gives the sample surface its stickiness. Finally, a brightness test enables an assessment as to whether the soil is clay: a cut sample of moist soil will present a bright aspect if there is a predominance of clay. Similarly, there are other tests that were traditionally carried out by masters of construction using earth, as, in the past, laboratory soil analysis was not feasible prior to construction for the assessment of soil quality in terms of consistency after compacting and drying. In this paper,this type of analysis was not

performed, as physical and geotechnical tests were carried out to characterize the soil and had a low margin of error.

Some authors use Feret's triangle, which takes into account the proportions of sand, silt and clay in soil in order to determine a point in the triangle which characterises the soil. An assessment can be made as to whether soil is suitable for earth building, in the present case using rammed earth, according to whether the point lies within a predefined area [4], as shown in Figure 1.

In this study, the soil contained 58% gravel, 18% sand, 14% silt and 10% clay. Ignoring the gravel content and considering the remaining 42% of sand, silt and clay content as 100% of content, we have 18% sand corresponding to 43% of content, 14% silt corresponding to 33% of content and 10% clay corresponding to 24% of content in the triangle (Figure 1). These percentages enable a soil intersection point to be found, which in this case falls within the predefined area for rammed earth [4], as can be seen in Figure 1.

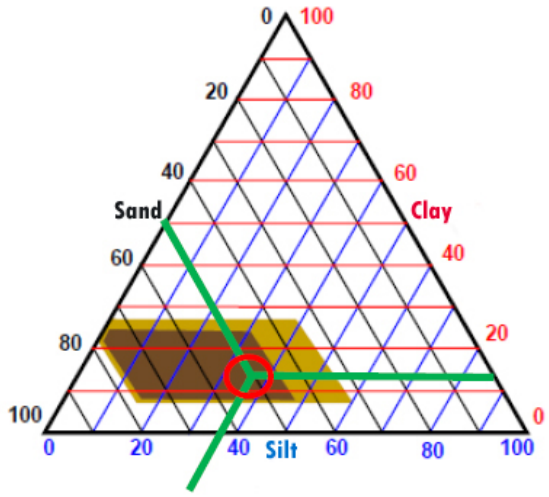

Figure 1 – Feret's Triangle: zone for the use of adobe bricks (dark area) and zone for the use of rammed earth (light area, which includes the dark area)

2.2 Mechanical soil properties (compressive strength)

As regards tests for the uni-axial compressive strength of samples, standard ASTM D 1633 - 00 was applied so that the periodicity used in tests would be adjusted for the time intervals between readings. Tests were performed after 21 days and after 28 days in order to gauge whether there were significant changes in strength. An increase in mechanical strength was shown to have occurred. In this paper, only the results of the tests performed after 28 days are presented, which are compared with samples of 100% soil (rammed earth) and soil with various mixtures and different types of material. Figure 2 shows that the compressive strength of samples of soil containing different percentages of expanded clay is not at all less, and by contrast there is a higher level of strength than for samples comprising only soil, with mixtures containing 10%, 15% and 20% of expanded clay.

Table 1: Strengths for rammed earth NZS 4297 [5]

Strength parameter	Stress (MPa)
Compressive strength (bending or simple compression)	0.50
Earth's shear strength	0.08
Tension strength due to bending	0.10

Table 2: Compressive strength for adobe and rammed earth according to type of stabilization [6]

Type of stabilization		Rammed earth (MPa)	Adobe (MPa)
No stabilization	Low resistance	0.60	0.75
	Average resistance	1.20	1.50
	High resistance	1.80	2.25
Stabilization with Portland cement	Low dose	3.00	3.75
	Average dose	4.80	6.00
	High dose	6.60	8.25
Stabilization with whitewash and Portland cement	Low dose	2.40	3.00
	Average dose	3.50	4.40
	High dose	4.80	6.00
Stabilization with whitewash	Low dose	1.80	2.25
	Average dose	2.40	3.00
	High dose	3.60	4.50

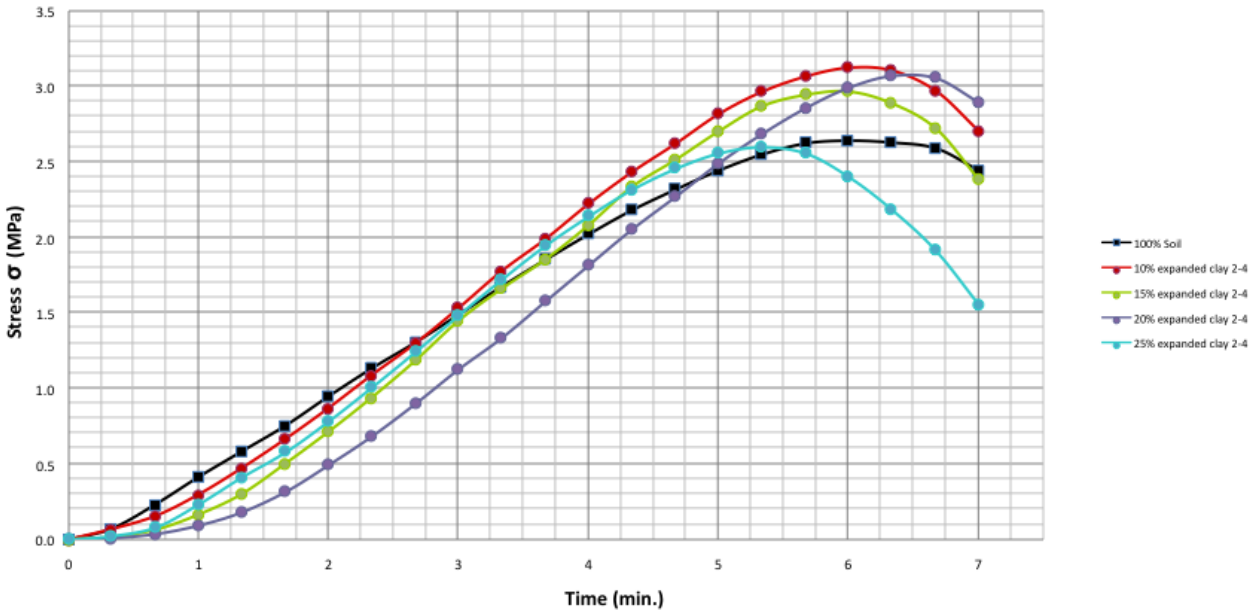

Figure 2 – Uni-axial compression tests for samples of soil with expanded clay 2-4

2.3 Thermal behaviour

The thermal conductivity (λ) of a material is a property which is essential for the characterization of its thermal behaviour and can be measured *in situ* or in the laboratory. There are several methods for measuring thermal conductivity in the laboratory. In this study, the thermal conductivity of samples which were identical to those used in tests to determine compressive strength was measured.

Thermal conductivity was measured using an ISOMET 2104 device (Figure 3), made by Applied Precision. Besides thermal conductivity, this device can be used to measure thermal diffusivity and volumetric thermal capacity, but in this study only the thermal conductivity of samples was measured. The ISOMET 2104 device allows for the use of various types of probes with different reading ranges. All readings were taken using an API 210412 surface thermal conductivity probe. Probes can be recalibrated using a standard method and each thermal conductivity measurement takes approximately 15 minutes to complete. Readings are

stored in the device memory and can be transferred to a computer by means of an RS 232 lead.

Figure 3 - ISOMET 2104 measuring device.

The cylindrical surface probe used for gauging the thermal conductibility of samples had a diameter of 60 mm (Figure 5), which means that the samples had to be bigger than this.

Thermal conductivity measurements were taken on the three sides of sample cubes which corresponded to one of three axes: X, Y and Z. Readings recorded on Side A correspond to the Y axis (Figures 4 and 5). This is the side on which readings are taken perpendicular to compression layers. Sides B and C correspond to the X and Z axes respectively, as shown in Figure 4, and are both perpendicular to compression layers. Of the sides perpendicular to the compression layers, the most regular sides were defined as B because they presented fewer cavities. Three readings were taken for each side of samples.

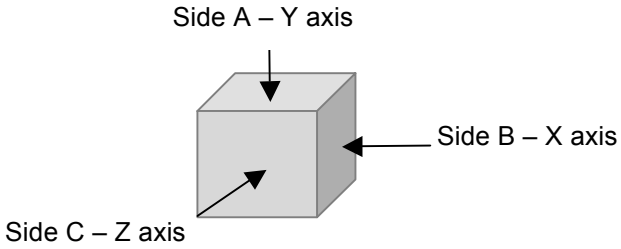

Figure 4 – Configuration of sample readings

Figure 5 – Determining conductibility on the different sides of a sample.

As thermal conductivity may vary from sample to sample of the same material (due to heterogeneity, degree of compaction, particle size) several readings were taken for the various soil samples. Thus, in addition to physical and geological characterization, it was felt that there was a need for characterizing the thermal conductivity of soil samples, which enables a reference value for thermal conductivity to be established for samples where other materials

are added to soil, that is, mixtures of soil and expanded clay aggregate. This allowed for the evaluation of the improvement of the thermal behaviour of samples through the addition of other materials, in accordance with the aim of this study: to find whether the thermal characteristics of samples can be improved in order to achieve a lower thermal transfer coefficient (U value). On the basis of the various measurements, an average thermal conductivity value – X axis – of 1.08 W/m.° C was obtained, with a standard deviation of 0.11.

In a rammed-earth wall, thermal flux occurs horizontally, hence perpendicularly to the direction in which compression occurs. Thus, the values of thermal conductivity obtained for the X or Z axes that are perpendicular to the direction of compression must be considered. Thermal conductivity values obtained for these two axes are analogous, thus X axis values were considered as this axis corresponds to B sides, which provide a greater level of reliability as they present fewer heterogeneities.

Values recorded for the thermal conductivity of samples containing different percentages of expanded clay of particle size 2-4 are presented. Thermal conductivity tests were performed on samples, as was done previously with samples comprising 100% soil (rammed earth), corresponding to the three axes: X, Y and Z. The conclusion was drawn that the findings that should be considered are those which relate to the X axis. X axis measurements are similar to the direction of the thermal flux of a wall.

Table 3: Thermal conductivity for samples of soil with expanded clay 2-4 (mean values and standard deviations)

Samples	λ (W/m.ºC)
100% soil	1.08 ± 0.11
Soil + 10 % Expanded Clay 2-4	1.04 ± 0.66
Soil + 15 % Expanded Clay 2-4	0.93 ± 0.15
Soil + 20 % Expanded Clay 2-4	0.94 ± 0.08
Soil + 25 % Expanded Clay 2-4	0.79 ± 0.15

As a result of the addition to soil of different percentages of expanded clay, a significant decrease in thermal conductivity was recorded, from 1.08 W/m.ºC to 0.79 W/m.ºC, as shown in Table 3.

3. Conclusion

According to the Portuguese Regulation on Thermal Performance of Buildings (RCCTE, Decreto-Lei n.º 80/2006 [1]), the reference value of the thermal transfer coefficient (U value) of the opaque and vertical elements of the exterior envelope in Climatic Zone I_1 (nearly the South of Portugal) is 0.70 W/m^2.°C. Let us compare this with the values obtained as a result of the tests carried out. In order to make this comparison let us determine the thermal transfer coefficient (U value) of a rammed earth wall with a thickness of 0.60 m covered with plaster with a thickness of 0.02 m on the inside and outside.

It should be noted that, as a result of the tests performed, a value was obtained for the thermal conductivity of the soil sample equal to 1.08 W/m.°C. In accordance with the methodology described by Santos and Matias [7], for the rammed-earth wall consisting only of soil and plaster the value U = 1.29 W/m^2.°C was obtained.

With regard to compressive strength, all the solutions tested would show a satisfactory level of compressive strength [5,6] which means soil with 25% expanded clay 2-4 is the best option. The thermal conductivity measured was: λ=0.79 W/m.°C, and the U value of the described wall is: U=1.02 W/m^2.°C. Comparing this with the sample consisting of soil without a thermal insulator, it was found that the thermal transfer coefficient of the option consisting of soil expanded clay aggregate is equal to 79% of the thermal transfer coefficient of the soil sample, thus, a substantial reduction was achieved.

Abstract

Preliminary research shows short coming of Building Performance field of research to measure outdoor performance of building manly EETP factors. Accordingly, this research aimed to Proposing future building performance toward Energy Efficient Travel Plan based on user friendly EETP factors. The research methodology engaged three research phase. 'Phase I' was to identify user friendly EETP factors. In this phase after a literature review, fix-format self reporting interview survey was conducted among experts in Travel Plan implementation in Malaysia. 'Phase II' was to investigate effective Building performance factors on user friendly EETP, within which literature review conducted on building performances followed by brainstorming with 5 experts in building management field of research. Final phase was to validate purposed building performance towards EETP in a futuristic cross-impact scenario study. In summary, research is concluded to introduce three main out comes, first: list user friendly EETP factors, second: EETP building performance factors and Third: future Building performance factors towards EETP based on futuristic cross-impact analysis. In conclusion, study introduced list of new innovative future building performances including; BCS (Building communication system), BEEM (Building Energy Education Management), EETP (Energy Efficient Travel Plan), BRc.S (Building recycling system), and BAgr. (Building agriculture) investigated as future building performance factors.

1. Introduction to Energy Efficiency Travel Plan

The idea of Energy Efficient Travel Plan (EETP) is under the umbrella of Travel Plan (TP) introduced science late 90's. Traditionally, TP provides policy planning to reduce transportation impact. Enoch and Ison (2010) defines TP as "a long-term management strategy for an organisation and its various sites or business park that seeks to deliver transport objectives through positive action and is articulated by a document that is regularly reviewed".

Wake et al. (2010) defines TP as "… is a package of actions implemented to manage travel generated by a workplace. Primarily, travel plans seek to reduce car trips and encourage the use of lower impact alternatives, such as walking, cycling, public transport and telecommunications."

Rye (2002) sates TP in UK is known as company (workplace) travel plan, while in Europe is known as mobility management, and in US is known as transportation demand management (TDM). Albeit, the three concepts are addressing one issue, this study used TP and EETP as refereed in report. Table 1.1 addresses some of measures in TP Adopted from Rye (2002).

In TP mostly the main concern is measuring, monitoring and reducing Carbon Foot Print of all the residents under issue of TP. TP is proposed normally in 'organizational bases'. Tyler et al. (2006) sates "….Initially, travel plans were required by regulation in the US. The 1990 Clean Air Act Amendment required employers with 100 or more employees to implement trip reduction".

The travel sector is a large and diverse issue, which is encompassing travel by land and the movement of both passengers and vehicles. But passenger vehicles, used for the daily travel of households, are the primary source of CO2 emissions within the travel sector. The controversial argument is that many technological innovations with the potential to reduce transportation emissions from passenger vehicles are possible but it needs more research and investigations. However, consensus is growing that technological innovations alone will not be enough to reach targeted reductions in CO2 emissions: changes in human behaviour are also essential (Rajan 2006; Lutsey and Sperling 2009). TP address this aim in principles.

Table1.1: Travel plan measures (Adopted from Rye, 2002)

Mode	Measure
Overall for whole plan	–Travel coordinator (member of staff) –Promotion and publicity –Implementation process, e.g. steering group
Walking	–Improved lighting and walkways –Incentives for walkers –Crossings in/adjacent to site –Changing/shower facilities
Cycling	–Pool cycles –Bicycle loan scheme –Good, secure parking provision –Discount purchases of cycles and equipment –Provision of PT information at workplace
Public transport	–Access to rail planner –Discounted season tickets, paid for by operator –Liaise with local operators to operate new services –Pay for new services –Pay for subsidies for fares on existing bus services –Staff travel survey to identify potential sharers –Priority parking spaces for car sharers –Guaranteed ride home (taxi)
Car share	–Reduce parking supply –Ration parking through permit allocation –Charge for parking –Flexi-time –Telecommuting/working
Parking	–Company car initiatives (phased out/ altered

2.0 Problem Statement

This section to explain the rational to study is divided to twofold; Gap in research on building performance factors to consider EETP, Need in practice for EETP.

2.1 Gap in Research on Building Performance Factors to consider EETP

This research tries to introduce consequences of Energy Efficient Travel Plan (EETP) on Building Performance factors, as Future Building performance factors. Mohammad (2012) states totally there are 15 building performance criteria to be considered as Building Performance Factors. He reviewed on POE (Preiser, 2008), POE (Minnesota Univ., 2004), Building Quality Assessment (BQA), ISO 6241 Performance standards for buildings, Orbit 2.1, Facilities Performance Evaluation (FPE) and some other researchers efforts and concludes in total 15 different evaluation criteria. Including; Health, Safety, Security, Functionality, Efficiency, Social, Environmental Psychology, Aesthetics, Operations, Comfort, Durability, Economic, Flexibility and culture. Study observes that all the mentioned performance factors are related to the building indoor and close out door of building, and no one is to consider performance of building in area, specially, with the responsibility of EETP. Besides, Intelligent Building concept for more than thirty years has been change the building performance criteria, but with the direction of Energy Efficient Travel Plan (EETP) seems that it can play more to help the travel behavior, and it can introduce new performance criteria to its designers and users.

2.2 Need in Malaysia to consider EETP

It is a common importance among all countries to improve Human development Index (HDI) as a measure of human Quality of Life. The increase in HDI will effect on higher energy consumption. Figure 1 is highlights correlation between HDI and Energy consumption contrast within various countries and shows the critical position of Malaysia. This confirms Malaysia has to foresee the future energy consumption and optimize its energy consumption in sustainable building design framework towards improving quality of life.

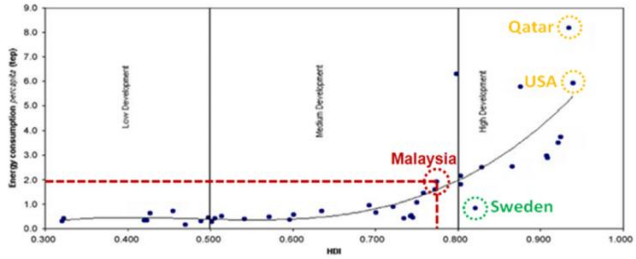

Fig.1: HDI versus Energy consumption within various countries (Adopted from Dias et al., 2006)

This momentum is obvious by Malaysian governments. The key Malaysian ministry and agency involved are the Ministry of Energy, Green Technology and Water, Energy Unit of Economic Planning Unit of Prime Minister's office, The Energy Commission of Malaysia, and Persatuan Tadika Malaysia (PTM). Furthermore, agendas have been sets for the different mentioned Malaysian ministry and agency by five year bases Malaysian plans. The Malaysian government in Ninth Malaysia Plan concerns strongly on Energy efficiency programs while, sustaining the quality of life for the needs of the population and at the same time to manage Malaysia's resources (Ninth Malaysia Plan 2006-2010). Furthermore, greater emphasis has been considered on energy efficiency under the Tenth Malaysia Plan (2011-2015).

In Malaysian building construction industry; environmental concerns, energy crisis, and technology advances, have brought up Energy Efficiency as the agenda for building performances since 80's. In 1989, the Malaysian Ministry of Energy, Water and Communication (MEWC) had introduced the Guidelines for Energy Efficiency in Non-Domestic Buildings. The guidelines were revised as the Malaysian Standard MS 1525:2001 which aimed to encourage the application of energy efficiency in new and existing buildings whist maintaining comfort, health and safety of the building-users. Best practices as stipulated in the Malaysian Standard MS 1525:2007 "Code of

Practice on Energy Efficiency and the Use of Renewable Energy for Non-Residential Buildings" have been adopted as guiding principles.

However, MS 1525:2007 in line with some internationally well-known standards (such as ASHRAE standard 55-2010, and ISO 7730:2005) does not support all requirement of building user in the energy efficiency. Indeed, updating and improving MS 1525:2007, with existence of complimentary tools and framework is considerably needed that ensures continues 'moving forwards' in energy efficiency standards of buildings in Malaysia.

Building based TP has potential towards energy efficiency. The behaviours underlying transportation foot print are complex. Vehicle-Miles-Travelled (VMT) is the direct result of a series of behavioural choices shaped by the physical environment and policy context over different time frames. The rate of emissions per mile is also fundamentally a function of behaviour, both the choice of vehicle type and the style of driving. As obviously location and function of building have direct effect on this CO2 emission.

Therefore, with investigating effect of Building Performance on Sustainable Travel Plan in future urban mobility, we will have new feature in term of opportunity of building to be part of EETP to eliminate and minimize the travel. Relatively, the research question is as followed:

"What would be the future of Building performance factors towards enhancing Energy Efficient Travel Plan?"

3. Aim, Objectives and Scope of Study

This research project aims to propose future building performance factors toward Energy Efficient Travel Plan. To address this aim, the following objectives were defined; First: To identify user friendly EETP factors, Second: To investigate effective Building performances (BP) towards user friendly EETP, and Third: To establish future Building performances (BP) factors towards user friendly EETP. Several area were investigated as scope in this study, including; building functionality, which was limited to cover only office buildings, Malaysia from other possible regions, and the building performance investigated was limited to those with direct effect on EETP.

4. Significant of Study

This study has been formulated the relation of BPs from EETP perspective. This investigation is fundamental for futures buildings to be more Green and Sustainable. Currently, construction building industry is practicing sustainable building assessment (SBA) tools to benchmark sustainability in building. One of key shortcoming of SBA stated by Lützkendorf and Lorenz (2005) "… it must be noted that social aspects and considerations related to sustainable buildings are not yet fully explored due to the complexity of the issue. For example, social aspects also include the interrelation between single buildings and community-level issues like urban design quality, social segregation, urban sprawl, etc." Significance of the current research is to propose future BPs in EEB. Indeed, such BPs will open insight in building construction R&D also towards building sustainable development. Introduction of BPs in this study is fundamental for R&D sector for further development of means to apply the BPs.

5. Research Methodology

This study was developed three research phases corresponding to the three objectives of study. In total, this study is to conduct using four steps. Which first step conducted prior to step 2, 3, and 4. The list below describes each step.

Phase I: (to fulfill requirement of first Objective)
Step 1: Literature review: A review of relevant literature was conducted by focusing on the following key words: EETP factors, user friendly EETP factors, Energy efficient Life styles.
Step 2: Expert input (data collection and data analysis): To validate the results of the literature

review an expert input session implementing Delphi close group discussion.

Phase II: (to fulfill requirement of second objective)
Step 3: Brainstorming (data collection and data analysis): To investigate effective BPs towards user friendly EETP factors in a Synectics session.

Phase III: (to fulfill requirement of third objective)
Step 4: Close Group discussion-CGD (data collection and data analysis): To implement futuristic study method on finding of second objective in an expert CGD session, implementing Delphi close group discussion.

6. Data Analysis

This section is to brief data analysis and discussion on first, second, and third objective. Mainly data analysis was conducted based on three answer presented for three questions corresponding to each objective in different interviews. Questions include;

Q1) It is a as user friendly EETP factor.
Q2) What you can propose as Effective BP to consider this factor?
Q3) There is a need in future on proposed BP based on the four mentioned scenarios.

For question 1 and 3, the research conducted expert input session by means of Delphi structured close group discussions. Thus study used five-point rating scale based on 1 for 'unacceptable' to 5 for 'Acceptable'. Respondent(s) perception collected based on each life style or TP measure, where investigated in literature review. Further explanation on data collection is presented in chapter 3.

As data analysis method WSM is used in this study. The formula (1) applied for each validation aspect. And formula (2) applied for validation conclusion. Table 1 indicates a sample-result of WSM.

$$\boldsymbol{WSM(a_i)} = \left(\sum_{j=1}^{n} \boldsymbol{w_j}\right) \boldsymbol{a_i}, \quad for\ i = 1,2,3,\dots,m \qquad (1)$$

Where,
'w_j', *referred to assigned weight by decision maker in close group discussion for sub-issue of discussion by participants number 'j'*
' a_i', *is sub-issue of discussion with the given ordering number of 'i',*

$$\boldsymbol{WSM(a_i)\ /\ WSM(a)_{max}} \textbf{ = Consensus in \%} \qquad (2)$$

Where,
$WSM(a)_{max}$ *, refers to maximum sum of possible weight can be given for one sub-issue*

Formula (4) indicts the consensus calculation. Albeit, consensus where accepted if more than % 70 consensuses were observed. One example is presented to calculate consensus using WSM (Table 2).

Table 2: Example of WSM process in the clacualtion of concenses

Validation Aspects	w_1	w_2	w_3	w_4	w_5	w_6	w_7	$WSM(a_i)$	$WSM(a)_{max}$	Cons. %
factor 1	3	4	5	5	5	np	5	27	30	90

Note . **np:** refers to cases where participants didn't assigned the weight to the sub-issue, **Cons.:** refers to consensus calculated based on furmula (4).

Question 2 is to address finding of 2nd objective. And Question 3 is based on futuristic analysis on final finding of question 2. The amount of production in supply side has correlation with demand. Thus, to conduct the futuristic study we must consider this correlation. It is to insure the common acceptable finding. It is a common trend in futuristic study to consider restrictions in study. Thus to consider clean Electricity& clean fuel as restriction there are four possible scenarios (in timely manner):

1st scenario: Current Electricity& fuel (not enough not clean)

2nd scenario: Production of Energy (in the form of clean electricity) will cover the needs and also more

3rd scenario: Production of fuel (in the form of clean fuel) will cover the needs and also more

4th scenario: Production of Energy (in the form of clean Electricity& fuel) will cover the need

In summary of data analysis applied in all three phase of research Table 3 is presenting the result. According to results of Table 3, BCS (Building communication system), BEEM (Building Energy Education Management), EETP (Energy Efficient Travel Plan), BRc.S (Building recycling system), and BAgr. (Building agriculture) were investigated as future building performance factors.

Table 3: Content analysis to identify 'user friendly EETP' based on adopted list of life styles from Leonard-Barton (1981)

Life styles and TP measures		Q1	Q2	Q3
Life style	Bike for exercise	61		
	Bike on errands	33		
	Bike on retail purpose	24		
	Change oil in car	60		
	Get instruction to increase self-reliance	72	**BEEM**	78
	Exchange goods or services	40

Car share	Reduce parking supply	87	**EETP**	74
	Ration parking through permit allocation	93	**BEEM**	78
	Charge for parking	93	**BEEM**	78
	Flexi-time	-		
	Telecommuting/working	98	**BCS**	95
Parking	Company car initiatives	78		

7.Discussion

This section is to briefly discuss findings of each objective in this study. First is to present finding of the first objective. Next is to discuss findings of second objective and finally it will address findings of the third objective.

Findings on first objective: The first objective of this study was to identify user friendly EETP factors. Based on literature review 'life style and TP measures' presented to the expert to validate acceptability of them as user friendly EETP. The data analysis of expert input conducted using WSM. Based % 70 saturation study resulted in list of user friendly EETP criteria as presented in Table 2.

Findings on second objective: The second objective of this study was to investigate effective Building performances (BP) towards user friendly EETP. Thus, based on findings of fist objective, user friendly EETP factors presented to the expert in a brain storming session. It was to propose the effective BPs. The data analysis of expert input conducted using WSM. Based % 70 saturation study resulted to list of effective TPs towards EETP as presented in Table 2.

Findings on third objective: The third objective of this study was to validate findings of second objective in a futuristic study. Thus, based on findings of second objective, BPs presented to the expert in a futuristic cross-impact analysis having four scenarios. The data analysis of expert input conducted using WSM. Based % 70 saturation study resulted to list of future effective TPs towards EETP as presented in Table 2.

8. Conclusion

In reference to Table 3 BCS (Building communication system), BEEM (Building Energy Education Management), EETP (Energy Efficient Travel Plan), BRc.S (Building recycling system), and BAgr. (Building agriculture) investigated as future building performance factors.

Acknowledgement

We would like to take this opportunity to thank Ministry of High Education (Vote No.00G22), and Institute Sultan Isklander, KALAM research center for their financial support in this study.

Short Summary

Keywords: ecological building materials, renewable resources, natural building materials, insulation, refurbishment, environmental and health impact

1. What are RRMs?

Renewable raw materials (RRMs) are agricultural and forestry-produced materials and biogenic rest or waste materials which are not used as food or feeding materials, but are used as raw materials in the industry or as energy sources. Unlike fossil fuels, they renew annually or in a reasonable timeframe. During combustion or composting, RRMs only set free the quantity of CO_2 that they have absorbed from the atmosphere during their growth period. Unlike fossil fuels, they are therefore largely CO_2 neutral under certain conditions. This CO_2-neutrality, however, is at risk, if the current CO_2 storage is affected by the expansion of cultivable acreage for renewable resources, or other greenhouse gases are released into the atmosphere, or the use of artificial fertilizers increases. The sustainability of products from renewable materials is ensured when regional cycles arise with ecologically compatible cultivation.

2. What is the objective of the k:a RRM programme?

The national awareness program climate:active promotes the material use of renewable raw materials in products, to achieve a better market penetration and acceptance by consumers and users.
The objective of this program is to support the sustainable use of renewable raw materials in Austria and to actively push the material use of RRMs. This will be done particularly in the following product areas:

- RRM biopolymer materials
- RRM insulation
- RRM oils, varnishes, paints, binders and
- RRM regional products

Since the project is integrated in the climate:active program, the overall goal is the reduction of greenhouse gas (GHG) emissions through substitution of fossil fuels by renewable raw materials in Austria. Assuming that the full market potential of RRM material use can be achieved, the technical CO_2-eq. saving potential is estimated at 326,000 t/a in Austria. To be able to fully exploit this potential, the mere focus on the CO_2-factor is insufficient. Therefore a holistic sustainability assessment of the entire production chain (including sustainable produced raw materials) forms a central point in the argumentation chain.

3. Climate:active RRM programme in the construction sector

Direct regional chains from the raw material to the end product are a realistically implementable target mainly in the building construction area. Analogous to regionally produced foods, a regional building culture (i.e. preferring construction materials from regional processing) would be part of the added value directly related to the use of renewable materials and to the creation of "green jobs".

The objectives in view of the renewable raw materials are the following:

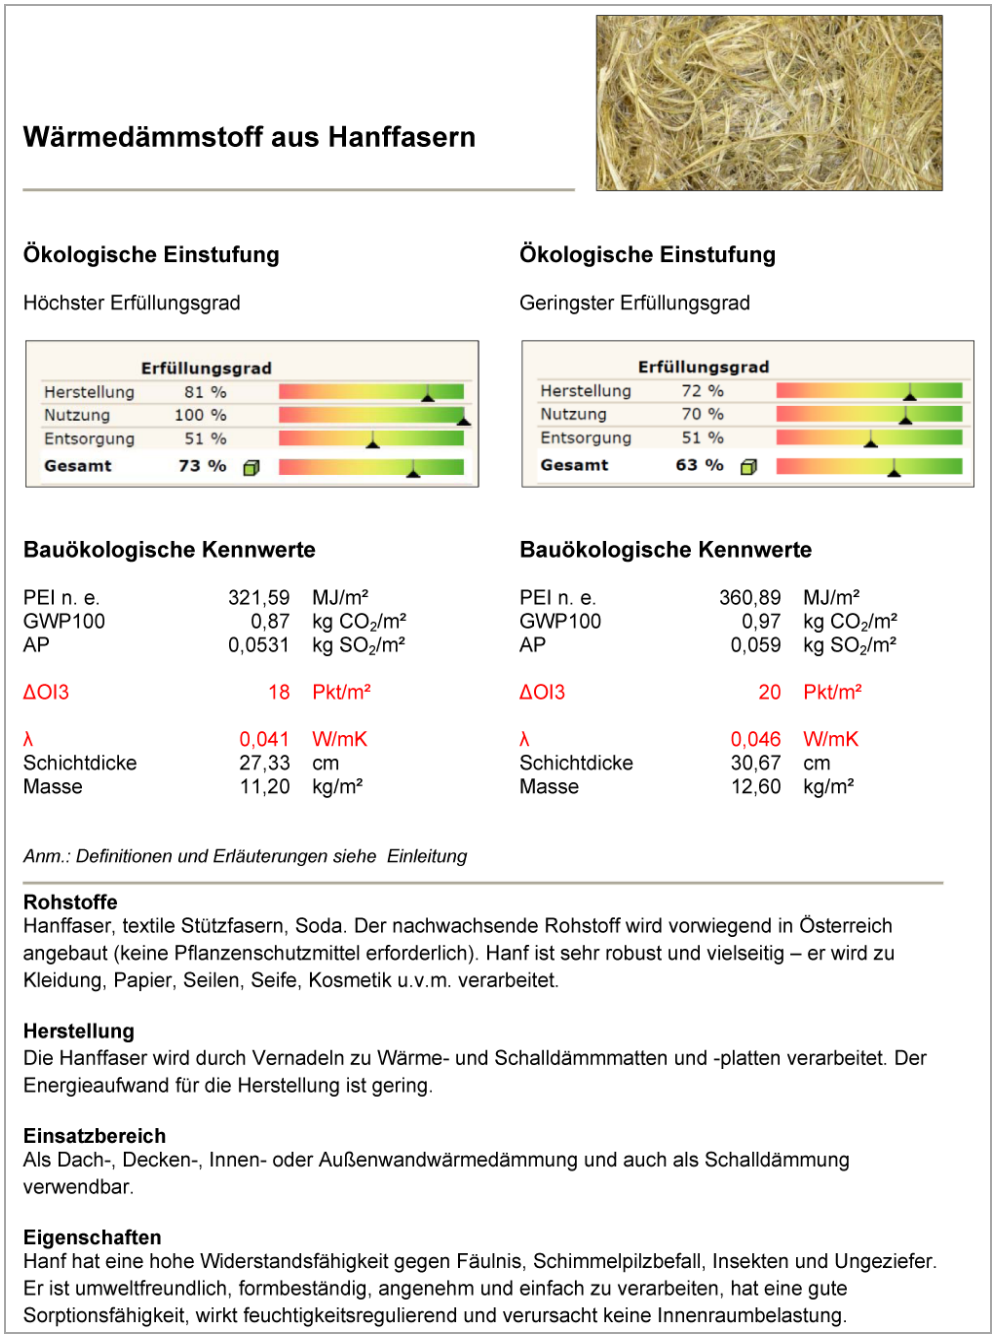
- Definition of quantitative and qualitative criteria for the efficient use of RRMs for concrete applications – especially in the field of construction materials for the raw materials sheep wool, hemp, flax, miscanthus, straw and wood residues.
- Identification of utilization cascades (optimized material and energetic value added from the cultivation of a plant or material or rather material use and subsequent energetic use of the product as an end-of-life option)
- Demonstration of the added value potential in the regional context and communication to regional decision makers

With regard to the markets, the objectives are aligned as follows:

- Strengthening of regional implementation networks eg. craftsman and salesman associations and refurbishment networks for the use of RRM construction materials
- Acquisition of a larger market share of RRMs in the insulation sector of thermal refurbishments
- Increase of the awareness of already successful products
- Influence over the development of the framework for the use of renewable raw materials (building guidelines, standards ...)
- Initiation of innovative product developments among manufacturers – even cross-industry collaborations are requested
- Initiation of research projects and information about adequate funding opportunities (eco innovation, FFG)
- Establishment of quality assurance as part of the climate:active program (product label / Eco-label)

4. RRM suitcase

The already provided **RRM suitcase** demonstrates the versatility of renewable materials and products in the construction sector. It contains a multitude of construction product samples made of renewable raw materials and gives explanations of its ecological assessment, it´s manufacture, use and characteristics.
Accordingly, the information and illustration samples serve for energy advice, training, education and public relation. Goal of the composition of the suitcase was to integrate some unconventional products to demonstrate the wide range of application possibilities of RRMs. The compilation of the information and documents primarily based on the construction materials are declared on the web platform www.baubook.at. On the website, in-depth information, technical parameters as well as manufacturer and salesman can be found.



The following contents are available in three different tools:

Information documents (wooden case) with an:

- Overview of the products and samples
- Detailed information about the products and hand patterns
- Ecological Construction Manual – Guide for cost-conscious builders with general information for building and construction products
- Product Information

Product samples (aluminum case) with detailed information about the products and hand patterns

Detailed information (web platform www.baubook.at) with:
- Technical principles and indicators
- Information technology applications, health and environment of construction
- Product Database (with retailers and manufacturers)
- Online computer component
- Ecological tender criteria

Rohstoffe
Hanffaser, textile Stützfasern, Soda. Der nachwachsende Rohstoff wird vorwiegend in Österreich angebaut (keine Pflanzenschutzmittel erforderlich). Hanf ist sehr robust und vielseitig – er wird zu Kleidung, Papier, Seilen, Seife, Kosmetik u.v.m. verarbeitet.

Herstellung
Die Hanffaser wird durch Vernadeln zu Wärme- und Schalldämmmatten und -platten verarbeitet. Der Energieaufwand für die Herstellung ist gering.

Einsatzbereich
Als Dach-, Decken-, Innen- oder Außenwandwärmedämmung und auch als Schalldämmung verwendbar.

Eigenschaften
Hanf hat eine hohe Widerstandsfähigkeit gegen Fäulnis, Schimmelpilzbefall, Insekten und Ungeziefer. Er ist umweltfreundlich, formbeständig, angenehm und einfach zu verarbeiten, hat eine gute Sorptionsfähigkeit, wirkt feuchtigkeitsregulierend und verursacht keine Innenraumbelastung.

Fig. 1: Example product description of hemp insulation

5. RRM Best practice examples

To raise acceptance and awareness of construction projects with RRMs among planners,

architects, building owners and promoters, the aim of climate:active RRM program is to evaluate and disseminate best-practice examples. Already successfully implemented construction projects, in which construction materials were used in large measure, will be presented on the climate:active webpage. For the project description special emphasis is made on the specifications of the construction materials used in the projects and particularities, such as the health aspects, in comparison to commonly used products.

The information about the selected construction projects in the areas of public and corporate buildings will be available online: http://www.klimaaktiv.at/erneuerbare/nawaro_markt.html

6. Meetings and Conferences

Two conferences focusing on renewable raw materials construction materials and best practice experiences are planned for 2013:

- On the 17 October 2013 the conference "Regional renewable building materials in the context of healthy and ecological hotels" is planned in Vienna. Especially in the tourism sector, ecological solutions are increasingly in demand. The use of renewable raw materials affects both, new buildings and renovations focusing on sustainability and healthy living. The planned conference will give experts and hotel keepers the chance to share experiences in the planning process of ecological of best practice examples.
- In collaboration with the project partner Vorarlberg Energy Institute, the conference "Implementation of RRMs in refurbishment strategies" will be organized in the framework of the conference “Win 13 – Wirtschaften mit neuen Energien und Ressourcen” in Bregenz on the 28–30 November. The congress with nationally and internationally accepted speakers, provides perspectives for successful economic development and shows new cross-industry concepts, practical solutions and innovative examples of best practice in the areas of construction, trade, industry, tourism and communities. In addition a one half day excursion is planned.

More information on the programs is available under: http://www.klimaaktiv.at/erneuerbare/nawaro_markt/Aktuelles.html

Short Summary

The Hometainer project set itself the aim to make sustainability, ecological thinking and resource-efficient construction to the basic module on the subject of living. In order to highlight this focus the draft has been specifically designed for developing and emerging countries. The Hometainer units should also feature the topic of a sustainable environment on a low expenditure and budget. The goal is the implementation of a prototype.

Keywords: sustainable development; lifecycle; developing countries; urban poor; ecological thinking, common property.

1. Introduction

„According to estimates of the United Nations Human Settlements Programme (UN-Habitat) in 2030, nearly two billion people worldwide must live under intolerable conditions in poor and overcrowded homes, often under the threat of expulsion, flood or crime.“

This quote and a comprehensive research were the starting point for the development of the Hometainer project.

The generated living space will be planned, built, maintained and exploited by the residents themselves. The support of the planning team should be lowered to a minimum.
The entire project is not only designed to educate people about ecology and sustainability. Instead they should live it. The building and the cycle of land use will contribute to a sustainable environment. Working together towards a sustainable future can open new perspectives to the residents.

2. Project development

The Hometainer project was developed in front of a realistic background and can be realized location-independent. The basic unit of the project are used 20’ and 40’ feet shipping container units. Therefore the entire system is extremely flexible and can be adapted to almost any size and condition.

2.1 Implementation – and the promotion of the natural cycle

Before starting the project a demand analysis of the existing social and economic structures should be made. The earlier local population is involved in the project the more likely will later campaign for it.

As possible building sites unappealing properties in slums or in its vicinity should be selected. The background of this plot choice is the earliest possible introduction of a working infrastructure.

Because of the operating lifetime the future use of the Plot has to support functions for the public use. E.g. like buildings of education, aid or administration. Also the restoration of the natural environment is desirable and should be seen as a sustainable upgrading of living space.

With the support and their personal contribution it is able to provide a most favorable living space for future residents. During the construction period the inhabitants also have the chance to join a career training e.g. as a construction worker, carpenter or metal worker.

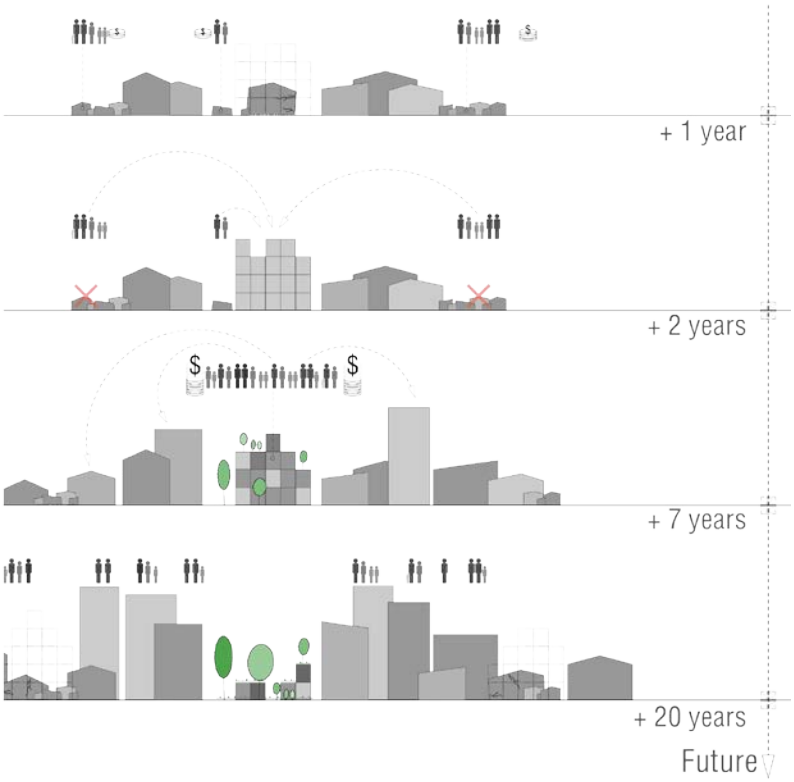

Fig. 1 Timeline of the Hometainer implementation

2.2 Structure - The variety of simplicity

A few basic rules, the standardized dimensions and couplings of the container, allow a simple implementation.

- A grid of 8 to 20 feet either set in length or width determines the positioning of the container. The rotation of the entire grid can accommodate the existing environment such as roads and buildings but is not bound to follow them.

- A Hometainer unit consists out of three up to six levels. One level is composed out of five times two 20 foot containers. This results in a square floor plan with 40 * 40 feet. Through the square ground plan of a Hometainer a rotation in 90 degree steps is possible.

- Due to the connection possibilities and an economic infrastructure a rotating stacking of the different levels by 90 degrees is not possible.

- Because containers are available in different heights it is important not to switch the heights within the container floors.

- If an existing Hometainer gets enlarged by another block the staircase of the new

Hometainer will be eliminated and will be replaced by an atrium. This serves ventilation and lighting by daylight. The accessibility of the new apartments is provided through a simple and slender extension from the existing staircase.

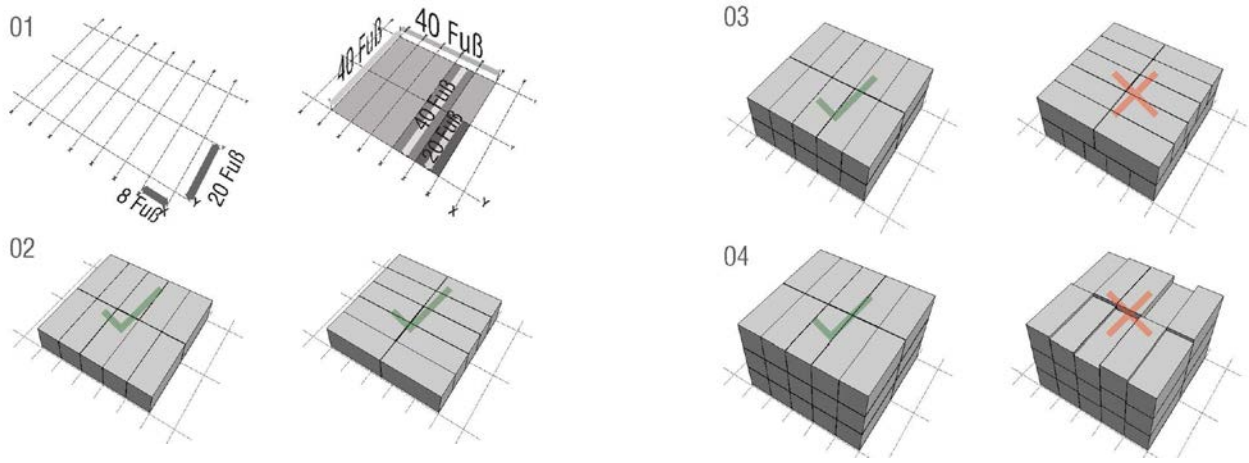

Fig. 2: Basic Guidelines for the container construction

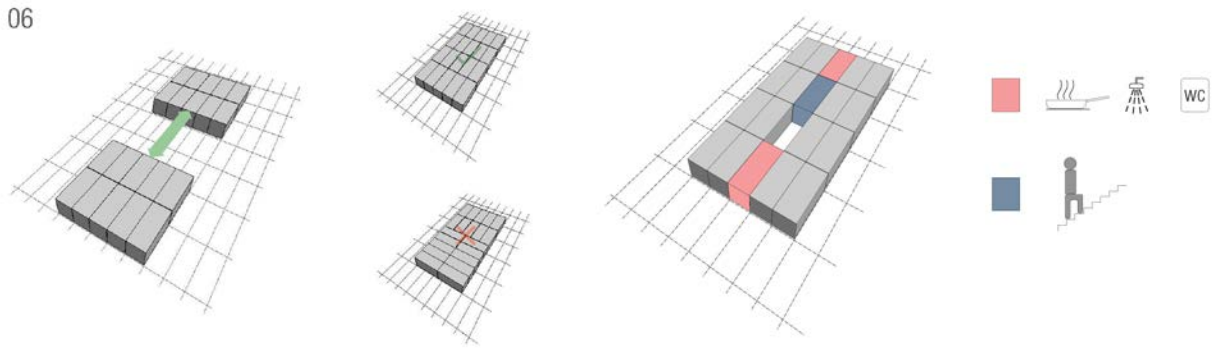

Fig. 3: Expansion of the Hometainer and distribution of infrastructure and stairwell

2.2.1 The Zoning

Through the vertical access and infrastructure in the middle the building is divided into two halves, each with two flats per level. All units consist out of a 40-foot and two 20 foot containers. The combination of the three modules provides an optimum solution for every requirement.

One half of the infrastructure module is assigned to an apartment. Depending on the size of the family and its needs a floor space of 47- 60 m² is available.
The decision to entrust the layout of the rooms and the choice of the façade to the resident is based on the fact that a high percentage of the poor population has good technical skills. The freedom of an autonomous decision and the opportunity to contribute their part will be encouraged.

The ground floor is used as a business, and community area. The roof areas are freely available to the residents. The usage should be referred to the Community, e.g.: for urban gardening, Rainwater harvesting or power generation.

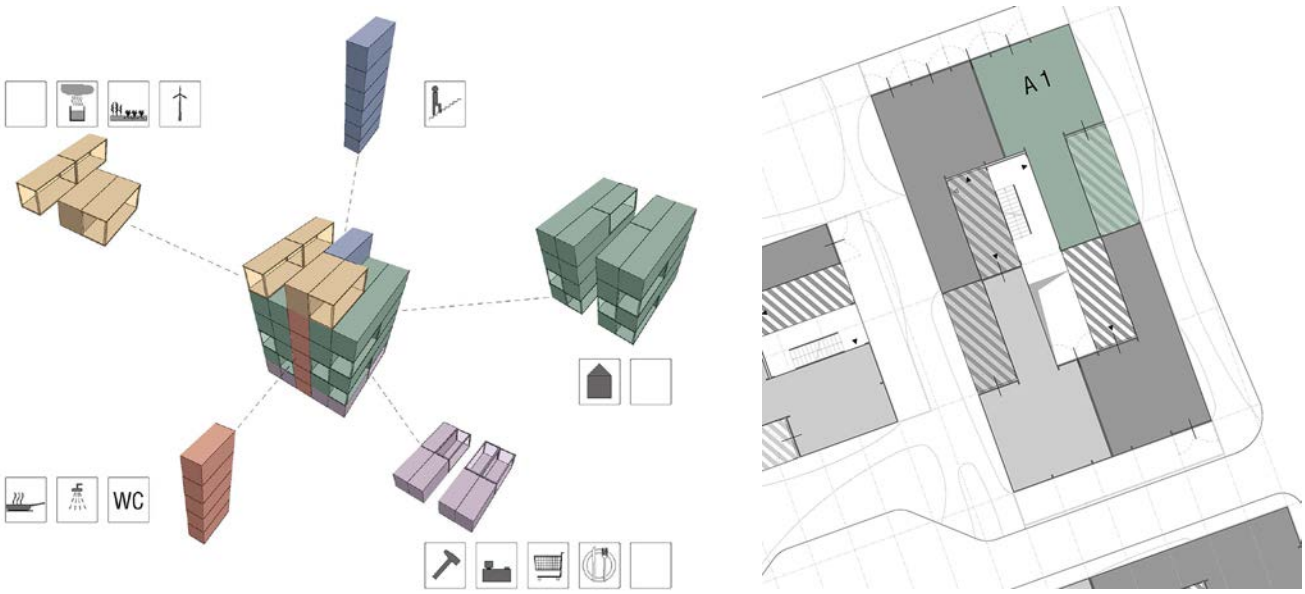

Fig. 4: Components of the Hometainer / exemplary site plan

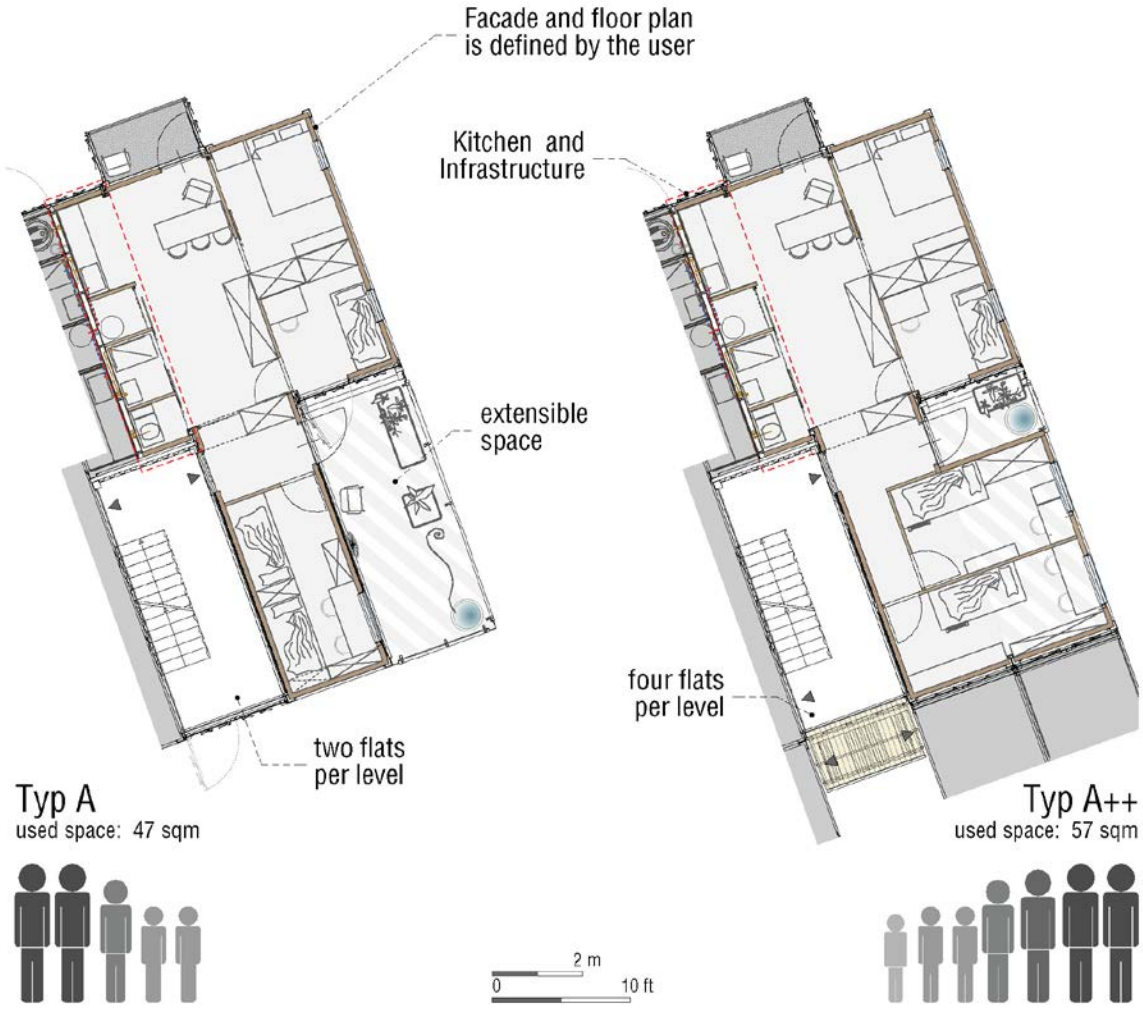

Fig. 5: Exemplary floor plan

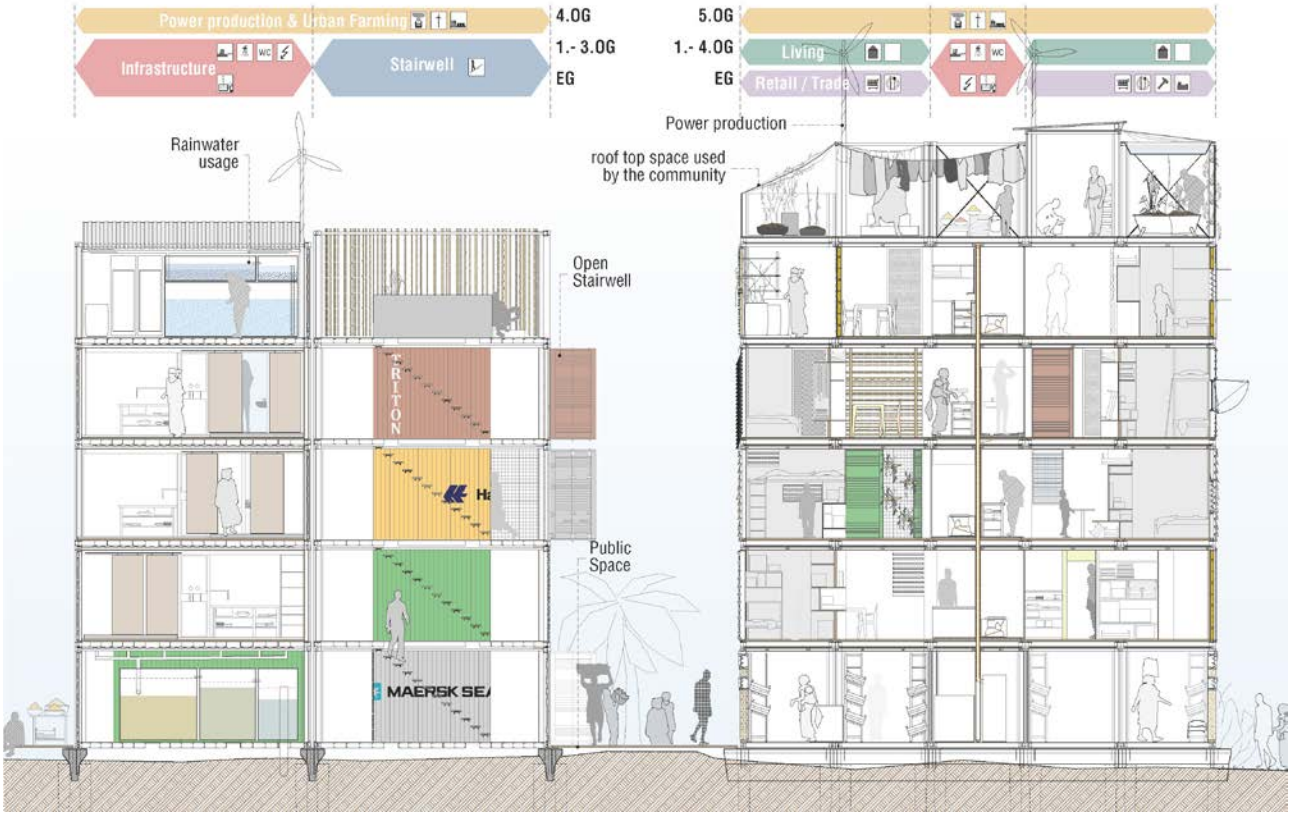

Fig. 6: A section through two Hometainer

2.3 Building materials

The Hometainer structure consists 100% out of used containers and represents the first major contribution to a sustainable cycle of use. In order to make the container habitable most parts of the steel walls will be removed. These parts can be reused on the building or sold as a recyclable commodity.

Instead of an expensive high-tech – façade solutions it will be set to local and freely available or repurposed materials that are joined to an inexpensive but effective solution. The variants range from single facade such as packed mud to multilayer components made out of wood, reeds, textiles and scrap. This diversity of outward appearance should reflect the freedom, self-determination and the participatory planning process of the Hometainer user and should show how to use resources sustainable and meaningful.

Behind all developed façades, the thought is that it can be built, maintained and adapted by the users themselves. In addition care was taken to use as often as possible materials which are natural products, ready-mades or simply to machine.

A wooden frame substructure that will be double planked from the inside with chipboards of agricultural waste constitutes the common basis of all variants.

2.3.1 Inner walls / Floor / Roof / Furniture

For the interior work Chipboards made from agricultural residuals will be used. The building board was developed by the Bern University of Applied Sciences and is 100% organic and contributes to a sustainable environment. Swarfs from corn cobs, peanut shells, and all types of cereals, rice and

bamboo can be used. In Africa, Asia and South America, these raw materials mostly grow all year round and the residual materials remain almost wasted. Here is an immense potential and a building material of this type could contribute significantly to a more sustainable environment.
A process for the preparation of these plates was developed by the Bern FH and is freely available (no patents).

2.3.2 Mud

Mud is one of the most natural building materials. It's easy processing and has temperature regulating properties. A long architectural tradition makes it an outstanding material. It is mainly used at the ground floor and in easily accessible locations.

Fig. 7: Façade section through an exterior wall made out of mud

2.3.3 Textiles / Bamboo

Textile fabrics or used Tilt Trucks with 600g / m² or more can be tensioned directly on the wooden frame or be cross threaded through a bamboo substructure. It also serves as a sunscreen. An open bamboo braid can be used in the areas of the enlarged housing.

2.3.4 rush / Grass Mats

This ecological natural material with a long tradition can be mounted as facade from the inside. The material appears as good as in all coastal regions and will continue and support local building traditions.

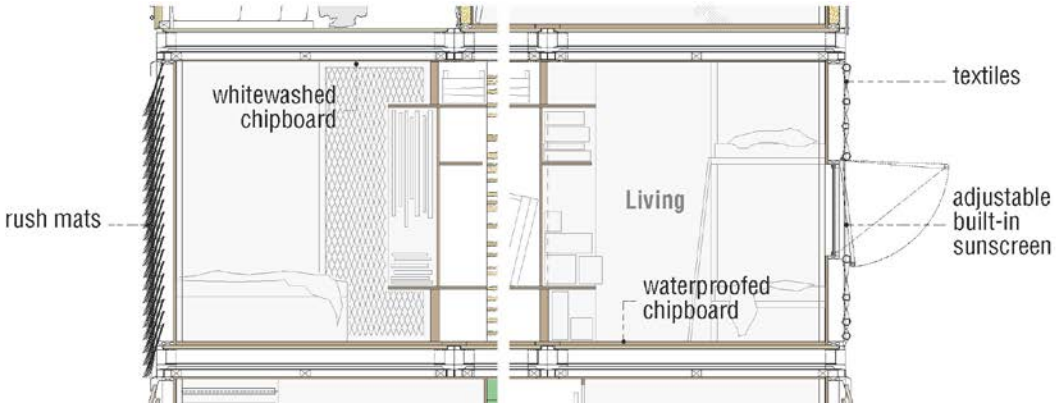

Fig. 8: Façade modification with textiles / bamboo and rush mats

2.3.5 Wood

Untreated boards in the shape of a horizontal shuttering provide a weather-protective level. Generous rear ventilation will keep the wood dry. It can also be mounted in front of windows as a permanent shade.

2.3.6 Structural steel / PET bottles

PET bottles filled with plastic waste (A substitute for thermal insulation) can be arbitrated in the wooden frame and planked on both sides. An exterior structural steel mesh can be covered with found materials and forms the outer protective sleeve. The structural steel mesh can be cut in front of the windows and bent outwards to serve as a sunscreen.

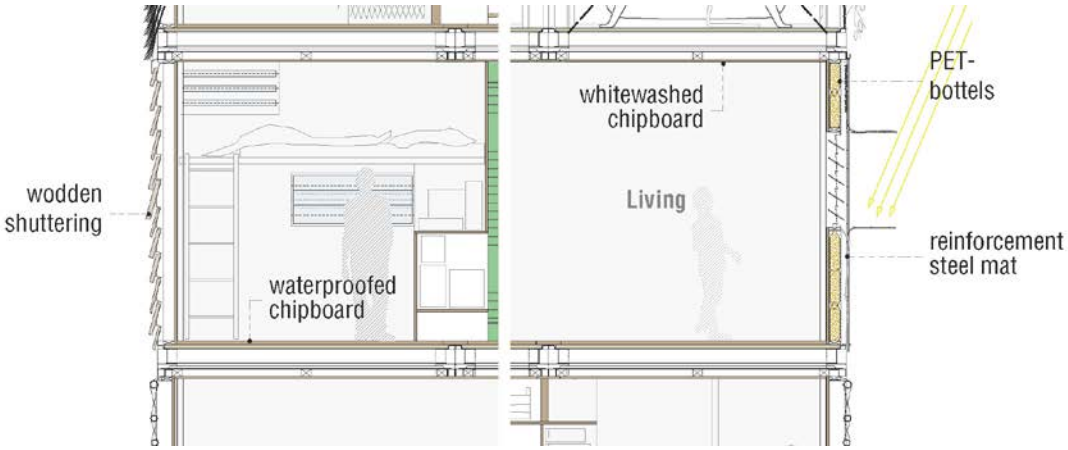

Fig. 9: alternative façade made out of wood respectively of structural steel and used PET bottles

2.3.7 Roof surfaces

The roof surfaces are used for the cultivation and sustainable building operations. (Rainwater harvesting, wind generators, hot water generators) The arising plants will help to improve the microclimate and replace a part of the lost ground surface.

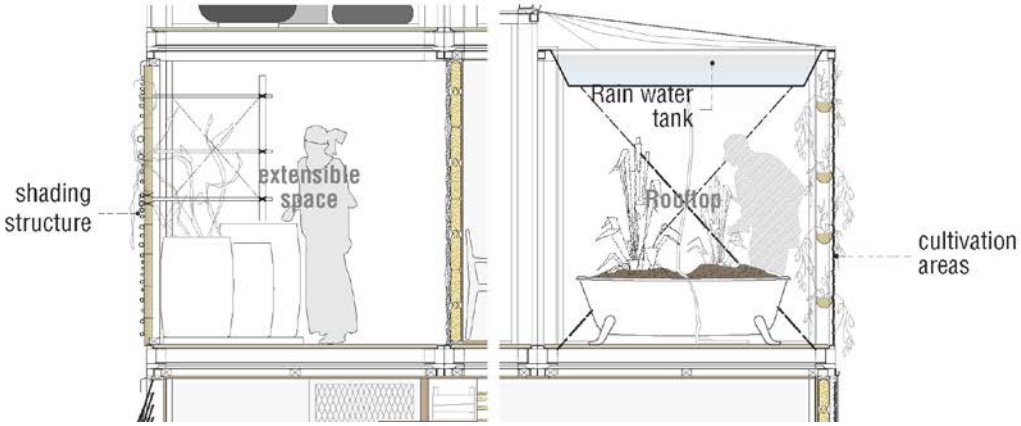

Fig. 10 possible usages of the rooftop and extensible space of the flats

3. Conclusion an future development

The Hometainer project includes three ideas.

- Every person should have a right to an appropriate accommodation. As mentioned in the introduction, more than two billion people live in the worst conditions. A further development with appropriate means is essential for reducing this grievance.

- To ensure a permanently development and progress a careful use of the available resources is necessary. To develop housing in forms of already used materials is actually just a sustainable continuation of the product lifecycle.

- The equitable use of common property (land) and the promotion of communal thought. Thus, the project will encourage users to see the progress from a new side, to create synergies and to work cooperatively towards a better future.

In further consequence of the development phase the implementation of a Hometainer prototype is desired. This allows checking the system for its suitability and effectiveness. In none of these steps the benefits for the project and people must not be neglected.

Short Summary

ELAS is the abbreviation of the research project “Energetic Long-term Analysis of Settlement structures” [1], in which the interrelations between spatial aspects as well as technical aspects of residential settlements and energy aspects were modelled. The results were transferred in a freely available online calculator for settlements, the ELAS-calculator: www.elas-calculator.eu.

Keywords: Energy calculator; sustainable urban planning; energy efficiency, renewable energy supply; sustainability assessment.

1. Introduction

Energy consumption linked to settlements is a major factor within the energy balance of society. In the European case much of the 27 % share of the energy consumption of households is defined by the infra-structure of settlements. This also holds true for a considerable part of the 33 % share of the energy consumed by transport, given that the location of settlements determines the mobility of their inhabitants to a large part; on top of the mobility of individuals, building houses and infra-structure such as roads, sewage systems and energy distribution grids also cause transport of goods, thus adding to the transport impact of settlements. Finally production of all these goods again requires energy in the industrial sector, appropriating a substantial part of the 24 % share of the industrial sector within Europe’s energy balance [2]. Therefore spatial planners need to be aware of the linkage between energy production/consumption and settlement structures. Beside legal conditions which need to be addressed [3], adequate tools will help planners and decision makers during the development process of construction sites. Decisions taken regarding site, structure and operation of buildings and settlements have a strong impact on energy consumption of society and all related environmental impacts. These decisions affect all sectors of life and may not be reduced to just the impact of household energy consumption. As these decisions tend to define energy consumption patterns of society in the long term they must be based on solid strategic evaluation of all available alternatives if sustainable development shall be achieved.
Any sustainability oriented energy strategy from the supranational to the local level rests on three pillows: energy saving, energy efficiency and renewable energy supply. This is also true for the European Energy Strategy as laid down in the Energy Roadmap 2050 [4]. The environmental overshoot of the current energy systems are caused by high energy intensity of society as well as the predominant reliance on fossil and/or nuclear based energy provision [5]. Housing and settlement infra-structure as well as the operation of buildings and the mobility of citizens living in them constitute a pivot for turning the energy system towards sustainability.
This pivot function can however only be realized when all actors in the field take informed decisions. Therefore tools are required that offer evaluation of impacts incurred by those decisions from all aspects of sustainability. If decision takers have a holistic view on the consequences of

their actions, including all ecological impacts along the life cycle of buildings and settlements, the life cycle costs and social implications the chance that they may opt for sustainable development pathways increases considerably. There is no shortage on evaluation tools regarding buildings and their impacts on the economy and environment. All these tools are useful and may help decision takers in their task to cut through the intricacies of finding the optimal solution for housing development. They offer however only partial information that has to be put together to obtain a comprehensive sustainability evaluation of decisions related to housing. This paper introduces a holistic decision making tool (The ELAS Calculator, www.elas-calculator.eu) that models complex systems of energy demand and supply of residential settlement structures and provides a basic sustainability appraisal considering

- energy demand and supply for
  - construction of buildings
  - construction of public infrastructure
  - operation of buildings including room heating, warm water and electricity
  - operation of public infrastructures as well as
  - mobility of residents depending of the demographic structure of the inhabitants as well as the location of the settlement and
- impact on regional economic turn over, revenue and labor market

The model can be applied to existing settlements as well as to planned projects spanning from

- new settlements as greenfield developments
- renewal and renovation of existing settlements with/without expanding them
- tearing down and reconstructing settlements on the same site or on a different site.

2. ELAS - Calculator

Basic decision like the site chosen for a building and the technical standard of building will have profound impact on the energy consumption during its whole life cycle. This has to be reflected in any reliable decision support tool. The life cycle in this case therefore more resembles a “life cycle-network” with the provision of housing at its center. It combines the life cycle of buildings, including the provision of building materials, transport of material, construction, renovation and up-grading as well as demolition and final disposal (or recycling) of building material with the life cycle of infra-structure (roads, sewage systems, energy provision grids) including their operation and maintenance with the life cycle associated with mobility of residents and the life cycles of energy provision to operate the buildings (including heating, cooling and electricity).
The concept realized in the ELAS Calculator is to evaluate the impact of a building or settlement as well as any planned changes to a building or a settlement (including radical changes such as demolition and construction at a different site with a different technological standard) on this “life cycle-network”. That means that all impacts generated along the life cycles constituting this network will be calculated and made transparent, not only in ecological but also in economic and social terms. This applies to current operation as well as all planned changes in to the existing structure as the status quo of buildings and infra-structure will not be rated according to their ecological, economic and social impacts. By this approach the users of the calculator can assess not only the direct impacts of their decisions but may also gain a comprehensive view on the consequences of their action on nature, economy and society.
The ELAS Calculator is designed to support informed decisions about design and operation of buildings and settlements by all relevant actors. It therefore addresses different audiences in order to provide actors on different levels of decision taking with coherent information thus enabling a discourse within as well as across different levels of actors. In particular the ELAS Calculator is designed to be used by

- *Single households* - to assess their individual decisions regarding design, operation and maintenance of their houses and flats, also including the impact their behavior has on construction, operation and maintenance of infrastructure supporting their buildings and mobility induced by their choices

- *Municipal administrators* - to assess impacts the ecological, economic and social impact of existing settlements
- *Planners* - to assess consequences of their activity regarding design and changes in settlements (enlargement, change of technical standards, changes regarding supporting infrastructure and measures concerning energy efficiency and energy provision systems, etc.), including impacts generated by necessary supporting infrastructure and induced mobility by residents.

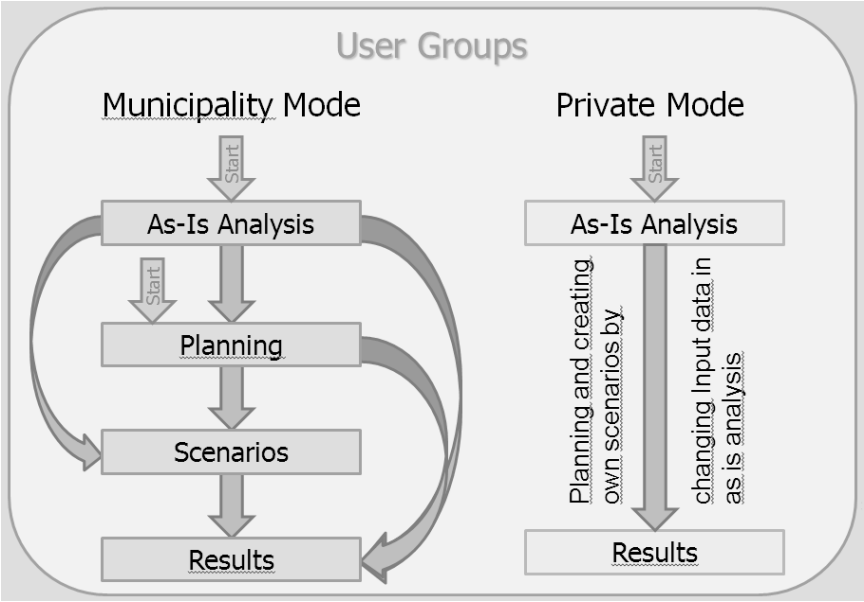

Fig. 1: ELAS-Calculator modes

This requires that the necessary data as well as representation of results must be adapted to the needs of these actor groups. Fig. *1* shows the overall architecture of the calculator. The two principal modes, the “private mode” and the “municipal mode” refer to the two main user groups, private households and professional users, respectively. Within the “municipal mode” the separation of assessment of an existing settlement (As-Is-Analysis) and planning of a new settlement (planning mode) represents the realization of the two tasks, analysis of impacts of existing settlements and planning of new settlements. It is however possible to change from the analysis of an existing settlement to the planning mode and thus assess changes for an existing settlement. Using this option municipal administrators as well as planners can evaluate not only direct impacts of enlargement of settlements and/or up-grading of technical standards of buildings and infrastructure but also impacts of measures of spatial planning and zoning.
Besides the assessment of the impacts of housing under current conditions, the ELAS Calculator offers the option to calculate these impacts under future scenarios (with a time horizon of 2050):

- Trend scenario: in this scenario total traveled distance for individual mobility increases by 25 %, 10 % of the fleet will be operated by biogas and 15 % by electricity, electricity demand it increases at a rate of 2.2 % p.a. This scenario follows projections by Kratena & Schleicher [6] and Friedl & Steiniger [7].
- Green Scenario: in this scenario energy demand of the settlement will decrease by 33 %, electricity will be provided entirely by renewable resources. Increase in traveled distance will again be 25 % however 70 % of cars will be operated on biogas and 30 % on electricity. Several studies were included to justify corrections made to the Trend scenario, including [8] [9] and the instructive analysis of the economic effects of energy price shocks. [10]

These scenarios enable the user to estimate the bandwidth of impacts of the settlement in future within reasonable boundaries.

Any evaluation regarding the sustainability of a settlement has to take the spatial situation in relation to locations providing all necessary functions for residents living in it into account. Construction and maintenance of infrastructure as well as mobility requirements for residents depend critically on the distance between settlement and the provision of functions such as retail stores, educational institutions, health provision, administrative centers, etc. The ELAS Calculator meets the challenge of systematizing this fundamental factor for the evaluation of settlements by defining different "levels of centrality" that define what services are provided in the community the settlement is located in (see *Fig. 2*).

Dependent variable of reachability **Route duration in minutes**				**higher-ranking levels of centrality are already including services of lower-ranking levels infrastructure**		
car	public transport			**Supply** (products = goods and services)	**Social Infrastructure**	**Spare time, Regeneration and Sports**
walking distance		Centrality	**Village without Centrality and Local Supply** Level 1	no supply of goods and services	***Public Administration and Security***	***Earmarked Public Space:*** e.g. graveyard
≤ 10	*≤ 15*		**Village without Centrality but with Local Supply** **Level 2**	***Convenience Goods***	***Educational Institution*** level 0 and 1 according to ISCED-97: ***Health Care-, Long Term Care - and Child Care Facilities:*** ***Cultural-Religious Facilities:*** ***Public Administration and Security:***	
≤ 20	≤ 30		**Center - Village** **Level 3**	***Convenience Goods with slighlty more specialised Character:*** drugstore barber financial institution post office or post partner	***Educational Institution*** level 2 according to ISCED-97: ***Educational Establishment (out-of-school):*** ***Health Care-, Long Term Care - and Child Care Facilities:*** dentist, drugstore, home forthe elderly ***Public Administration and Security:*** police station	***Earmarked Public Space:*** open air pool indoor swimming pool *gastronomy* café restaurant bar
≤ 30	≤ 45		**Regional Center** **Level 4**	***Shopping Goods:*** health food store, toys clothing, footwear bookshop, stationery sound carrier florist, gas station sport goods watchmaker, jeweller electric shop movie, picture, data processing, telecommunications dinnerware, household goods	***Educational Institution*** level 3, 4 and 5 according to ISCED-97: ***Educational Establishment (out-of-school):*** e.g. adult education center, language school ***Health Care-, Long Term Care - and Child Care Facilities:*** e.g. medical specialist, hospital, hospice service, migrants facilities ***Cultural-Religious Facilities:*** museums, galleries event center ***Public Administration and Security:*** district administration facilities chambers of social partners (labour-, economic- and agriculture chamber; federation of trade unions) court	***Public Space:*** spots ***Service Facilities:*** sauna solarium gym cinema club
≤ 60	≤ 90		**National or Supra-Regional Center** **Level 5**	***Special Shopping Goods and not frequently consumed Products:*** furniture, furnishing domestic appliance do-it-yourself store tools and gardening tool specialist shop musical instruments, sheet music other one-line shops (e.g. art trade, weaponry)	***Educational Institution*** level 5 and 6 according to ISCED-97 ***Educational Establishment (out-of-school):*** archive ***Cultural-Religious Facilities:*** theater, cabaret opera, concert hall ***Public Administration and Security:*** facilities of regional government authority	***Public Space:*** parks and green areas ***Earmarked Public Space:*** botanical and zoological gardens allotments, stadiums ***Semi-Public, useable Public and Green Space:*** inner courtyards, community area ***Provision of Service Facilities:*** e.g. amusement and theme parks

Fig. 2: Degree of centrality definition (compressed version) (Source: [11])

Higher levels of centrality refer to communities offering a broader spectrum of functions. The calculator offers a step-by-step help function to support the user in defining this fundamental set of data. Using the distances to the different locations providing basic functions for residents (and using demographic information and modal split information explained later) the ELAS Calculator is able to evaluate the part of the impact of settlements and buildings related to their location.

3. Results of the ELAS Calculator

The ELAS-Calculator offers a holistic numerical evaluation of buildings and settlements from a

sustainability perspective based on a coherent data base. This requires providing a comprehensive ecological assessment, an evaluation of the economic impact of the settlement on the regional economy and insight into its influence on the job market. The ELAS Calculator does not evaluate issues that are less amenable to numerical assessment but are no less important to sustainability such as the impact on biodiversity and landscape and the impact of settlements on social equality, gender issues and inter-generational equity.

3.1 Holistic environmental Appraisal

A holistic environmental appraisal requires looking at the ecological impact of the life cycle network providing housing from perspectives. The ELAS Calculator meets this challenge by offering different ecological measures based on the same data base. By this approach the ELAS Calculator provides a comprehensive, multidimensional picture of the ecological pressures exerted by a certain building, settlement or development project from different angles without requiring the user to care about coherence of life cycle limits or data as the use of the calculator intrinsically guarantees congruence of these critical foundations of evaluation.
In this approach a fine line has to be treaded between providing a comprehensive picture of ecological impacts and deluging the user by information overload that hinders taking clear decisions. Choice of ecological measures represented in the calculator therefore becomes critical.
In the ELAS Calculator the following ecological evaluation methods are implemented:
Cumulative energy demand: this measure was chosen to provide insight into the energy flows (grey energy from construction, renovation and infra-structure provision, energy for operation of the building or settlement, mobility of residents) caused by the life cycle network providing housing, accepting the fact that energy use is responsible for a considerable share of ecological pressures across many impact categories. This measure also provides clear indication of the consequences of energy efficiency measures.
Life cycle CO_2 emissions: This measure corresponds to a particularly important ecological pressure, the emission of CO_2 and the subsequent impact on global warming. This measure also captures the efficiency of the energy provision system regarding global warming and hence may be used to compare different alternatives for providing energy to the building or settlement.
The ecological footprint, calculated according to the Sustainable Process Index (SPI) method: this measure allows the inclusion of the impact of nuclear energy but also the evaluation of all relevant ecological pressures linked to provision of resources and the generation of emissions and wastes (also including greenhouse gases) from the life cycle network. This measure therefore can be used to compare different alternatives regarding their overall ecological impact.
The three methods are described in more detail below.

3.1.1 Life cycle wide energy demand

Energy is a major factor in the ecological pressure exerted by a building or settlement. The ELAS Calculator accounts for all energy flows generated by the whole life cycle network. This includes the energy to operate the buildings (heating, cooling, electricity demand of appliances), the necessary supporting infrastructure (energy to operate sewage systems, street lighting, road service, etc.) and mobility of residents. The calculator however also includes all “grey energy” that is necessary to provide the materials of construction for buildings and infrastructure or used in construction, renovation or demolition and disposal (when appropriate) for any planned changes to the current structure. This grey energy is calculated using the methodology of the “Kumulierter Energieaufwand – KEA” [12]. Grey energy input will be related to one year by taking lifetimes of buildings and infrastructures (66 years) into account.

3.1.2 Life cycle wide CO_2 emissions

The calculation of CO_2 emissions is directly coupled with the calculation of the ecological footprint (see below). All fossil carbon inputs across the whole life cycle network are the base of the CO_2 calculation. This includes also CO_2 emissions from synthetic materials used in construction of new buildings and infra-structure as well as in renovation, depreciated over the life time of the building and the renovation interval respectively.

3.1.3 Ecological footprint according to the Sustainable Process Index (SPI) method

The SPI is a method to calculate ecological footprints that emissions to air, water and soil besides resource provision into account [13]. The method compares anthropogenic and natural flows according to the following sustainability critera [14]:

- Principle 1: Anthropogenic mass flows must not alter global material cycles;
- Principle 2: Anthropogenic mass flows must not alter the quality of local environmental compartments.

The results of the footprint calculations are broken down into partial footprints for direct area consumption, fossil resource consumption, renewable resource consumption and emissions to air, water and soil.

3.2 Socio-economic Appraisal

Socio-economic impacts are calculated using the economic input-output analysis [15]. This method calculates the impact of particular economic activities throughout the whole economic system by modelling the interaction of the sectors of the economy, using appropriate input-output coefficients linking the activities of different sectors. The sectors in this analysis were defined following the NACE-systematic of economic sectors [16] however splitting the sector E “Electricity, Gas and Water Supply” into non-renewable energy, renewable energy and water supply. Activities evaluated with the ELAS Calculator are supposed to provide products summarised in building construction, building operation, municipal services construction and operation and external effects (mainly concerning transportation).
The ELAS Calculator will evaluate socio-economic impacts regarding the concrete region the settlement is located in. This requires regionalisation of the input-output coefficients, starting from national data provided by Eurostat [17] and using regionalisation techniques according to [18][19]. This method counters the main drawback of mainstream regionalization techniques, i.e. the overestimation of multipliers and transformators.
Using this model the ELAS Calculator will provide an evaluation of regional and national turnover, value added and jobs induced by the operation of the existing building or settlement and the planned changes to the settlement respectively.

4. Conclusions

Decisions concerning construction and operation of buildings and settlements are pivotal to achieving sustainability and in particular to arrive at a sustainable energy system of society. This is due on the one hand to the large fraction of energy used in buildings (in particular in Europe) and on the other hand to the considerable influence the way settlements are situated has on other energy uses, in particular by shaping mobility requirements of residents and modal split of travels. As such decisions, due to the longevity of buildings, have long ranging consequences thorough and reliable decision support is necessary.
Providing such comprehensive decision support for individual house owners as well as for municipal administrations and planners was the goal of the “energetic long term analysis of settlement structures” (ELAS) study that forms the background to this article. Based on a thorough analysis of ten settlements in different spatial situations and featuring a variety of building types and demographical set-ups of residents, a web based calculator was developed that evaluates buildings and settlements from the point of view of their sustainability.
The major challenges addressed with the ELAS Calculator were on the one hand the complexity of the ecological impacts of buildings and settlements and on the other hand the necessity to provide ecological and socio-economic valuation on the base of a coherent data set. Regarding the complexity of ecological impacts housing was represented as a “life cycle network”, combining the life cycles of energy provision as well as buildings and infra-structure. Comprehensive inventories for these different aspects were included in the ELAS Calculator. They were then used to evaluate the whole system of activity linked to buildings and settlements with three different ecological valuation methods, namely the total energy consumption, the life cycle CO_2 emissions and the ecological footprint using the SPI calculation method to provide a comprehensive picture of the ecological impact of buildings and settlements.

These same inventories were then coupled with economic input-output analysis with regionalized technology coefficients. This evaluation renders a comprehensive picture of the socio-economic impact of buildings and settlements, providing information about turn over, value added imports and jobs created by operating building and settlements or by renovation of buildings or changing settlement structures.
Within the research carried out it became obvious that infra-structure construction and maintenance as well as site-induced mobility are crucial for the sustainability of settlements. For both the site of the settlement is a defining factor. The ELAS approach addressed this by introducing different levels of centrality, differentiated according to the services available in the town the settlement belongs to. Thorough studies linking these levels of centrality and the demographic set-up of residents with daily and leisure mobility allow the evaluation of these factors within the ELAS Calculator without requiring excessive data acquisition from the user.
The ELAS Calculator offers free accessible evaluation for stakeholders involved in long ranging decisions regarding buildings and settlements. With this tool stakeholder can readily integrate aspects of sustainability in their decisions, both regarding the operation of buildings and settlements as well as in planning renovations, enlargements or even relocation of settlements.

5. Acknowledgements

The model was developed by the team of authors in an interdisciplinary research project named “ELAS – energetic long-term analysis of settlement structures” co-funded by the Austrian Climate and Energy Fund, the Provinces Upper Austria and Lower Austria as well as the Town of Freistadt. Therefore, we will further refer to the model as ELAS-model. The ELAS-model was transferred to an open-access internet tool, the ELAS-calculator, available on www.elas-calculator.eu. This paper reveals the ELAS-concept, the main approaches to calculating the outcomes and the way the database for the calculation was created.

DI Dr. Ulla Ertl-Balga, BOKU-Vienna, Austria, ulla.ertl@boku.ac.at

Short Summary

Cities like Vienna are obliged to achieving energy policy targets. The GUGLE – master plan originates from the need of collective actions at regional, national and EU levels, while considering user needs in an urban area and incorporating sustainable technologies and actions. Although a transition to a more sustainable path is commonly acknowledged, it has been proven to be rather difficult to change the incumbent system. In order to implement appropriate concepts and strategies for achieving sustainability and for assessing the potential impact of novel clean technologies and measures, GUGLE serves as a gate towards advanced regional, national and EU demonstrations, by building upon Bottom-Up-Approaches.

The comprehensive integration approach used in GUGLE aims at drawing a technical feasibilty study (TFS) for two Viennese districts, Penzing and Alsergrund, considering within their borders every aspect of a smart city life and energy services. The TFS serves as a gate towards advanced regional, national & EU demonstrations by designing, implementing and validating a plausible scientific framework for proper actions and co-operation towards future sustainable energy policies in end-use sectors for the EU-targets 2020 / 2050.

The objective of this scientific study relies on developing a comprehensive interdisciplinary urban quarter concept as a trendsetting business model in close co-operation with related envisaged investors and industrial partners. Based on selected lighthouse projects and on related promotion activities of empirical results the wishful market extension will be pushed on mid-term. Proposed future scenarios and measures of the GUGLE Master plan are not new, but have been intensively discussed with all relevant stakeholders within project meetings and workshops and are specified for extended deployment at district level.

Keywords: urban quarter concept, smart city development, sustainable energy policies, future scenarios

1. Introduction Smart Cities

1.1 Background of Smart City Initiatives

In one decade about two thirds of the world's population will live in urban areas. Only cities with a functional ecology can offer the prospects of saving natural landscapes from urbanization in order to secure high quality of life for its inhabitants [1].
This is the background of many so called „smart city" initiatives - they pursue the goal of creating more attractive and liveable cities, which have the highest potential for energy-efficient way of live, because of their density.
Some of the most effective instruments of smart city projects are ambitious refurbishments of the existing building stock, the creation of new highly energy-efficient living quarters, the switch from fossil energy sources to renewable energies and the development of intelligent traffic and transport solutions.

1.2 National and European initiatives on smart cities

In 2010 the EU enacted the so called „Strategic Energy Technology Plan" („SET-Plan"), which was designed to function as a steering tool for the strategic collaboration of European Nations in order to fundamentally transform today's energy system and to reach the European 2020 energy targets (reduction of greenhouse gas emissions by 20% compared to 1990 levels, increase of the share of renewable energies of 20% and the increase of the overall energy efficiency of 20%).
The Seventh Framework Programme (FP7) issued by the European Commission currently grants subsidies to innovative projects promoting sustainable developments – including smart city initiatives as one main emphasis.

In Austria the national programme „Smart Energy Demo - FIT for SET" was issued by the Austrian Climate and Energy Fund, which emphasizes on the establishments of Austrian smart city initiatives. The aim is to accompany and support cities, as well as companies and research institutes implementing smart city measures.
The programme was received with great interest, during the starting phase in March 2011 a total of 20 projects from different cities across Austria were granted subsidies. Among these was the research project "GUGLE" (Green Urban Gate towards Leadership in sustainable Energy), which focuses on the energy-efficient refurbishment of two Viennese districts, Alsergrund (9th district) representing the inner city and Penzing (14th district) representing suburban settlements, which contains very opposite types of existing building developments.

2. GUGLE

2.1 Initial situation

The research project GUGLE - Green Urban Gate towards Leadership in sustainable Energy was initiated by the workgroup Sustainable Constructions at the University of Live Sciences and Natural Ressources (BOKU), Department of Structural Engineering and Natural Hazards, Institute of Structural Engineering under the scientific leadership of Univ. Prof. Arch. DI Dr. Martin Treberspurg.

GUGLE builds on the objectives of the previous „Smart City Wien" project, which was striving for solutions for an overall smarter Vienna. In its course a roadmap addressing several areas of activity was developed in order to ensure ambitious targets related to energy and climate protection. Those goals should be achieved at city level by 2020 and 2050. The „Smart City Wien" project-team has identified various areas of activities, comprising the topics of urban extension, mobility, new construction and renovation of buildings, utilisation of various types of energy and energy related user behavior.
The comprehensive approach used in GUGLE is in line with these smart city actions and aims at drawing an energetic master plan for the two Viennese districts Penzing and Alsergrund. This

master plan addresses every necessary aspect for a smart district life and also covers the topic of energy services and supply. The aim of the project is to find intelligent and innovative ways at district level which eventually can be applied to full city scale, based on a bottom up approach.
The objective of this scientific study based on the thematic fields presented in fig.1 relies on developing a comprehensive interdisciplinary city quarter concept as a trendsetting business model in close co-operation with related envisaged investors and industrial partners. The goal was to use and integrate existing Viennese strategies like the climate protection program (KLIP Klimaschutzprogramm der Stadt Wien) and the city development plan (Stadtentwicklungsplan) as well as other programs.

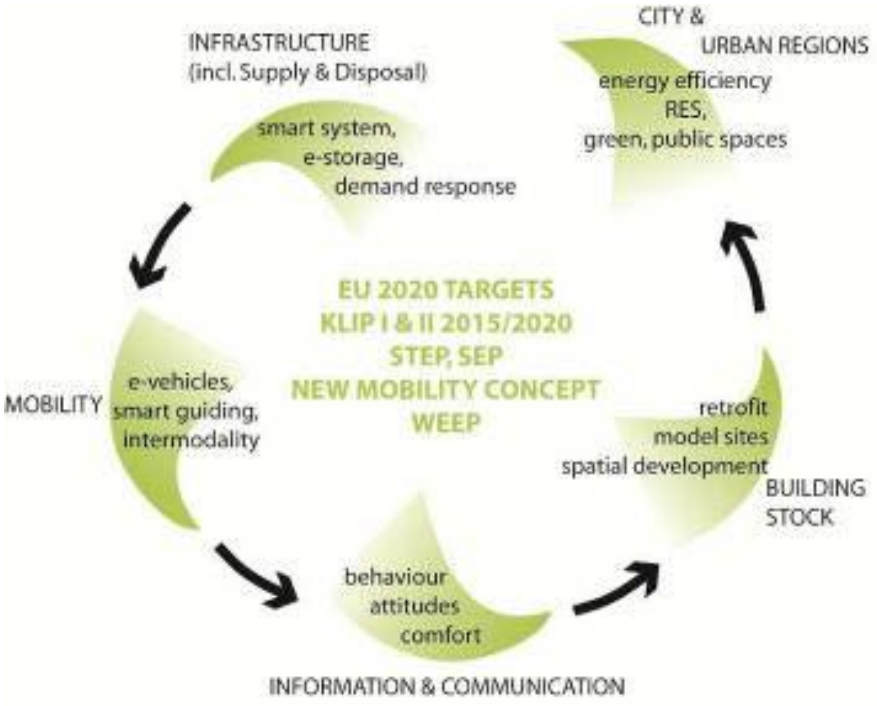

Fig. 1: Relationship between the thematic fields of GUGLE and the energy-political frame of Vienna [Source: BOKU Vienna].

2.2 The historical development of the Viennese districts Alsergrund and Penzing

The spatial development of the city of Vienna can be retraced by looking at its different urban patterns. Originally Vienna consisted of an inner core (today's first district), which was protected by a city wall (which was replaced by the "Ringstraße" - boulevard during the historic period).
Starting off in the 15th century, the first medieval suburbs were formed outside the city wall ("Vorstädte"). Until the 19th century they remained sparsely populated, which abruptly changed in 1850, when they were affiliated to Vienna as its new settlement areas because the inner city was already over-crowded.
The Viennese district Alsergrund represents one of these former suburbs, which are still characterized by the buildings and typical urban patterns stemming from the period of promoterism (Wiener Gründerzeit, 1840-1918). Some characteristics the former suburbs all have in common are: a high percentage of historic buildings and a very central location around Vienna's old town with an optimal access to public transport. The lack of green spaces and a high heat-energy demand of the historic buildings, which results in an overall reduced living comfort can be identified as their main disadvantages.

Penzing on the contrary represents one of the early settlements which existed in the form of a rural-urban fringe around Vienna ("Vororte", today's 10th – 19th district). These settlements developed as autonomous towns around the previously mentioned new suburbs and were incorporated to the city of Vienna under the regiment of Austrian emperor Franz Joseph in 1892.

Because of their distinguished settlement history, their urban structure differs from those districts located around Vienna's city center.
Today, the district of Penzing contains former working-class quarters constructed during the later period of promoterism and a large building stock of multiple dwelling units from the 1950-70ies.

2.3 Energy Scenarios developed in the GUGLE – master plan for Penzing and Alsergrund

Beside urban layout, mobility and energy supply a special focus was on the building stock within the master plan. Based on the actual building stock, different scenarios were developed to show possible optimizations. These scenarios will be exemplified in the following section.

2.3.1 Data

In the course of the development of a GUGLE-master plan the heat demands of Viennese districts Alsergrund and Penzing were analysed closely. Based on the actual consumption data, four scenarios of future energy consumption were calculated based on the simulation model Invert/EE-Lab (based on Kranzl et al., 2011) [2]. These scenarios simulate the building related final energy demand for space heating and hot water of Alsergrund and Penzing until the year 2030. The considered buildings are residential and service buildings and exclude buildings for industrial purposes. Invert/EE-Lab is a dynamic bottom-up simulation tool which uses disaggregated data for the building stock, such as available roof area and currently existing heating systems. The model simulates different scenarios (price scenarios, insulation scenarios, different consumer behaviors, etc.) and their respective impact on future trends of renewable as well as conventional energy sources on a national and regional level. Beside that the model evaluates effects of different promotion schemes (different settings of economic and regulatory incentives) on the energy carrier mix, CO2 reduction and costs. The Vienna University of Technology/EEG worked out these scenarios with the Invert simulation tool.

In order to apply the Invert/EE-Lab model for the Penzing and Alsergrund, data of the district's building stock, as well as their heating supply (by fuels used and by system type) were required. This data has been derived through calibration of data from Vienna (Statistic Austria (2011)) [3] to the districts data from Statistic Austria (2004) [4]. However it must be kept in mind that this approach is associated with a certain level of uncertainty as the latest data concerning heating systems reflects the status as of 2001. For the future development of building stocks, future expectations from ÖROK (2011) [5] have been taken into account.

2.3.2 Description of Scenarios

In order to pre-estimate the final heat energy demand development up to 2030 under the aspect of different levels of refurbishment four scenarios have been conducted. The key characteristics of these scenarios are the quality as well as the quantity of the thermal refurbishments conducted in the scenarios. The following four scenarios were identified:

- Business as Usual - "BAU Scenario":
This scenario reflects the current trends of refurbishments in Austria based on given information in Tabula Brochure [6] . This scenario includes entire building renovations (i.e. renovation of all building elements), however, due to the lack of information or economic support instruments, it is estimates that a considerable number of buildings will be refurbished without thermal improvement. The BAU scenario also assumes that, to certain extend, the NRfNB (National Regulation for New Building) standards will be disregarded.
This scenario results in a low rate of thermal building refurbishment of less than 1% per year.

- “Alternative Scenario_1”:
This scenario assumes that all new buildings will be built based on NRfNB Standards. It is also assumed that until 2020 refurbishments will be conducted based on current trends, but from 2020 on, refurbishments will be based on NRfNB standards. Again, due to economic conditions or a lack of information, there is a considerable share of buildings renovated without improving their thermal standard. Furthermore it is assumed that all heating systems will be replaced by high efficient heating systems (e.g. high efficiency boilers) after 2020.
The resulting thermal refurbishment rate of Alternative Scenario_1 is slightly higher than of BAU-Scenario.

- “Alternative Scenario_2” (“Gugle_Penzing” and “Gugle_Alsergrund”):
The difference between this scenario and Alternative Scenario_1 is the assumption that refurbishments as well as new constructions starting from 2020 on are based on NZE (Nearly Zero Energy) standards. This scenario is therefore called “Gugle_Penzing” and “Gugle_Alsergrund” Scenario, as the intended demonstration projects within the Gugle Project for these districts are incorporated in the scenario development. More precisely, the assumption is taken that these refurbishments will be based on NZE isolations standards.
In this scenario the thermal refurbishment rate of buildings is slightly higher than in Alternative Scenario_1, but still a number of buildings are renovated on low-level thermal insulation standard.

- “Potential”:
The fourth scenario “Potential” indicates the possible heat energy demand reduction of Penzing up to 2030 under the assumption that all building refurbishments will be based on NZE standard and that no building renovation activities will be conducted without thermal improvements or with lower standard than NZE. Thus, we assume that for those buildings renovated, there are no extra costs for renovating to NZE standard. However, it is assumed that there will be no advanced investments in building renovations, such as investments in integrated thermal refurbishments of buildings ahead of the end of lifetime of building components.
Therefore, the overall resulting thermal building renovation rate is still moderate (yearly average rate up to 2030: 1.5% for Penzing, 1.75% for Alsergrund), though it would mean more than a doubling of the current renovation rate. More ambitious scenarios would only be possible with a higher share of advanced investments in building renovation.

2.3.3 Total final heat demand – Penzing

The development of Penzing's total final heat demand is shown in fig.2. Choosing 2006 as the starting year with a total building related heat demand of 912 GWh in Penzing, it shows the estimated heat demand reduction until 2030 based on the four calculated scenarios.

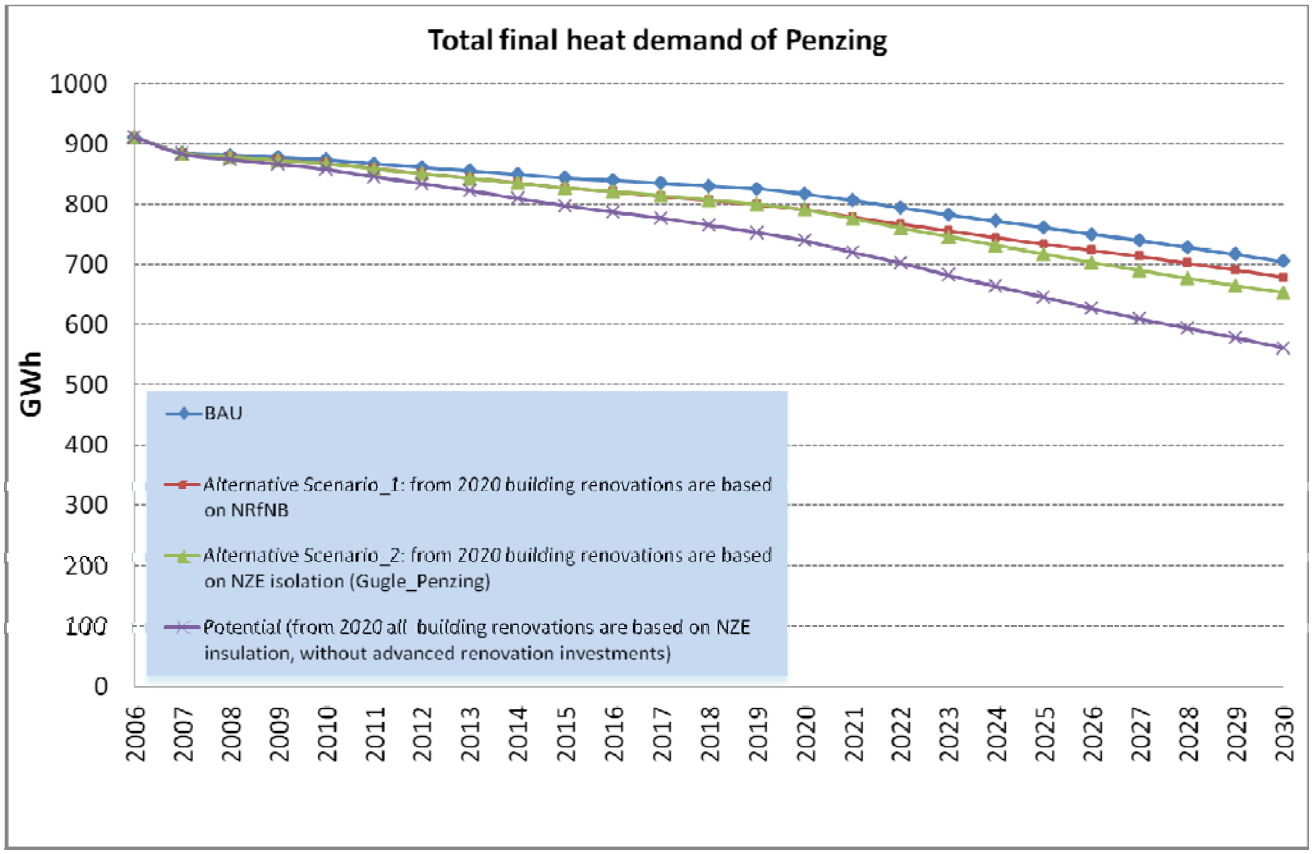

Fig. 2: Development of final heat demand (space and water heating) of Penzing up to 2030 [Source: TU Vienna/EEG 2012]..

According to the simulation based on:

- "BAU Scenario", the heat demand will decrease by 23% to 705 GWh.
- "Alternative Scenario_1", setting standards from 2020 on, the heat demand of buildings in Penzing can be reduced by 26% to 679 GWh.
- "Alternative Scenario_2", the heat demand can be decreased by two more percent to 653 GWh, if buildings are thermally renovated based on NZE standards (intention of GUGLE demo projects).
- "Potential Scenario", a maximum 38% reduction of Penzing's heat demand is possible.

2.3.4 Total final heat demand – Alsergrund

The development of the total final heat demand of Alsergrund is shown in fig.3. Setting 2006 as the starting year with a total building related heat demand of 376 GWh, it shows the estimated heat demand reduction until 2030 based on the four calculated scenarios.
Within the simulation of the ninth district, the heat consumption of Vienna's General Hospital (AKH) located in Alsergrund is not represented in the Invert/EE-lab model.

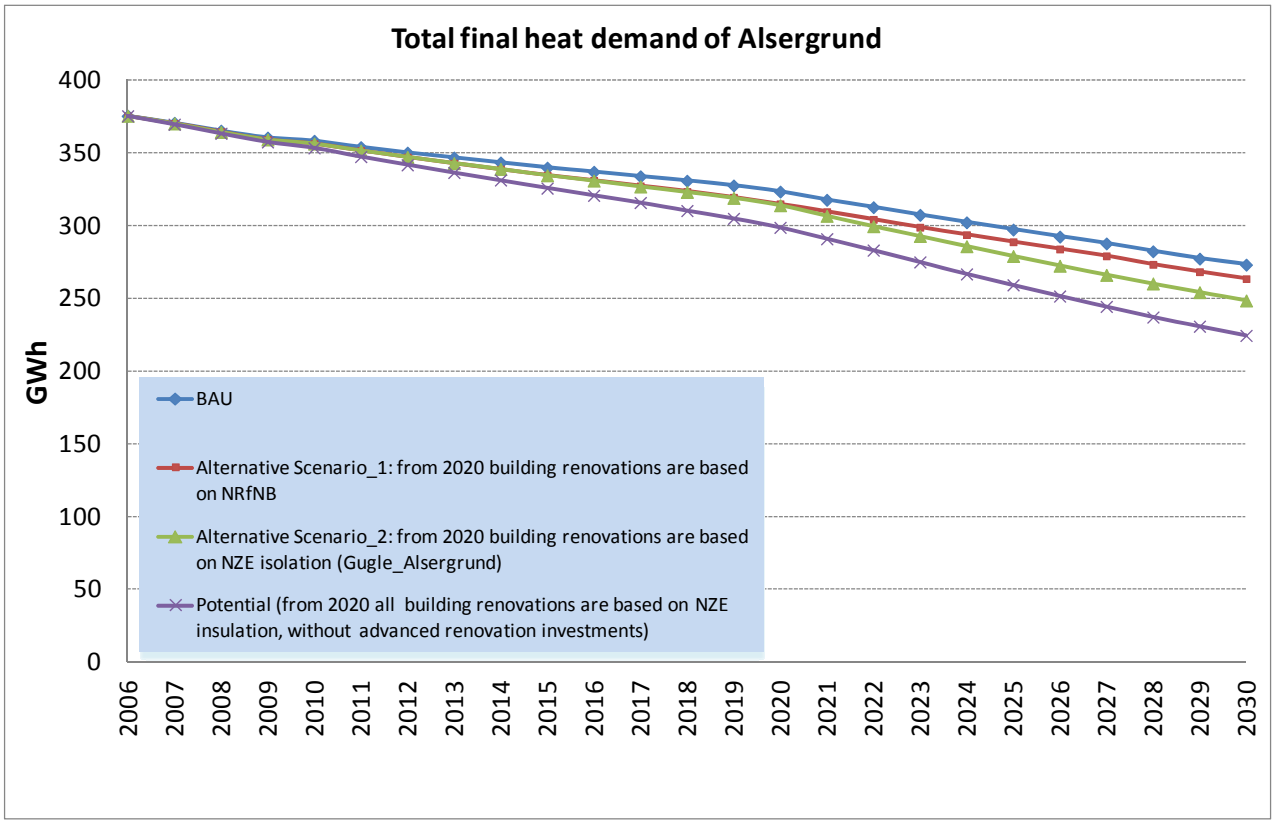

Fig. 3: Development of final heat demand (space and water heating) of Alsergrund up to 2030 [Source: TU Vienna/EEG 2012]..

According to the simulation based on:

- "BAU Scenario", the heat demand will decrease by 27% to 273 GWh.
- "Alternative Scenario_1", setting standards from 2020 on, the heat demand of buildings in Alsergrund can be reduced by 30% to 264 GWh.
- "Alternative Scenario_2", the heat demand can be decreased by four more percent to 249 GWh, if buildings are thermally renovated based on NZE standards (intention of GUGLE demo projects).
- "Potential Scenario", a maximum 40% reduction of Penzing's heat demand is possible.

2.4 Results Roadmap

As the main result of GUGLE a master plan for the future development of Alsergrund and Penzing was created, which suggests measures in various fields:
One focus is the development of strategies for improving the performance of the building stock. For this purpose smart refurbishment solutions for different representative buildings were developed by the GUGLE team. As an important additional measure, an evaluation sheet was designed, to give residents of newly refurbished buildings the chance to feedback the measures taken on their building. This sheet can contribute to highering the acceptance of refurbishment measures overall by portraying the individual needs of users in the district and learning from individual problems of users.

2.4.1 Building Stock and City Planning

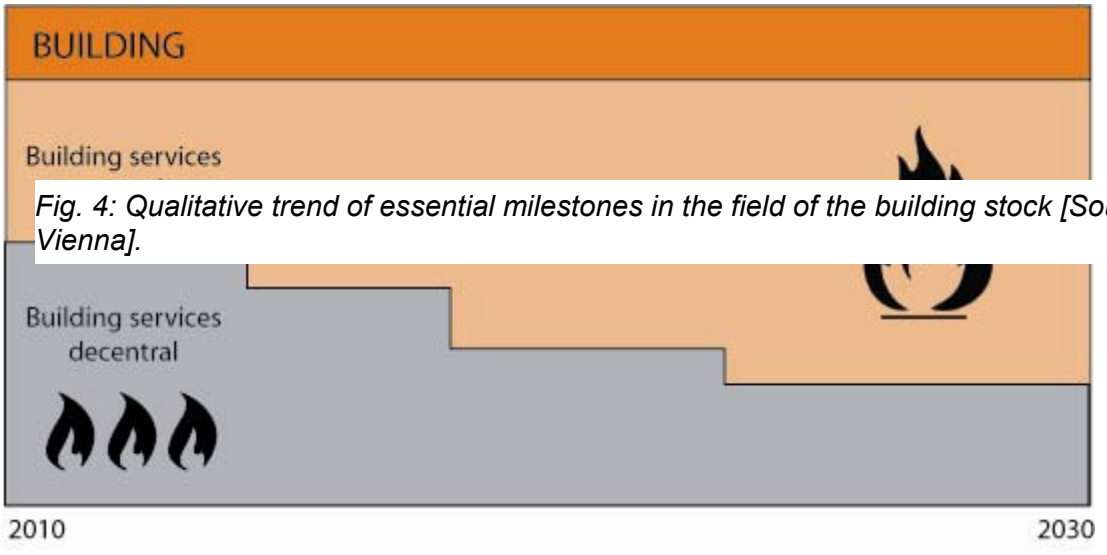

Fig. 4: Qualitative trend of essential milestones in the field of the building stock [Source: BOKU Vienna].

- Finding cost-optimized solutions for refurbishments under the aspect of lifecyclecost according to the European Buildingcode
- Increase of refurbishment activities by pushing towards the creation of new attractive subsidy schemes adjusted to the legal situation (e.g. tenancy law/property law)
- Continuous increase of energy efficiency in order to bring refurbishments to NZE standard until 2020.
- Switch from decentralized to centralized building equipment solutions as a necessary precondition for the widespread implementation of renewable energies.

Influence of different regulations – right of abode

The three individual Austrian laws, regulating the right of abode - the “Mietrechtsgesetz MRG” (tenancy law), the “Wohnungsgemeinnützigkeitsgesetz WGG” (for housing corporations) and the “Wohnungseigentumsgesetz WEG” (for property owners) - play an important role in the context of executing refurbishments.
In case of the MRG, reduced consumptions and consewquently cost reductions must be confered directly to the tenant and only actual investments can be accounted by the owner. The bypassing of cost by interposing service providers with flat charges is invalid. Tenants must recieve compensation for the phase of refurbishment according to the principle “acceptance in return for money or another type of benefit”. Rent must be used for repairing measures and a balance must be accounted for the period of ten years. If the owner does not meet his obligations of maintenance, tenants can file a suit for renovation. (This is the reason why apartment buildings are regularily put up for auction.) A switch to renewable energies during the contract period involving higher cost cannot be transmitted to the tenant, unless it represents the cheapest option. Momentarily, despite all substitutions, renewable energies are more expensive than other energy sources and therefore the status quo is obtained. At the moment, only the most cost effective option can be inflicted on the tenant – therefore it is nearly impossible to implement renewable

energies in the course of a refurbishment against the will of tenants.
The WGG adresses non-profit housing corporations which can also be corporate entities. It allows the installation of technically adequate shared equipment in order to reduce the building's energy consumption. The housing coorporation can decide on any building measures, if the tenants demand them during a residents meeting and if there are sufficient reserve funds of the object.
The WEG foresees that under certain circumstances appartment owners are authorized to conduct renovations, if all cost is covered by the initiator.

Generally it must be stated that all three laws of abode in their current way are prejudicial to the introduction of renewable energies in the course of refurbishments of residential buildings. The WGG offers the widest scope for tenant-contracting models and further measures.
Furthermore the law regarding heat cost billing has a large influence on refurbishments - it states that measures replacing existing systems, which are undertaken in the interest of reducing energy consumption and are justified by a cost-benefit equation can be equated to maintainance measures.

2.4.2 Mobility

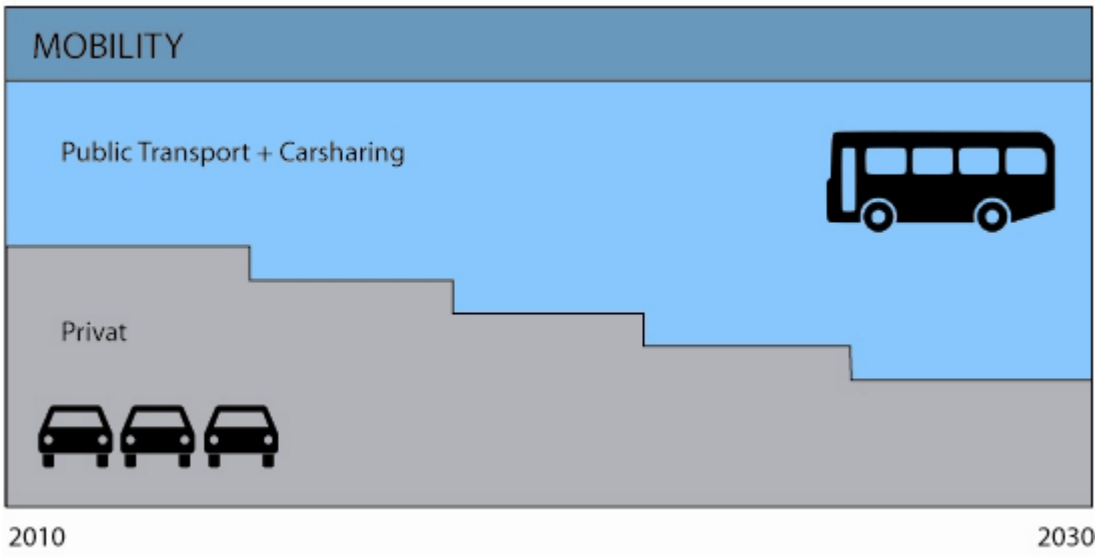

Fig. 5: Qualitative trend of essential milestones in the field of the mobility [Source: BOKU Vienna].

Milestones

- Mobility management strategies for urban settings:
  - "car-reduced living" – apartments are sold together with a parking spot and a five year ticket for the public transport.
  - Integration of information and service: delivery service for groceries and laundry service in cooperation with local amenities, installation of delivery boxes in designated spaces of apartment buildings
  - Car sharing – widespread provision of car sharing facilities, reserved parking space, special packages for first-time users such as free memberships or reduced fees for a certain amount of time
  - Bicycle facilities: sufficient bike parking spaces inside and outside of residential buildings, as well as public buildings and local amenities. bike-service-stations
- Implementation of new mobile information technologies
- Management of the stationary traffic
- Provision of infrastructure for e-mobility

Shaping of „Smart City Consumers" - quality of live and prosperity through a sustainable consumerism and lifestyle (2010 – 2030)

Through mobility-management measures in the area of housing, the resident's choice of transportation can be influenced positively:

- Regular information packages matched to conditions regarding location - focus group: new residents
- Special classes for the use of public transportation (e.g. how to use ticket vending machines, how to read timetables) – focus group: elderly people
- Coaching by specialized "mobility-trainers" for local residents: workshops about personal cost saving strategies through change of means of transportation
- Activities at local schools with a playful character: workshops about mobility, experiments and competitions for classes (e.g. prize for the class with the lowest individual traffic volume)
- Promotion of communal traffic solutions such as "bike & ride" facilities including e-bike stations with the possibility of reserving filling stations. Securing of connection to public transportation.
- Expansion of the Citybike system (free/very cheap public bike rental with dozens of rental/return stations) with a focus on highly-frequented locations in the city)
- Stimulation of e-mobility: by integrating electric cars to the vehicle fleet of car sharing providers, by providing exception regulations for e-vehicles (e.g. parking time, financial amenities for parking), by changing building codes by establishing the right to provide electricity filling stations in private or public garages

2.4.3 Communication

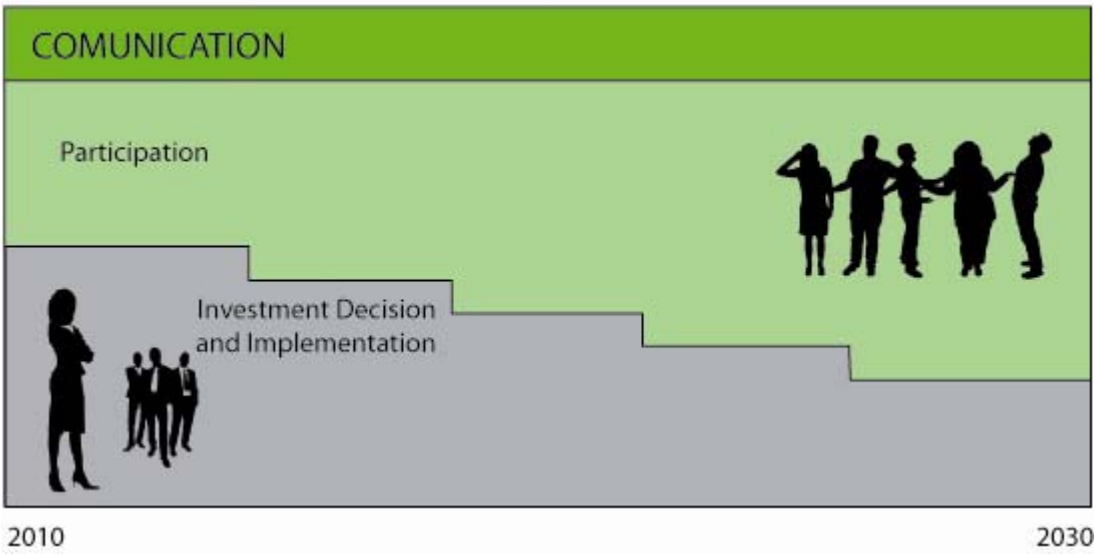

Fig. 6: Qualitative trend of essential milestones in the field of communication [Source: BOKU Vienna].

- Active PR for GUGLE
- Establishing networks between local groups and initiatives in Alsergrund and Penzing and creation of an active GUGLE-Platform (2013 – 2015)
- Raising awareness for future landmark projects and accompanying bottom-up initiatives (2016 – 2030)
- Observation of participation and knowledge transfer (2020 – 2030)

2.5 Local Networks

2.5.1 “Wiener Gebietsbetreuung Stadterneuerung”

One focus of urban redevelopment in Vienna since the foundation of its urban development plan in the 1970ies has been the modernization of its large building stock from the period of promoterism. Ever since then refurbishments have been accompanied by special funds and a variety of consultation opportunities with a focus on the needs of the local residents. Through these actions, the amount of substandard apartments in Vienna could effectively be reduced from 300.000 during the 1970ies to around 50.000, without banishing the local population.
The “Gebietsbetreuung Stadterneuerung” is a Viennese institution actively involved in these “gentle” urban redevelopment projects.
Recent goal of the urban development in Vienna is the improvement of the quality of life in densely populated city quarters. This goal is currently targeted by refurbishments, which are the main focus, the provision and strengthening of local amenities, the boost of local cultural activities and the enhancement of the design and layout of public spaces.
The Gebietsbetreuung Stadterneuerung works on behalf of MA 25 and is lead by private contractors under the business group of living, housing and urban redevelopment (Geschäftsgruppe Wohnen, Wohnbau und Stadterneuerung).
http://www.gbstern.at/teams/gb14-15/

2.5.2 Local Agenda 21 Plus (LA21+)

Local Agenda 21 Plus was created in 2002 in order to boost public participation on district or city level in Vienna. The task of Local Agenda 21 Plus is the support of citizens who actively want to get involved in actions towards more sustainability and quality of life for their neighbourhood. Local Agenda stands in direct contact with local authorities such as the district administratian, politicians and city planners. http://la21wien.at/

2.5.3 Wohnpartner

“Wohnpartner” is a service institution for the residents of appartment buildings owned by the city of Vienna.
There is a total of nine “Wohnpartner” service centers in Vienna, which take care of residential buildings all over the city. They offer multifaceted activities to boost the community inside these buildings in order to improve the overall quality of life for the residents.
http://www.wohnpartner-wien.at

3. Outlook

For the GUGLE-master plan the interdisciplinary consortium identified the most important measures for the upgrading of urban sites towards sustainability and in particular for the two Viennese districts Penzing and Alsergrund. These consist of:

- The renovation of existing buildings,
- the integration of renewable energies and
- a sustainable design of urban mobility.

These actions will help to tackle national and European CO_2 reduction targets at district level. Based on selected lighthouse projects and on related promotion activities of empirical results, the market extension will be pushed on mid-term.
The proposed future scenarios and measures of the GUGLE Master plan have not been implemented yet, but were intensively discussed with all relevant stakeholders during several project workshops and were specified for extended deployment at district level.

4. Acknowledgement

We would like to express our sincere thanks to:
- Klima- und Energiefonds for funding this project,

Our project partners for their support and necessary inputs
- Allgemeine Baugesellschaft A. Porr Aktiengesellschaft
- ENERGIECOMFORT Energie- und Gebäudemanagement GmbH

Short Summary

The construction sector has a large share on the global warming potential. Concrete generates a substantial part of the environmental impact especially due to its content of Portland cement clinker. To quantify the ecological effects, concrete has to be assessed over his whole life cycle.
The method of Life Cycle Assessment (LCA) [1,3] helps to identify opportunities to improve the environmental performance and provides informations for a strategic business planning.
The literature review in the presented paper provides a survey of the state of the art in the D-A-CH (Germany – Austria – Switzerland) countries. An analysis of the regional concrete constituents is the background for the comparison with typical types of Austrian concrete.
Based on these results the optimization potential for concrete is addressed.

Keywords:Life Cycle Assessment (LCA); global warming potential (GWP); concrete

1. Introduction

The majority of their time (90%) people spend in buildings or use infrastructure. This fact points to the importance of the construction sector. It generates about 10% of the global warming potential in the European Union [2]. Buildings and infrastructure have the highest product lifetimes (decades, often centuries).
On the other hand, the construction sector also causes huge mass flows. Concerning the large amount of concrete which is used for those constructions, the environmental effects have to be investigated in detail.
To provide a basis for research, an evaluation of the current situation is necessary.

2. Methodology

The literature survey is mainly focused on results from the D-A-CH countries. Databases and research findings were screened for results for the environmental performance of concrete.

Method of Life Cycle Assessment (LCA)

The requirements for the creation of an LCA are shown in ÖNORM EN ISO 14044 [3] and ÖNORM EN ISO 14040 [1] in detail. The LCA refers to the environmental aspects and potential environmental impacts during the life cycle of a product from raw material acquisition through production, use, waste treatment, recycling and final disposal (i.e. from “cradle to grave”). Usually, economic or social aspects in Life Cycle Assessment of a product will not be considered.

The scope of an LCA study consists of Goal and Scope Definition, Life Cycle Inventory, Life Cycle Impact Assessment and Analysis (Figure 1).
The scope, inclusively the system boundary and the level of detail, depends on the object of investigation and the intended application of the study.
A Life Cycle Inventory (LCI) is the inventory of input and output data, which refer to the considered system. An impact assessment is used to provide additional information to support the assessment of the LCI of a product system for a better understanding of its environmental relevance.
As part of the analysis the results of LCI or Life Cycle Inventory Analysis (LCIA) or both are discussed and summarized as a basis for conclusions and recommendations.

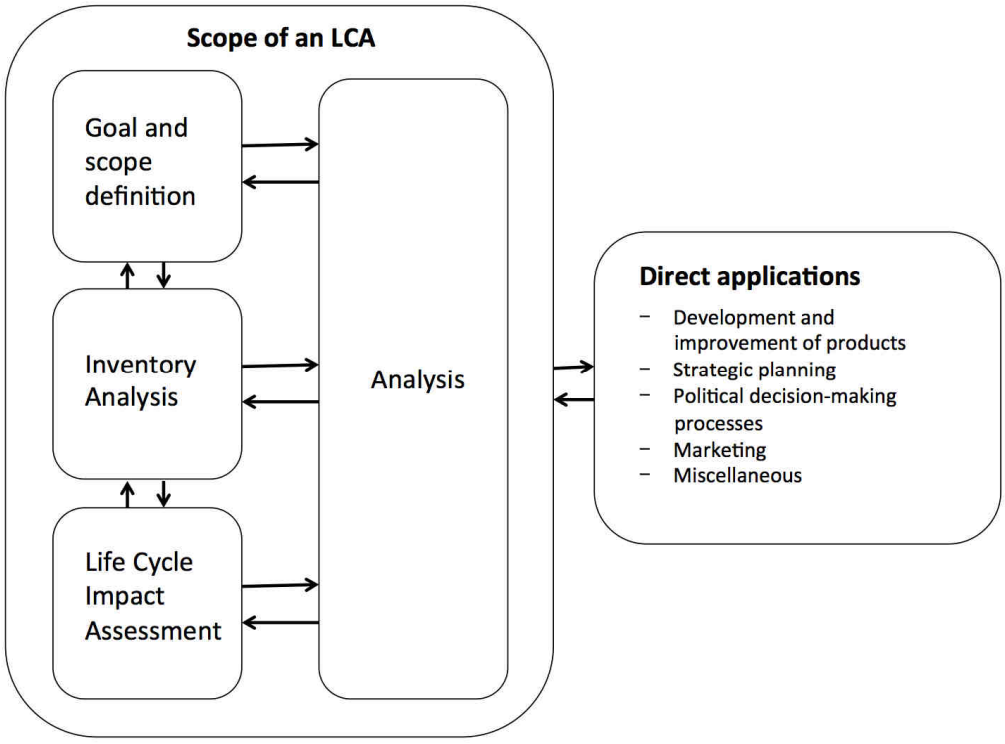

Figure 1: Scope of an LCA according to EN ISO 14040:2006

An LCA can help:

- in identifying opportunities to improve the environmental performance of products in various stages of their life cycle;
- to provide information for decision-makers in industry, government or non-governmental organizations
- in selecting relevant indicators of environmental performance, including the associated, measurement methods,
- with marketing (eg. when implementing an environmental label, making an environmental statement or creating an environmental declaration for a product).

Characterisation factors according to ÖN EN 15804

Indicatores, which are essential for a Life Cycle Assessment and the corresponding impact assessment, are described below, cf. [4].

Global Warming Potential (GWP), [kg CO_2-equivalent]
The global warming potential describes the contribution of a certain amount of greenhouse gas to the greenhouse effect. Carbon dioxide (CO_2) is used as a reference gas for an assessment of the GWP. Greenhouse gases also include methane (CH_4) and nitrious oxide (N_2O). The global warming potential is an essential feature for the environmental assessment of concrete. The main

part of the GWP of the concrete is caused by its content of portland cement clinker.

Ozone Depletion Potential (ODP), [kg R11- equivalent]
This indicator discribes that amount of ozone, which can be completely reduced by a given amount of a chemical product. Trichlorofluoromethane is used as a reference substance for the ODP.

Acidification Potential (AP), [kg SO_2- equivalent]
The adification potential describes the influence of certain substances on the pH-value of air, water and soil. Here SO_2 is used as a reference substance.

Eutrophication Potential (EP), [kg PO_4- equivalent]
The eutrophication potential shows the risk of an possible eutrophication of an ecosystem as a result of emissions from product manufacturing and the product itself. This indicator is estimated using an equivalent amount of phosphate PO_4.

Photo Optical Ozone Depletion Potential (POCP), [kg C_2H_4- equivalent]
The accumulation of ground-level ozone is based on a reaction of certain trace gases in cojunction with UV radiation. As an equivalent value ethene (C_2H_4) is used.

Primary Energy (PE), [J or MJ]
Primary energy is that quantity of energy which is required to produce a given amount of a product. The dimension unit is Joule per kg or m^3. A determination between renewable and non-renewable energy has to be done.

Cumulative Energy Demand (CED), [MJ/kg]
This energy expenditure represents the sum of the primary energy input for the production, use and disposal of the product. It is used for comparative analysis of primary energy demand of technical processes and product systems [13].

3. Results

Table 1 shows the GWP-100 for different kinds of cement based on literature and databases. Out of this it is easy to see that there is a difference between CEM I and CEM II caused by the different amount of cement clinker. For the “average cement” no specification about its amount of cement clinker is given. This table also shows the need for a more detailed analysis of cement GWP due to the big variation of the results.

Table 1: GWP-100 values of different types of cement

CEM I 42,5		CEM II 42,5	CEM II /A - L 32,5	CEM II /A-S 42,5
Müller (GER) [4]	*SimaPro (CH) [7]*	*SimaPro (CH) [7]*	*SimaPro (CH) [7]*	*SimaPro (CH) [7]*
956,0	902,6	820,7	718,0	704,0

"Average cement"		
Krispel (AT) [8]	*ökobau.dat (GER) [5]*	*Ecosoft (AT) [9]*
796,0	738,0	673,0

GWP 100 [kg CO_2-eq./m^3]

The GWP-100 values for cement are a basis for the results for concrete as described below.

Germany:
In Germany there are results for specific types of concrete and also for average concrete available. The german database “ökobau.dat” [5] provides datasets only for concrete with average cement. The example for “ökobau.dat” in Figure 3 shows the GWP-100 value for a transport concrete C25/30 with a mass of 2365kg/m^3 (Reference Year 2011). There is no information about the amount of cement available. The LCA was calculated “cradle to gate”, the deliverable product at gate frames the system boundary. The source for “ökobau.dat” is the software “GaBi 4” [10]

database 2006. The GWP-100 value is 240 kg CO_2 equ./m^3 .
More specific values are listed by Proske [2,11]. As a reference concrete a “DIN C25/30 XC4/XF1” is listed. The amount of cement (CEM II/A-LL 42,5R) is 275kg, which corresponds to the minimum cement content required in DIN standard, the water-binder ratio is 0,63. The estimated GWP value is 220 kg CO_2 equ./m^3.

Austria:
An example for an average Austrian concrete is the result by “Ecosoft v5” [9]. The chosen “Füllbeton” (id 570,kat.ID 1) is listed with a density of 2300 kg/m^3. The source for this dataset is “IBO” [12]. The GWP-100 value is 218 kg CO_2 equ./m^3 .
According to ÖN B 4710-1:2007 [15] own calculations were made. In “simapro” [7], which refers to the datasets of „ecoinvent“ [14], the basis was the suisse dataset for a transport concrete B35/25, which is comparable to Eurocode 2 - C25/30. According to the exposition classes B1 to B12, which refer to the required performance against environmental attacs (from low to high exposure)- in ÖN B 4710 the amount of cement was varied from 280 kg to 375 kg. Furthermore the water-binder ratio and the gravel changed with each calculation. An other adaptation was the use of the austrian electricity mix. The calculations were made for CEM I 42,5 and CEM II 42,5 seperately with the appropriate values shown in Table 1.
As shown in Figure 2 the result for GWP-100 is in a range of 268 to 353 kg CO_2 equ./m^3 for CEM I and between 245 and 322 kg CO_2 equ./m^3 for CEM II. These values refer to the minimum required amount of cement for a specific exposition class. In praxis often higher amounts are used, in Austria 400 kg/m^3 (376 kg CO_2 equ./m^3 for CEM I and 343 kg CO_2 equ./m^3 for CEM II) are plausibel as a practical value.
Switzerland:
In Switzerland the results bases on “simapro” and accordingly “ecoinvent”. The calculation, done with the original dataset as described above (with 300 kg CEM I 42,5), leads to a GWB-100 value of 285,6 kg CO_2 equ./m^3 .

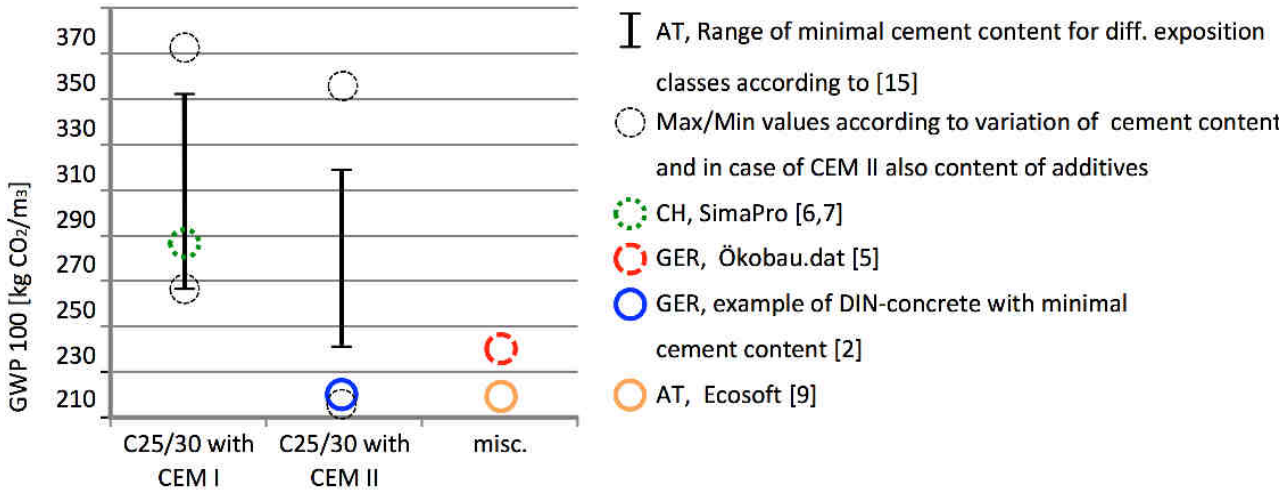

Figure 2: GWP-100 values of different types of concrete

Environmental performance of an average Austian concrete
Based on an ecoinvent dataset a calculation for all characterization factors for an idealized average Austrian concrete was made (Figure 2). The amount of cement was defined with 300kg/m^3 of CEM II/A 42,5 and the Austrian electricity mix was considered. There were four sectors differentiated, Portland cement, gravel, production & transport and miscellaneous. Other constituent parts of concrete were merged due to their low influence on the calculation.
The figure shows relatively the high influence of cement clinker on the environmental performance of concrete.

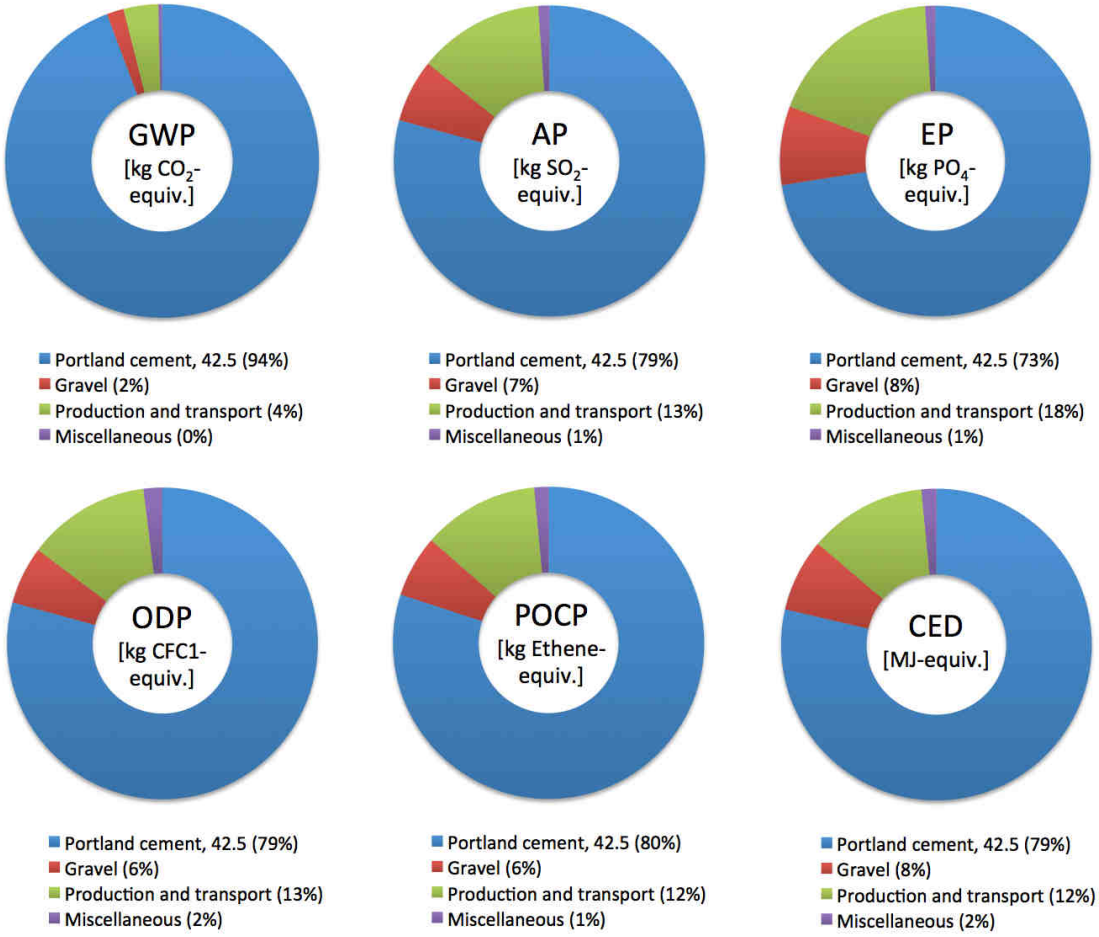

Figure 3: Environmental performance of an average Austrian concrete

4. Discussion and Conclusion

The result shows a wide range of the GWP depending on the amount of cement and country-specific conditions. Another point is the share of cement on the GWP of concrete, which is up to 94%. In actual literature data for different concrete mixtures are given without taking into account the same functional requirements (class of strength resistance, cement ratio, exposition class etc.). Due to this reasons, it is indispensable to take into account national requirements, specifications and standards as a basis for a LCA of concrete and to differentiate between concrete types according to their performance requirements.
In an on-going research project carried out at the Institute concrete for precast application is optimized technologically with the aim to reduce its environmental impact while ensuring identical technical performance.

Summary

The Finnish building stock is young in a European perspective, and was rapidly built. Suburbs consisting of mainly concrete apartment buildings were built with a foreseen life-span of approximately 40 years. Now we are encountering the need for comprehensive refurbishments on large scale.

The need and demand exists, but the refurbishment of residential buildings in Finland faces particular legal and economic challenges, due to the ownership of homes, challenging decision making processes of housing companies, building permit processes allowing for local interpretations and new regulations for energy efficiency improvements, a lack of financial incentives and support.

Case Virkakatu 8, the second energy retrofit in Finland realized with the TES Energy Facade method, revealed economic incentives and advantages but also shortcomings in current building regulations and decision making processes with regard to deep retrofits. The case shows the interests of an institutional owner of a building complex in comparison to the interests of owner-occupied housing cooperatives.

The case study additionally showed that there is a lack of know-how and competition with regard to deep retrofits of existing buildings. The demand exists but there is a lack of supply. The question remains: How to achieve a competitive edge, and foster cost efficient deep retrofits in cold climates?

Keywords: refurbishment, housing company, energy efficiency regulations, TES Energy Façade, E2ReBuild

1. Introduction

The Finnish building stock is young in a European perspective, and was rapidly built during the reconstruction era and as to satisfy the needs of rapid urbanization. Suburbs consisting of mainly concrete apartment buildings were built with a foreseen life-span of approximately 40 years. Now we are encountering the need for comprehensive refurbishments: the total Finnish renovation debt has in 2013 been estimated to between 30 and 50 milliard euros [1].

Regardless of the identified need, the refurbishment of residential buildings in Finland faces particular legal and economic challenges, due to the ownership of homes, challenging decision making processes of housing companies, building permit processes allowing for local interpretations and new regulations for energy efficiency improvements of existing buildings, lack of financial support.

2. The Finnish context

2.1 Finnish residential building stock

The Finnish building stock derives mainly from the Post War Era, with 75% built after 1960 [2]. An increasing urbanization lead to a rapid extension of urban settlements in the late 1960´s and early 1970´s. Today, every fifth Finnish apartment is in a suburban, multi-storey residential building from this time. These buildings are typically 3 or 4 storeys high concrete apartment buildings with a load bearing frame of concrete and facades in concrete sandwich elements. Many of them represent early prefabrication and element technology using standardized, precast elements and joint details, the so called “BES-system”, developed in Finland in the late 1960´s. The buildings are in the need of major renovations including improved indoor air quality, renewed facades and building services, improved energy efficiency, and in the need of elevators for improved accessibility. [3]

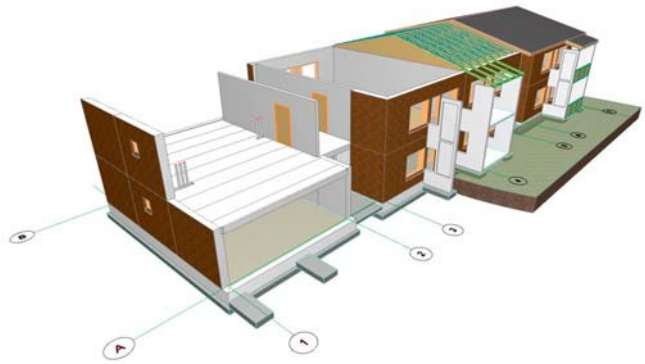

Fig. 1: The BES system as exemplified by case Virkakatu 8, Oulu.

2.2 Ownership of dwellings in Finland

The majority of Finnish homes are owner-occupied, single family homes. In 2011 44% of all homes were situated in multi-storey houses, 29% of the Finnish homes were rentals, and most rented dwellings were situated in multi-residential buildings. [4]

The majority of multi-residential buildings in Finland are owned and controlled as Limited Liability Housing Companies, occupied by housing company shareholders. Shares confer the right of possession to apartments, and all shares carry equal rights in the company. The housing company is responsible for utilities and the building facade. Shareholders pay for common expenses used for acquisition, construction, use, maintenance, renovation, expansion and modernization.

Modernization is decided by majority vote if the obligation to pay does not reach an unreasonable level and buildings are modernized to current standard requirements, and may not violate the equal treatment of the shareholders. The expenses to undertake modernization that exceeds current standard level shall be collected from shareholders that consent. [5]

Conflicts in interests within the decision process are resolved in favor of the majority, and investments typically reflect conservative consensus. A shareholder majority may prevent renovations with long payback periods, or a minority may be obliged to pay for renovations not in their personal interest. Shareholder demographics are decisive. Owners faced with the prospect of a massive energy retrofit, may opt to neglect or postpone the renovation, in fear of high investment costs related to energy efficiency targets.

Institutional owners of rental residential buildings are more likely to make proactive long term investments in high quality refurbishments, while housing companies with resident shareholders postpone investment decisions and accumulate maintenance burdens until major repairs are unavoidable.

2.3 National building regulations

In Finland the development of the national building code towards targets set by the recast Directive 2010/31/EU on the energy performance of buildings [6] and the Commission Delegated Regulation (EU) no 244/2012 supplementing the Directive [7], started in 2010 by establishing a group of experts to develop a roadmap, the ERA17 Energy-Smart Built Environment 2017 action plan. The target is to position Finland as the leader in energy-efficient building [8].One outcome is a roadmap for the development of the National Building Code of Finland, including the establishment of regulations for existing buildings undergoing renovations and alteration works.

As a result the first Finnish statutory regulation regarding renovations and alteration works on existing buildings was published on 27.02.2013 [9]. It is applied to public authority buildings starting 01.06.2013 and all buildings from 01.09.2013 onwards [10]. The regulation is applicable to buildings in which is done renovation or alteration works requiring a building permit. [11] The emphasis is on measures to improve the energy efficiency of existing buildings with an overarching target impact by 2050 of 25% estimated decrease of total energy consumption, and 45% decrease of carbon dioxide emissions caused by existing buildings. [12]

The regulation does not imply any comprehensive interpretation or definition of renovation and alteration works. It suggests alternative solutions for improving and proving an increased energy efficiency of the building. According to existing practice, regulations for new buildings are applied when a building is renovated to such an extent that it is comparable to new building. What differentiates a refurbishment comparable to new building from a deep retrofit including the target of improved energy efficiency? Practice will show, through case by case interpretation, whether the new regulation will be applied to cases of deep retrofit or if they will be compared to new building.

2.4 Economic prerequisites

Estimated costs by 2050 for implementing the new regulations are, based on a typical yearly refurbishment rate of 2.5% of buildings built before 1980, between 10 and 25 milliard euros. Savings as a result of decreased energy consumption are estimated to 0.5 – 2.4 milliard euros yearly. [13]

However, according to the Finnish statutory regulation regarding renovations and alteration works, the obligation for building owners to improve energy efficiency is bound to such measures that are subject to building permit. [14] Owners faced with the prospect of a massive energy retrofit, may opt to neglect or postpone the renovation, in fear of high investment costs related to energy efficiency targets and regulatory requirements. The possibility to influence investment decisions and decisions related to energy efficiency is additionally limited by the Finnish building permit process, where designs are brought to building inspectors at a late state when all the main decisions have already been made.

Solutions and strategies proposed to achieve sustainable high quality refurbishments require a detailed analysis in order to meet goals for economic efficiency, anticipate risks, and satisfy shareholders' perceived values. Good communication to include residents' values for social sustainability, careful project planning and a flexible legal framework are essential to the broader implementation of ecological high quality refurbishments. An effective adoption and implementation of the new regulation would require economic incentives, financial support for housing companies.

3. Deep retrofit, case Virkakatu 8

3.1 Framework for the retrofit

Case Virkakatu 8 in Oulu, Finland is an example of a deep retrofit of an institutionally owned rental apartment housing block. It is a small student apartment building with 8 flats, part of a housing cooperative of five buildings and communal facilities, owned by PSOAS Student Housing Foundation of Northern Finland [15]. The building was completed in 1985 and has now been refurbished completely including the upgrading and makeover of student flats according to today´s standards. Construction works on site started in August 2012 and were finished by the end of February 2013. The

building is one of seven demonstrations throughout Europe within the framework of project E2ReBuild *Industrialised energy efficient retrofitting of resident buildings in cold climates* [16].

Aims for the retrofit included a reduction of the building´s energy use for heating, as occupied, to 30 KWh/m^2/y through a facade retrofit using prefabricated timber facade elements and standardized retrofit measures with high replication potential, including new ventilation with high efficiency rotating heat recovery ventilation units, LED lightning, energy efficient appliances and building automation that tracks energy performance, indoor air quality, and monitors the building physics. The heating is based on an existing district heating system, but with retrofit flow control (valve actuator) based on real time supply and return temperature monitoring and outdoor temperatures controlled by new building automation to optimise the heating supply. [17] The Oulu demonstration is the second retrofit in Finland realized with the TES Energy Facade - method [18].

Fig. 2 and 3: Case Virkakatu 8, Oulu: during and after retrofit.

3.2 Relation to building regulations

The building works in Oulu took place before the publication of the new Finnish statutory regulation on the improvement of energy efficiency of buildings during renovation and alteration works. Hence, in the Oulu project, decisions made by local building inspectors were steered by existing practice and based on existing regulations for new buildings. Regulations for new building were applied to the project due to the extent of the retrofit including a complete reskinning of the building envelope, a new floor slab, new building services and new interiors. The energy efficiency target was set to the Finnish VTT passive house recommendation [19] and went up to and above current new building regulations. The EnerPHit Certificate for Energy Retrofits with Passive house Components [20] is currently being considered.

The deep retrofit resulted i.e. in assumptions regarding the renewed useful life of the building, its fire safety classification, stretching of the regulations for sound insulation of party walls, the addition of sound insulation to floors.

The case revealed that to a large degree current Finnish building regulations do not anticipate the real risks of deep retrofits and requirements for new built are not directly applicable. Regulations for new buildings are focused on fire risks, concrete construction and safety. However, the case shows that when using i.e. TES elements, there is a need for inspection of repair tolerances, sealing for airtightness, differential structural movements, and quality control of timber structures.

3.3 Incentives for refurbishment

Drivers for the retrofit in case Virkakatu 8 included social values in the form of upgraded living spaces for students, economic values based on market positioning with desirable student housing, market segmentation through the change from shared flats to family apartments and the desire to pilot deep refurbishment with the energy efficiency target of passive house using the TES Energy Façade method, an industrialized retrofit method based on the use of timber construction. These drivers highlight the interests of an institutional owner.

The refurbishment was realized with PSOAS own funding and supported by EU Fp7 project funding. The EU funding was critical for research and development work, and follow-up monitoring of the project. However, the total refurbishment was expensive, with one third of the costs caused by energy retrofit and total construction costs comparable to new building at passive house level.

The project showed that contractors are interested in and prepared to take on extensive and deep retrofits. It also shows that ambitious energy efficiency targets for the retrofit of existing buildings in cold climates demand investments. Regarding the construction works, it became clear that there exists little supply and competition in the prefabrication of TES timber based façade elements.

4. Discussion, conclusions and acknowledgements

4.1 Discussion and conclusions

In the Finnish context, there is a growing need for refurbishment and deep retrofits. Until recently, the National Building Code of Finland has only recognized new building. However, starting June 2013 the first regulations with regard to the upgrading of existing buildings came into force.

Case Virkakatu 8 revealed shortcomings in new building regulations when it comes to the implementation of them to deep retrofits, especially with regard to renovation related risk scenarios, air tightness and detail solutions. The new statutory regulation with regard to renovation and alteration works of existing buildings does to some extent include additional requirements on the building envelope and technical systems. According to § 10: in connection to measures improving the energy efficiency of the building envelope a sufficient airtightness of the building envelope, window and door connections to surrounding structures must be ensured, as to protect thermal insulation layers from the performance-degrading effect of air flows. When designing and realizing retrofits of the building envelope and technical systems measures should be taken as to ensure correct levels of thermal and sound insulation, hygrothermal performance and fire protection. [21] However, practice will show what these measures should be and how they should be proven. Due to the nature of deep rerurbishments, they cannot be regulated as clearly and unambiguously as for new building. However, problems of interpretation which repeat and which are replicable could be considered for specific instructions for retrofits.

The Finnish building stock forms slightly over half of our national capital stock and 60% of this is based on the value of our residential building stock [22]. It should be a national interest to care for this capital and ensure the future condition of our buildings. Yet currently there exists no financial incentive or support to refurbish buildings, and hence the renewal process and decrease of energy consumption of the built environment are prone to progress slowly and are, due to the Finnish ownership structure of residential buildings, dependent of individual investment interests. Such interests seem to occur more likely among institutional owners.

The case study also revealed that there is a lack of know-how and competition with regard to deep retrofits of existing buildings. The demand exists but there is a lack of supply. The question remains: How to achieve a competitive edge, and foster cost efficient retrofits in cold climates?

4.2 Acknowledgements

The paper is based on research and development support for the passive house demonstration in Oulu, Finland, realized within the EU Fp7 funded project E2ReBuild *Industrialised energy efficient retrofitting of resident buildings in cold climates*, coordinated by Christina Claeason-Jonsson, NCC AB. The project started in January 2011 and ends in June 2014. Partners from Finland include the Aalto University, NCC Rakennus Oy and PSOAS.

The research leading to these results has received funding from the European Union's Seventh Framework Programme (FP7/2007-2013) under grant agreement n° 260058.

Martin Behnisch, IOER Dresden, Germany, M.Behnisch@ioer.de

Short Summary

Spatial data on land use, buildings and their development is of importance for sustainable planning approaches on all planning levels and the development of smart concepts. The monitoring system “Monitor of settlement and open space development” (www.ioer-monitor.de) of the Leibniz Institute of Ecological Urban and Regional Development (IOER) describes the state and the development of land use for the entire Federal Republic of Germany. On its basis different indicators with focus on settlement, open space, nature reserves, population and traffic can be derived automatically. In addition, official building footprint data are integrated. It has now become possible to quantify the amount of buildings in Germany on a very detailed level for the first time. The calculated indicators are stored in a database and can be visualised in thematic maps via a WebGIS-based internet platform. In addition to administrative spatial units (federal state, region, district, municipality), indicators are also visualised in regular raster maps with different cell sizes. This allows spatial and temporal comparisons based on constant reference areas. In addition, we give an insight into tools and developments which are useful for data acquisition. Firstly, the technology of the tool SEMENTA® is presented, which is based on an automated analysis of analogue topographic maps at scale 1: 25.000 (TK25 and DTK25(-V)) and which has recently been further developed. By means of digital image analysis building footprints are extracted, vectorised and classified according to a pre-defined building typology. On the basis of the building footprints, various indicators (e.g. building density, floor space ratio, building volume, no. of housing units, households and inhabitants) are derived to describe the settlement structure on a very detailed level. The development of the module SEMENTA®-CHANGE allows to measure settlement dynamics on building level. Another tool for automatic georeferencing of scanned topographic maps supports the data preparation and makes it more efficient.

Keywords: Monitoring Technology, Spatial Analysis, Land Use Development, Building Stock Analysis, Building Footprints, Geographic Information System (GIS)

1. Introduction

Creating smart built environments entails making the best of new technologies available in order to optimise municipal services (for further Information on Smart Cities see Deakin et al., [1]. The optimisation of built environment resources provides welfare and sustainable development. Spatial data on land use, buildings and their development is of importance for sustainable planning approaches on all planning levels and the development of smart concepts. Despite their significance for both researchers and planners, area-wide statistical data with high resolution is sparse. In

Germany official statistical data are currently only available on municipality or on districts level. For research and planning issues spatial data with higher resolution are therefore necessarily needed. Information and communication technology has made a large contribution in supporting planning and management of the built environment. Against this background the article gives insights into the research unit “Monitoring of settlement and open space development” of the Leibniz Institute of Ecological Urban and Regional Development (IOER).

2. Monitor of settlement and open space development

2.1 WebGIS-based internet platform

Within the context of achieving long term sustainability the IOER established a monitoring system focusing on the computation and visualisation of land use indicators for Germany [2]. The concept of the “Monitor for Settlement and Open Space Development” (IOER Monitor) sets up on the nation-wide Digital Basic Landscape Model (ATKIS® Basic DLM) which is available for all federal states in homogeneous quality [3]. It is a product of the Authoritative Topographic-Cartographic Information System (ATKIS) and serves as the basis for the authoritative topographical map production at scales of 1:10 000 to 1:25 000.

Due to the following facts the Basic DLM is a suitable data source for land use analysis:

- The data is defined to be a topographical description of the current state of land use.
- The data is based on standardisations of detailed object catalogues.
- The mapping authorities of the federal states ensure regular updating of the data regardless to economical conditions of certain areas. Thus, the data quality is homogeneous throughout all regions.
- The object based data model enables an automatic analyses by means of a script-based geo-processing.
- The data enables to derive land use indicators with high spatial resolution ranging from 100 m raster data to whole-country statistics.

To gain a proper land use calculation the Basic DLM data has to be examined according to a defined land-use typology (Fig. 1). To ensure unambiguity it was necessary to define rules to assign certain topographical objects to specific land-use types. Thus, it is possible to summing up the categories to the whole reference area.

The results of the nation-wide analyses are presented to the public free of charge via internet on the online platform of the IOER Monitor accessible at www.ioer-monitor.de. The user is able to browse through a categorised list of indicators which are available for four two-year time periods beginning in 2006 and (for the present) ending in 2012. Thus, for each administrative unit including municipalities (ca. 12 000), districts (ca. 400), federal states (16), and the whole country as well as for regular rasters with a cell size ranging from 100 m to 10 km a number of more than 50 indicators can be visualised as maps. The maps in Fig. 2 show examples for raster maps of 5 km cell size showing typical land-use patterns for Germany.

Furthermore, a tabulation tool enables the exploration of histograms and the comparison of values of several time steps. Both map and table views can be exported and downloaded for an offline usage and further statistical analysis.

2.2 Land Use Indicators

Based on the established official indicator set used for land-use reports we defined a hierarchal land use typology to provide a detailed landscape structure description. In few cases the IOER Monitor land use scheme typology differs in the assignment of land use categories to upper classes from the approach used by the authoritative statistical reports. Thus, mining areas are considered to belong to open space rather than being settlement sites (Fig. 1).

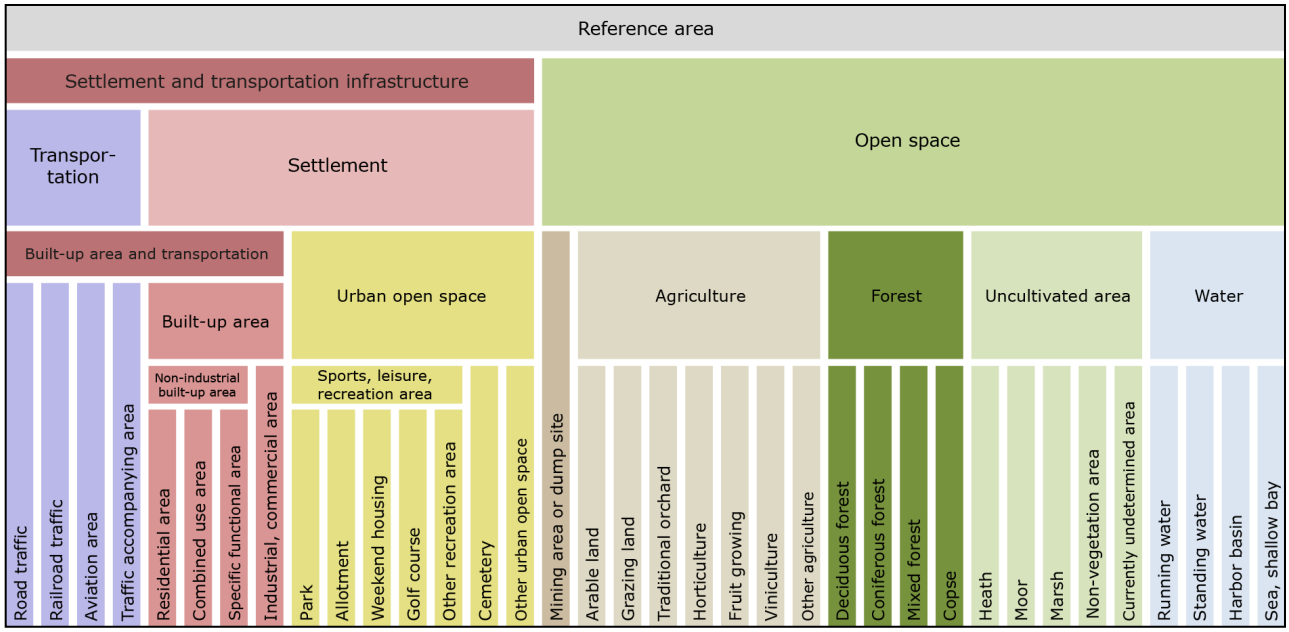

Figure 1: Land-use typology of the IOER Monitor. (Source: own editing)

Land use is generally divided into the three main categories of settlements, transportation, and open space. The transportation category comprises all kinds of infrastructure for individual, public and goods transport. This includes roads, railway lines, airports and all functionally accompanying areas. Due to the fact that roads and railways are provided as linear objects by the Basic DLM it is necessary to buffer these features to gain their real dimension. This is realised by extensive geo-processing of the data since the buffered features cause overlaps with adjacent polygons which are to be dissolved. The linear features are additionally used to calculate transportation network indicators which do not actually fit into the land-use typology but give important information on the infrastructural development level. Shipping transportation is not being considered, since ports are defined as economical sites, whereas harbour basins and water surfaces used for shipping routes are assigned to the stretches of waters category. Transportation routes like road and railway networks do not fit into the land-use typology. Nevertheless, network lengths are provided alongside the transportation areas indicators.

Settlement areas include built-up residential, mixed use, and industrial areas as well as urban open space facilities such as parks, allotments, recreational areas, and cemeteries. Thus, an appropriate differentiation between several types of settlement structures is made possible which was called by the ministerial conference on spatial planning in 2010 [4].

Open space category is, generally spoken, the sum of all land uses which are not assigned to settlement or transportation. Yet this does not necessarily mean that these areas are anthropogenically unaffected, since they include mininig sites, agricultural areas, forests as well as uncultivated sites like heath, bog, and all kinds of natural and artificial water surfaces.

Further indicators which do not fit into the hierarchal typology focus on qualitative aspects of land use such as effective mesh sizes [5] and hemeroby index values [6]. The latter is calculated by use of a more extensive set of attributes available in the Basic DLM [7]. Additionally, indicators referred to the population of administrative units relating the amount of certain land-use classes to the number of inhabitants are provided. Hence, in connection with area related indicators the effectivity of land use can be explored by the users.

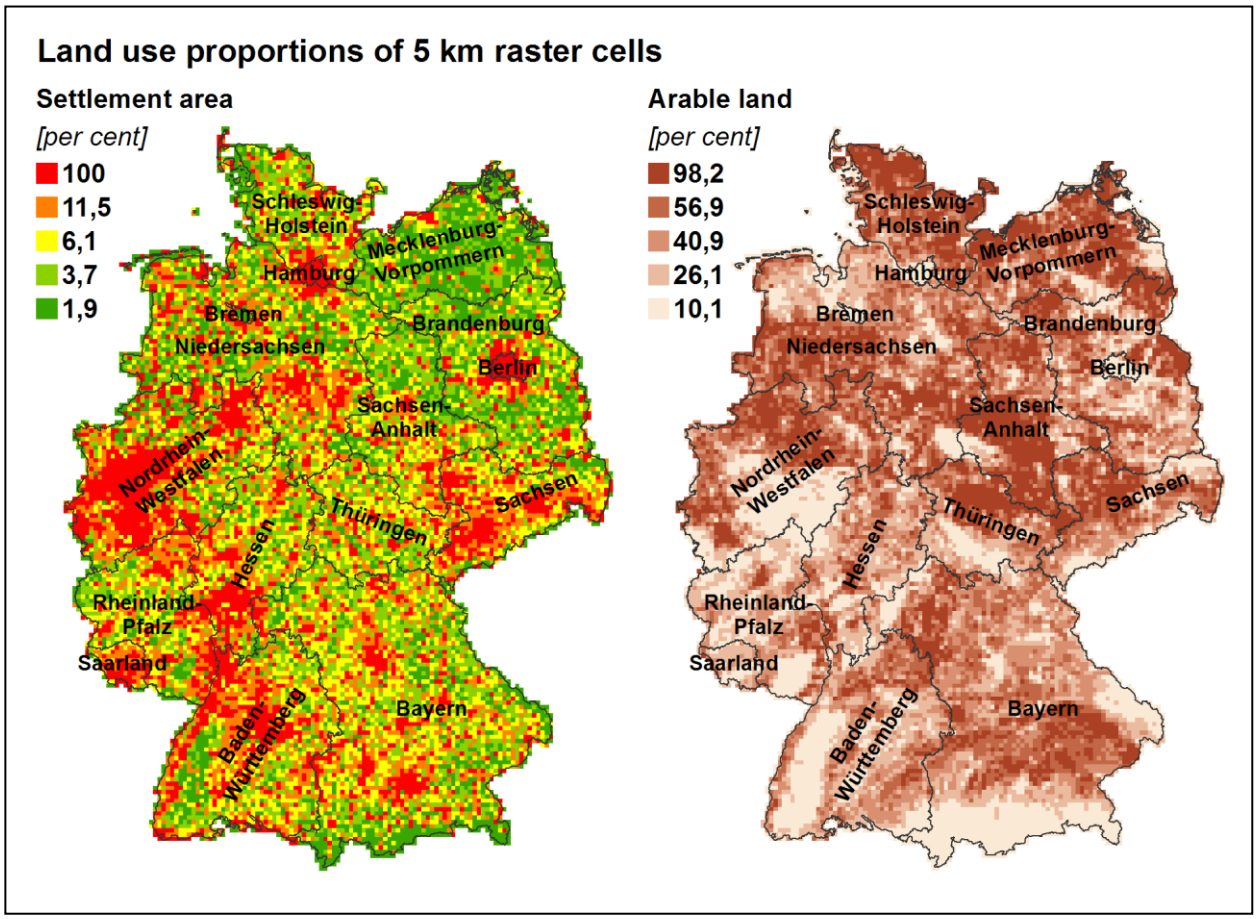

Fig. 2: Land use indicators calculated for 5 km raster cells showing typical spatial patterns for settlement and agriculture in Germany (Source: Own editing).

2.3 Building Indicators

In Germany several institutions record different kind of data about buildings. Unfortunately there are just a few basic statistics about the current number of buildings. Collection of data is very complicated, often expensive and the handling of missing data is one of the biggest handicaps. Recently the combination of new digital geodata sets is suitable to quantify the whole German building stock and later on to study its spatial distribution and patterns. The building stock is covered by the data set of the official building polygons of Germany (GeoBasis-DE, 2010/BKG 2011). This data set consists of a two-dimensional geometry (building footprints), which are introduced from the cadastral data. Unfortunately the only attribute per building is the official municipal code AGS (in German: Amtlicher Gemeindeschlüssel) which is to identify German administrative units by an 8-digits number code. Nevertheless the official building polygons allow easy combinations with other (statistical) data sets as well as visualisation and analysis on a finer level.

To improve the quality of the data set and the information content of the buildings some data enhancement was needed. In the case of one federal state of Saxony, the building footprint data was not complete. Hence, missing buildings were substituted with the buildings from the ATKIS data set. In another case, adjacent buildings (e.g. terraced houses, building blocks) are not consistently modelled. These buildings can be either modelled as multiple building footprints or these are modelled as one huge polygon representing two or more buildings. In the latter case, the polygons need to be divided into single buildings by making use of the official postal address coordinates data set (in German: Georeferenzierte Adressdaten Bund). In addition, all buildings were allocated

to a specific land use class. Such classification is based on the official topographic and cartographic information system, ATKIS Basic DLM. Depending on the building location and the ATKIS land-use class, the buildings were classified as follows: industrial building, building with special functions, residential, and other buildings. In addition, some other attributes were given (e.g. label of the federal state, label of the municipality, building's centre point, etc.). The applied procedure of the processing of the German building stock is illustrated in Figure 3.

The resulting data base contains nearly 50 million objects. Figure 4 shows the German building stock in a grid representation. The grid is specified by the directive INSPIRE (infrastructure for spatial information in Europe) which regulates the establishment of EU-wide data infrastructure and spatial data harmonisation with the background of environmental policies that should be implemented by 2019. The raster values represent the number of buildings having their geometric centre points (centroids) inside the grid cells. A majority of the buildings are located in Nordrhein-Westfalen. The conurbations in Germany are easily seen. For example, Berlin, Hamburg, the Rhein-Ruhr, and Rhein-Main regions are characterised by a large amount of buildings. As indicators on buildings are calculated for Germany as a whole, they are also publicly available via the IOER Monitor described above.

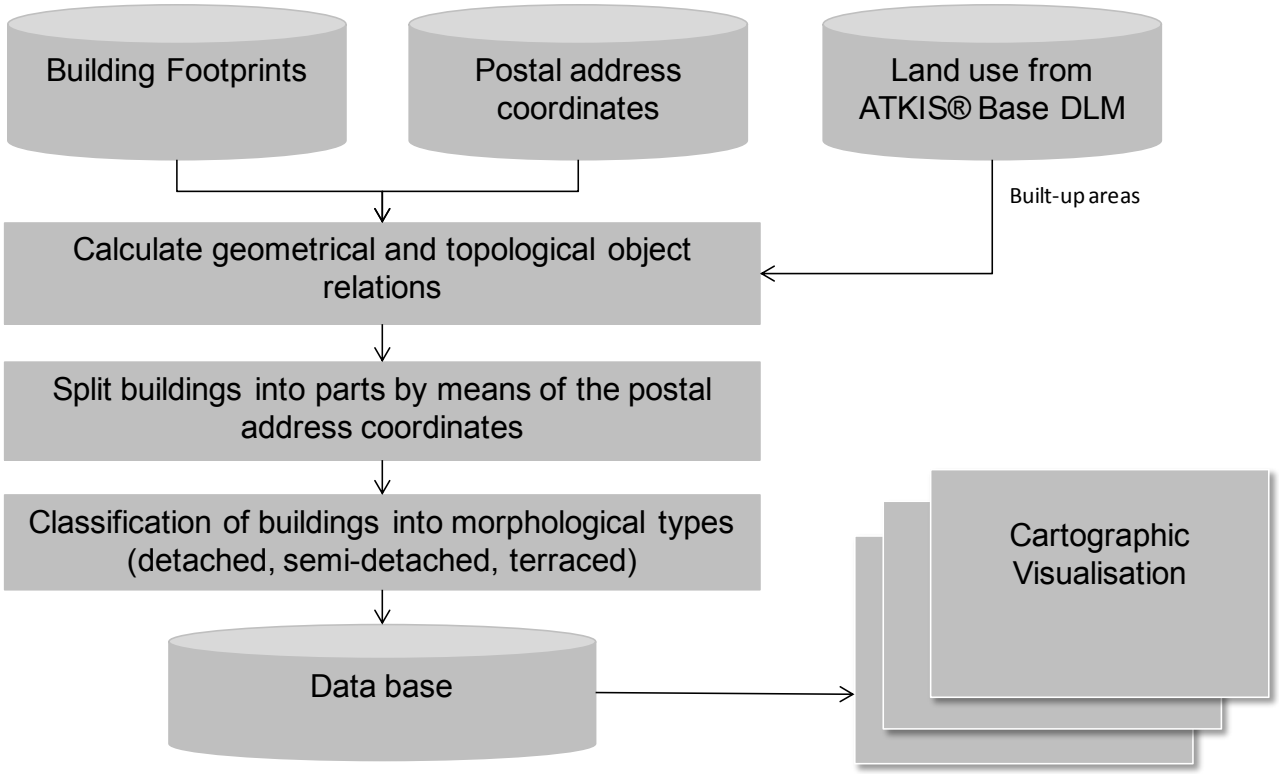

Fig. 3: Procedure of the building data processing (see also [9]).

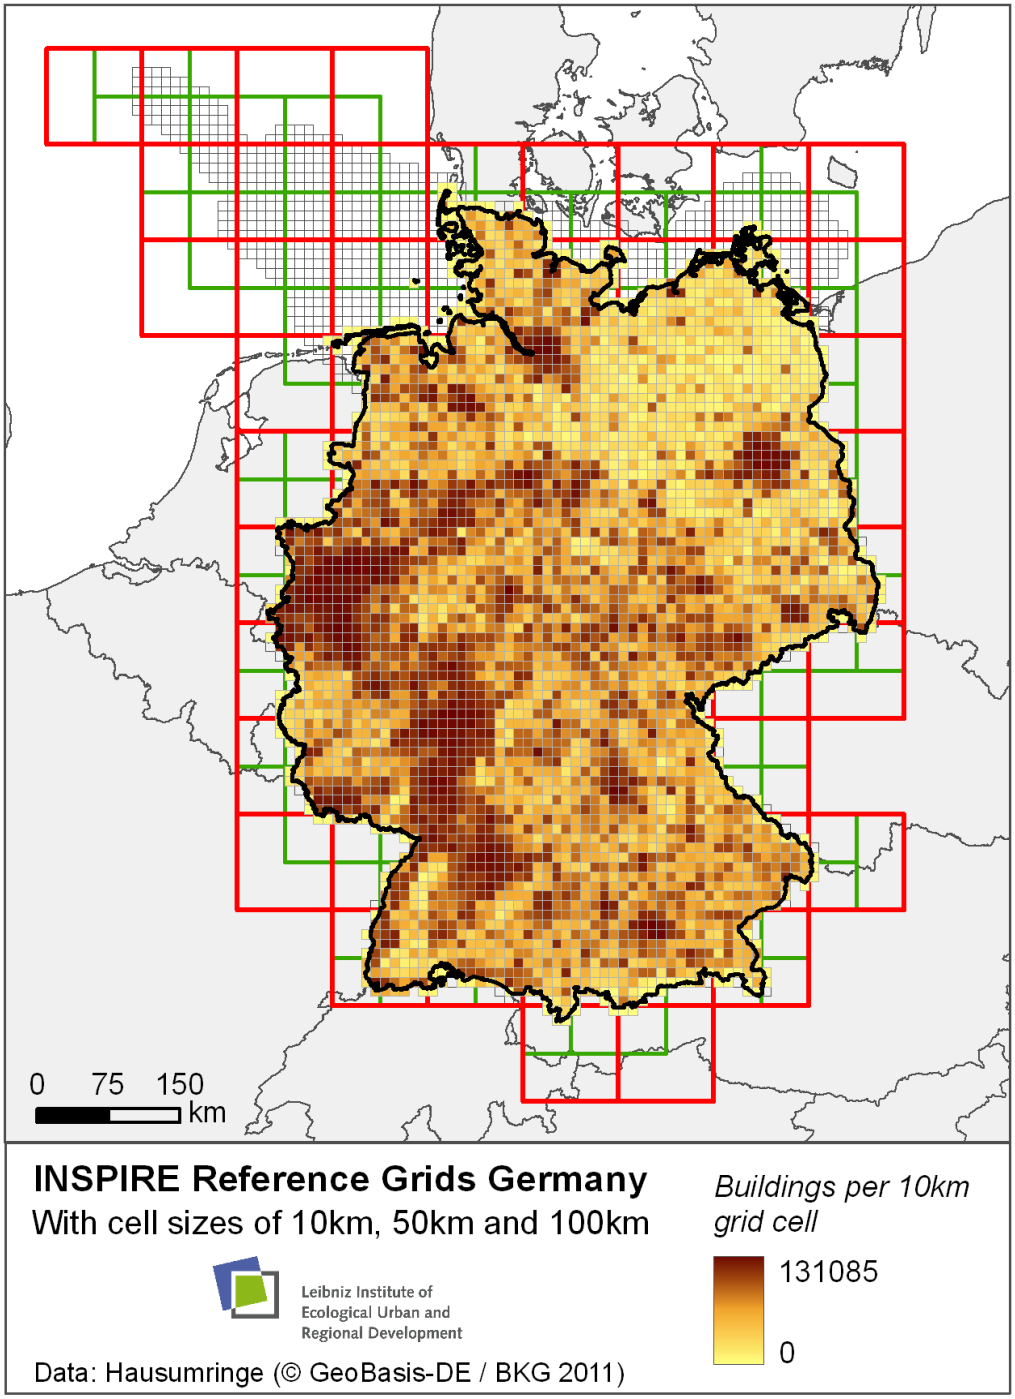

Fig. 4: Building Density per 10 km grid cell (Source: [10])

3. Tools for the small-scale description of settlement structures

Spatial analysis techniques and Geographic Information Systems (GIS) help to describe the settlement structure. In this section we give an overview about some developments at the Leibniz Institute of Ecological Urban and Regional Development (IOER), especially a tool for the automatic derivation of settlement indicators, current developments to measure dynamics and a tool for automatic map georeferencing.

3.1 Settlement Structure Analysis with SEMENTA®

Small-scale information on functional, morphological and socio-economic structure is an important component to solve research and planning issues in urban and rural areas. Buildings are of key importance here, since they determine the morphological structure of a settlement and there usage defines functional and socio-economic patterns.

With the help of spatial analysis and GIS it is possible to describe and analyse the settlement structure. One example is the SettlementAnalyzer (SEMENTA®), which is a tool for the automatic extraction and classification of building footprints from scanned paper maps or digital topographical data and to derive various indicators to describe the physical structure in detail. By combining the building stock model with official statistical data it becomes possible to estimate distribution patterns of dwellings and the residents. In the following, the basic processes are described briefly. For a detailed description of the method see [11] and [12].

The method sets up on topographic maps at scale 1:25.000 (e.g. German TK25, DTK25-V or DTK25) and the land-use information of the Basic DLM [3]. Topographic maps are usually available as a raster scan with an image resolution of 508 dpi (1.25 by 1.25 m in nature). The black layer of the map shows the buildings almost completely and only slightly generalised. One challenge is to extract the buildings from the binary raster image, in which they are merged with other elements such as traffic, vegetation symbols and lettering elements. By means of image processing techniques like morphological operations (opening) thin elements (traffic and block boundary lines) can be eliminated at first. In a second step the buildings are separated from lettering and symbols using various object features like compactness, convexity, anisometry, and orientation.

After building extraction, the building footprints are classified according to a given building typology. The typology differentiates 7 residential and 2 non-residential building types. For the classification a knowledge-based rule set has been developed, which sets up on derived building features (e.g. building area, circumference, compactness, distance from neighboring buildings, distance from block boundary). The rules consist of comprising conditions (premises) and actions (conclusions) and the buildings are classified by means of ‘if-then’ rules in combination with defined threshold values.

The classified building footprints are the basis for the derivation of various indicators to describe the settlement structure. With the help of assumptions (e.g. typical number of floors, dwellings and residents) further socio-economic indicators can be estimated. The following indicators can be calculated per spatial unit (regular raster cell or urban block unit):

- Urban structure type (7 residential and 2 non-residential types)
- Number of buildings and building density
- Sum of building footprint area and building coverage
- Average number of floors (weighted average of the number of floors of all buildings in a block)
- Floor area and floor area ratio (sum of all building footprint area multiplied by the average number of floors)
- Building volume and density of building volumes
- Number of dwellings and dwelling density
- Number of residents and density of population.

Figure 5 shows the automatically derived foor area ratio map for a section of Dresden, Germany.

Fig. 5: Map of the foor area ratio for a section of Dresden (Source: [12])

All the procedures for pre-processing, image processing for building extraction, feature extraction, classification and spatial analysis to derive settlement structure indicators have been implemented in the Esri ArcGis Desktop environment, which is widely used by planning and regional administrations. SEMENTA® was initially designed for users who do not have access to spatial building databases. If users have access to building footprints from digital cadastral vector maps, the building extraction procedure can be skipped.

Small-scale information on the settlement structure can be useful in a wide spectrum of applications. It mainly improves the information base used in planning and decision-making processes.

3.2 Spatio-temporal modelling of dynamics with SEMENTA®-CHANGE

Capturing the land use dynamics by visual interpretation based on historical maps and aerial photography is a common but time-consuming process. Therefore, since many years the development of methods for automatic urban change detection by remote sensing techniques is a research focus for the scientific community exploring spatio-temporal settlement dynamics. Previous approaches focus on the detection of land use changes and are only suitable for applications addressing large and medium scales. Measuring the dynamics on building level is a relatively new field. Despite the availability of very high-resolution (VHR), hyperspectral remote sensing imagery and LiDAR techniques, the acquisition of spatio-temporal information from multisource and heterogeneous data still remains a challenging task.

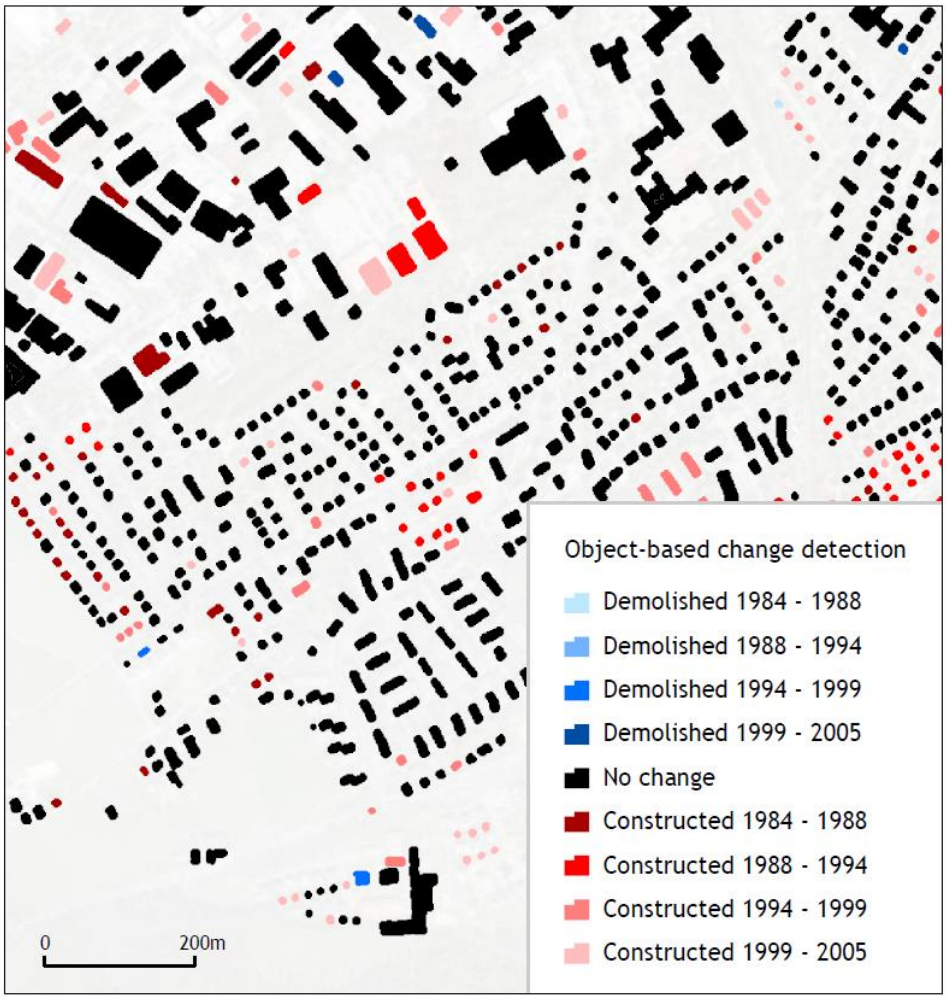

Fig. 7: Sample result of building-based change detection (Source: [13])

Here, the focus is set to the automated analysis of topographic maps. Compared to the multitemporal analysis of satellite data, the data availability is not limited to the last few decades. Topographic paper maps and plans have been existing for centuries. At the latest since the standardisations during the land surveying inititatives in the 18th and 19th century, these maps are relatively homogeneous in terms of map layout and symbolisation.

The methodological approach builds on two major steps [13]: Firstly, an object-based segmentation and classification of each of the multitemporal maps is applied in order to extract the building footprints (see section 3.1). In this process the buildings of each time period are extracted and stored in a spatio-temporal database. Secondly, a change detection algorithm based on the retrieved objects in different points in time is employed. Starting from each building object in the most recent data set, its existence in the older data sets is examined. The automated procedure follows the concept of backward editing in manual digitisation of multitemporal data sets. The temporal information on the construction period of newly constructed buildings is inferred by operational object-based comparison of segmented footprints from the historic maps (see Figure 7).

The methodology has been implemented and tested using the machine vision and image analysis software MVTec HALCON and the geoprocessing scripting engine in Esri ArcGIS. Currently, the approach is limited to the proof of object existence in old data sets. Structural changes of buildings are not yet considered. The spatio-temporal database allows the monitoring of the above mentioned (see section 3.1.1) settlement indicators such as the change of building density over time.

3.3 Automatic Map Georeferencing

The methodology described above bases on land-use information that is retrieved from recent and historic topographic maps. Recent maps are usually available as georeferenced data sets and thus are ready-to-use for building extraction. Historic topographic maps are by nature available as printed hardcopies. Thus, these paper maps have to be scanned and geocoded in order to use the automatically extracted information for spatial analyses within GIS. Considering an application on a national level, thousands of maps have to be manually georeferenced. This is an extremely time-consuming and hardly feasible task. Therefore, we have developed an automatic procedure [14]. In contrast to previous approaches (see [15] and [16]) we aimed for handling and processing maps with varying layouts over time. For this reason our approach is based on the least common features for referencing: the map margins and the map identifier comprising sheet number and name. The recognition of the former is achieved by means of a sequence of morphological filtering operations and a best-fit linear regression estimator. This procedure yields the image coordinates of four map corners. The latter is achieved by applying an optical character recognition (OCR) algorithm to the map number. The corresponding real world coordinates of the map corners are inferred from the national map sheet line systems and are subsequently assigned to the corresponding image coordinates. As in our approach only four points of each map are used for referencing, the method only allows affine image corrections. Figure 8 shows the general principle of the procedure.

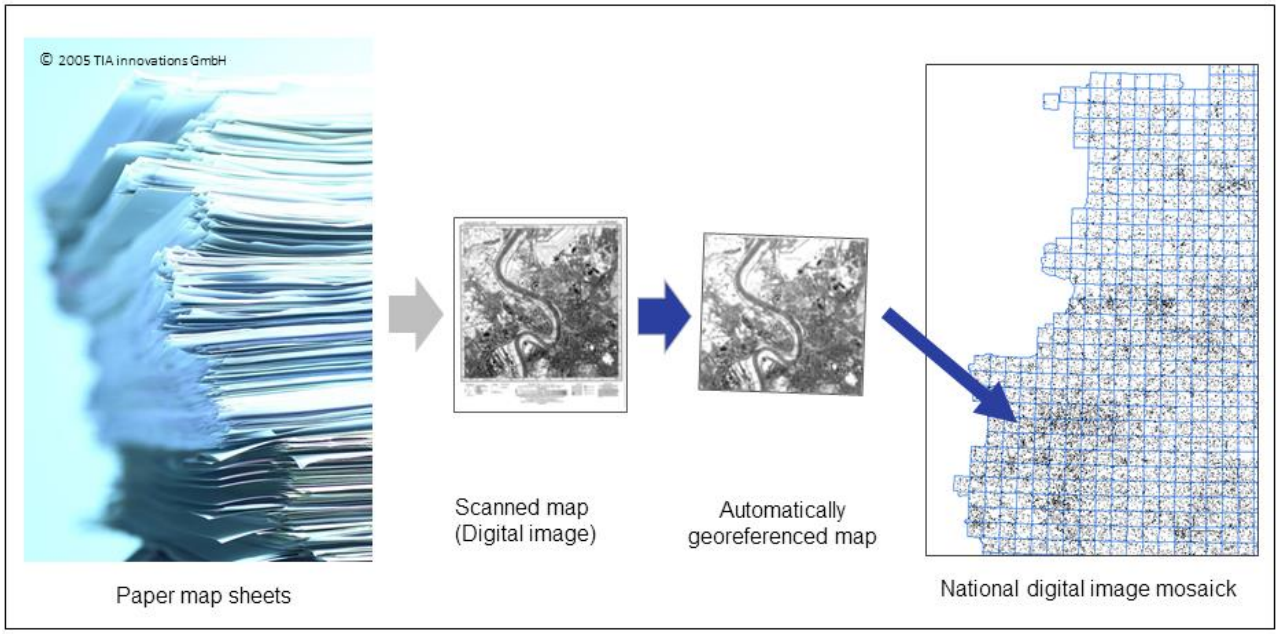

Fig. 8: Map georeferencing procedure.

4. Conclusions & Future Work

The presented methods could be of particular interest for spatial sciences as well as planning. Currently, different machine-learning techniques are tested in order to enhance accuracy, efficiency and the flexibility of the classification process [17]. We have also developed a tool to detect the changes in urban areas on building level by use of historical maps. The findings and the achieved automation enable micro-scale retrospective analyses of urban land-use dynamics on regional and national levels. Thus developments may support the nationwide land-use monitoring system for Germany, proposed in [2] and [8]. Current developments are merely based on the data availability in Germany, but the methods can be transferred to data of other countries, too. In this context, the standardisation and harmonisation of national spatial data sets, which is induced by INSPIRE, becomes very important for a cross-border monitoring.

Creating an Ecosystem of Innovation

Orona IDeO – innovation city is the flagship design of the new extension of San Sebastian's Technology Park that frames in public-private collaboration between ORONA and the Technology Park. ORONA's activity centres on the design, manufacturing, installation, maintenance and modernisation of mobility solutions, such as lifts, escalators and moving walkways.

The project is an answer to the need of common networking space of an international company, creating a place that is both a flagship and a common home for its more than 4,000 employees and a hub for researchers and students on elevation, urban mobility, energy and eco-technology branches.

The purpose of this project is to house ORONA's Innovation Ecosystem, which stands out as it brings together different synergetic activities –business, technology canters and university- and it will be a laboratory where leading-edge technologies in sustainability and energy management in buildings will be applied.

Orona IDeO is overtaking the future with the cutting edge bioclimatic design of its buildings and urban spaces, a district heating cooling system using 100% renewable energy sources and a perfectly integrated photovoltaic roof aimed at its own consumption as well as for research on electricity storage linked to elevator systems. The construction started in mid 2011 and is under way at this moment. Its opening in 2014 will coincide with the company´s 50th anniversary.

Keywords: bioclimatic architecture, solar roofing, District Heating-Cooling, sustainability certification, Urban Cell, Leed & Breeam, biomass, geothermal, cantilever

1. A project for innovation must be innovative in itself

The company and the architects stated that a Project for Innovation had to be Innovative in itself, which includes a range of aspects where the project incorporates cutting edge solutions that will help evolve a new common corporate culture for Orona IDeO - innovation city, i.e.:

-Urban design: integrative, environmentally friendly and open to citizens.
-Architecture: mixed-use, innovative, and high identity design.
-Mobility and accessibility showroom of ORONA's cutting edge technology.
-Sustainability: to be certified simultaneously both in LEED Gold and BREEAM excellent.
-Energy Lab: onsite 100% green thermal energy production and integrated PV design managed by an ESCO.
- Orona Foundation's activities will strengthen the local knowledge network.

Figure 1. Aerial view showing the cladding works of the buildings.

2. Master planning a 21st Century Knowledge Park

Donostia-San Sebastian is a medium size city located in the Basque Country, in the north of Spain. The city and its metropolitan area have been highly dynamic attracting innovative activities in recent years with the aim to diversify cities activity into a more knowledge-oriented economy.

The project incorporates the asset of being located within the extension of the Technology Park of San Sebastian and offers a mixed-use environment that will attract people of the neighbor companies. The location permits easy public transport and is next to the urban tissue where you can find dwellings, sports facilities, urban services and easy accessibility to bicycle and pedestrian network. By means of the hybrid building approach of the Orona Foundation, Orona IDeO will offer a cafeteria, a library and a kindergarten to the local community. The outer public space will be open to citizens and will be suitable to house open activities related to technology, culture and leisure using the Orona Gallery building as an attractor.

Master planning a 21st century Technology Park requires a design that takes into account the uses in the neighbor urban tissue, accessibility to public transport and landscape integration among others. In this respect, the project updates the concept of the city as something that agglutinates and acts as a meeting point for activities in its streets, squares and public spaces and in the care of its landscape.

The EcoBoulevard is the linear park shaping the backbone of the Technology Park's new extension. This space is an image and reference point for the whole of the Park, and is characterized by its rich vegetation and careful landscaping in the recreation areas where pedestrians will have preference over cars. The EcoBoulevard ends in a sculptural observation point that offers a view of the landscape and connects with the city. The inside of Orona IDeO – innovation city is structured around a pedestrian axis which will join the public entrance area around the existing roundabout with the EcoBoulevard.

Figure 2. View of the EcoBoulevard on foreground and the Orona IDeO buildings in the background.

3. Buildings and connectors

Orona IDeO - innovation city is made up of different buildings and the connection spaces among them:

3.1. Orona Zero

Orona Zero is a highly iconic building of ca. 11,000m2 that will house ORONA's corporate headquarters and Orona eic (Elevator innovation Centre). Its design is based on a circular shape, which has always accompanied the Orona brand image. The idea of ascent (positive and dynamic), is transferred to the final design via an even more sophisticated idea than elevation per se, via a suspended 90 m diameter and 16 m high cylindrical shape which creates a large entrance projection. This structure is inclined 15º horizontally to create a door effect and provide access to the inside of the building. This inclination provides the façade with a good orientation for solar energy collection, and presents a friendly façade towards the square.

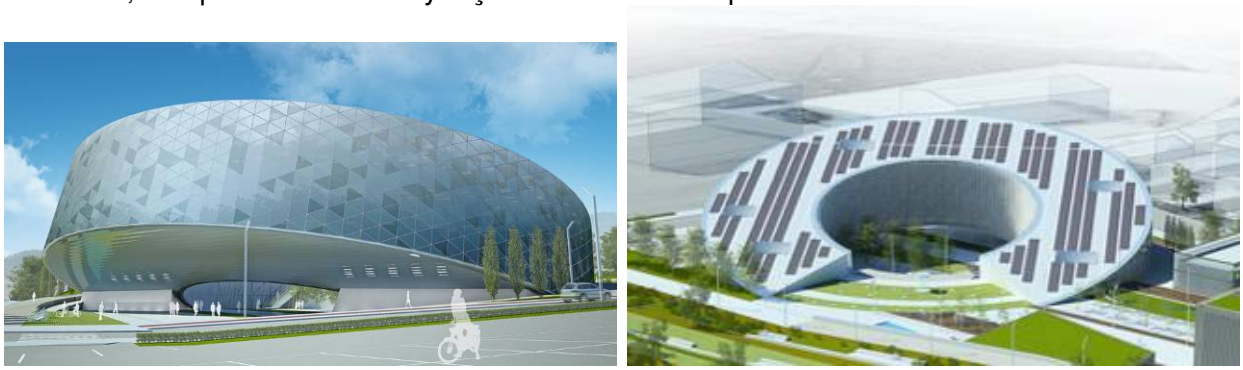

Figure 3. Front and rear view of the Orona Zero building.

3.2. Orona Foundation

This building is a "collage" facility of around 10,500m2. The two lower floors are for common and shared facilities such as the canteen, auditorium, library and crèche. Its façade onto the plaza acts as a backdrop for the public space and aims at being permeable and polyvalent.

This building will host the Orona Corporate University and the Mondragon University. The two upper floors are for use as teaching facilities at graduate and post-graduate level in energy-related subjects like two new Eco-engineering bachelor degrees.

3.3. Orona A3 research

This building encompasses two prismatic volumes holding office space and laboratories aimed at research on advanced applications on electrical storage systems. The purpose of this research is to develop technology for its application to elevation systems and in energy management in buildings. The laboratory building has a glowing U-glass façade, whereas the office building of the researchers has a more light-hearted, brightly-colored façade that helps provide diversity to the architectural ensemble.

3.4. Orona Gallery

This building will be a museum and a pavilion for visitors and its purpose will be to teach and transmit the Orona IDeO philosophy. It will contain a Showroom for demonstrating the monitoring of energy in the buildings in real time and will be the access point for visitors to the facilities for producing energy from renewable sources: biomass, solar thermal, geothermal and photovoltaic.

3.5. Orona IDeO Plaza

The Plaza will describe an urban hall with a series of pedestrian areas welcoming researchers, workers and students who will share these spaces aimed at encouraging relationships and the exchange of ideas. The design of this urban space seeks to afford all of Orona IDeO's building a recognizable character on the pavement through a striped design that raises the idea of the geological strata and the rich landscape of its setting.

4. Ecodesign and bioclimatic architecture

To achieve efficient energy performance in the buildings, the bioclimatic design and the environmental issues must be present from the initial architectural design. The Architects' objective is to fully profit from the passive measures applied and to choose the most suitable energy generation and consumption systems for this specific project.

Every building has integrated bioclimatic measures from the early design phase, but the conception, orientation and diversity of users of each one of the building has led to radically different solutions. The Orona A3 research building, for example, has three patios that flank the lab and office volumes and permit the entry of natural light to the basement labs. The Orona Foundation building, meanwhile, is clad in a perforated folded sheet to protect the building from the heat gain that comes from the rising and setting sun.

The Orona Zero building stands out for its singular design and its rich architectural composition. It is mainly devoted to office space that has large internal loads due to its occupants and to the density of the electronic equipment which dissipates heat and, at the same time, requires diffused light to avoid glare. The ground plan places the workplace near the outer façade which is mainly north facing, whereas the south-facing ring-shaped gallery distributes the flow of people and overlooks the building's central void. This is a space of a more social nature where sun capture is welcome and does not interfere with the work space. The service ring with stairs, lifts, toilets, utility shafts, etc. acts as a buffer between the two areas and structures the depth of the bay, creating different spatial situations due to the building's inclined geometry.

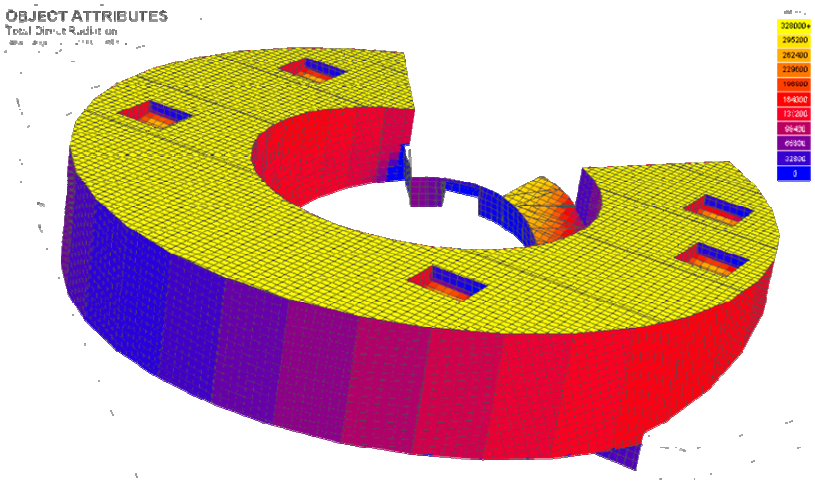

Figure 5. Simulation of accumulated radiation on the different façades of the Orona Zero building during the summer months.

The cylinder façade is made up of a curtain wall with a skin composed of triangular pixels which change from: opaque, translucent and transparent, depending on their position and the different circumstances regarding exposition to solar radiation, access to views, the relation with the use of internal space, etc.

With the aid of the superposition of these variations on the façade development, and taking into account the overall transmittance and a reference threshold for heat loss, the solutions for the outer and inner façades are designed, each with a different ratio of openings and opaque areas.

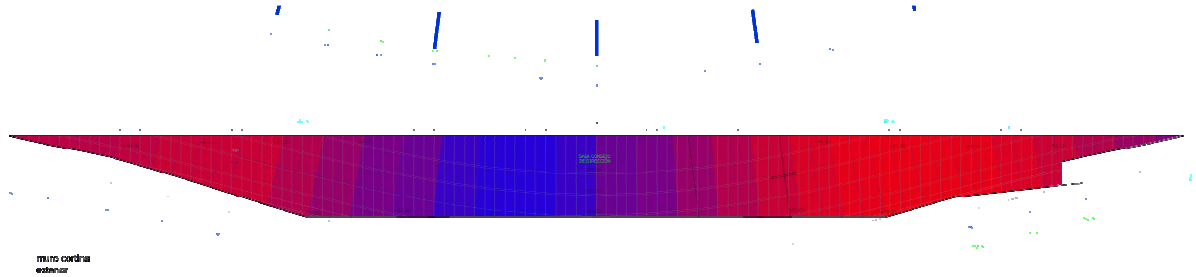

Figure 6. Studies on the façade of the Orona Zero building

5. Energy concept

The energy use in the buildings is based on the premise of making the most of the District Heating-Cooling system of the whole. This system is powered on 100% renewable energy sources: biomass, thermal solar and geothermal. The water that is heated or cooled using the District Heating-Cooling system is distributed to the substations located in each of the buildings, and, at these points, the flow of energy is adapted to the different conditioning systems.

Figure 7. The energy distributed by means of the District Heating-Cooling system is shown, in blue for electrical energy and orange, for thermal energy.

Heating and cooling are carried out using a radiant flooring system. Its distribution was designed in line with the climate-adjusted areas programmed for the building, so that the system allows for the distribution of heat and cold at the same time.

More than 1,000 polycrystalline photovoltaic modules are integrated on the inclined rooftop of the Orona Zero building that will have an annual electricity output of 220,000 Kwh, similar to the consumption of 100 average flats. This energy will be both used for self consumption as well as to investigate on new Net Zero Energy Lifts and new battery technologies at real time balance.

In short, energy production from renewable sources is highly competitive when properly calculated to meet the expected consumption over a large number of hours a year, with the result that the installation is cost-effective. Within the design's global energy scheme more conventional systems occasionally cover energy consumption peaks, thus ensuring that the best is made of each installation. The existence of an ESCO aimed at the sale of energy in Orona IDeO is an asset for the optimum performance of the renewable energy installation.

It is important to underline the fact that this experience will be viewable inside Orona IDeO itself, as the Orona Gallery will offer tours of the District Heating-Cooling facilities, and real-time energy performance together with the adjustment and control system for the buildings will likewise be visible.

6. Sustainability Certification

Orona IDeO – innovation city is the first project in Spain that is being certified simultaneously both in Leadership in Energy and Environmental Design (LEED®) and Building Research Establishment Environmental Assessment Method (BREEAM®). The fact that the project has a common design and share centralized facilities is a very interesting feature of the project that benefits the overall sustainable design approach.

It is important to underline that Orona Zero has been awarded the First Extraordinary Point for Innovation ever awarded by BREEAM ES. At Orona Zero, the point of innovation has been achieved in the field of energy efficiency and more specifically the requirement ENE 8 related to Lifts.

ORONA's innovation is a practical contribution towards giving shape to the Nearly Zero Energy Buildings standard that will be implemented throughout whole Europe by 2020. Orona IDeO is a step forward towards this goal and a Living Lab where these future technologies are being tested.

Figure 8. Current works at Orona IDeO – innovation city.

7. Facts Chart

7.1. Location

Donostia-San Sebastian, Basque Country, Spain
Latitude: 43.275987
Longitude: -1.986938

7.2. Team

The project is signed off by the architects:
Xabier Barrutieta (ORONA)
Eneko Goikoetxea (ORONA)
Javier de la Fuente (LKS)
Santiago Pérez (LKS)
ORONA, LKS ingeniería, Cenit Solar, Cener, MC2 ingeniería and Garrigues have all been involved in drawing-up, construction and managing of the project.

7.3. Data

Total built surface area above ground: 23,000 m2
Corporate use: 4,000 m2
Orona Elevator Innovation Centre: 4,800 m2
Technology center and laboratories: 3,000 m2
Shared use: 6,000 m2
Teaching use: 5,200 m2
Total built surface area below ground: 27,000 m2
Budget: 70M€
Completion: 12/2013

2012 Austrian State Prize for Architecture and Sustainability

Helmut Krapmeier, Vorarlberg Energy Institute
Stadtstrasse 33/CCD, 6850 Dornbirn, Austria,
helmut.krapmeier@energieinstitut.at, www.energieinstitut.at

Short Summary

The Austrian State Award for Architecture and Sustainability is conferred under the auspices of klima:aktiv, the Austrian Ministry for Agriculture, Forestry, Environment and Water Management's climate change initiative. The prize is significant because it provides definitive proof that architectural and aesthetic needs can be combined seamlessly with ecological, social and economic responsibility. The special feature of this award is that a building is eligible only if it can show both excellent architecture and outstanding sustainable construction

Keywords: architecture, energy efficiency, ecology, sustainability, award, lighthouse projects

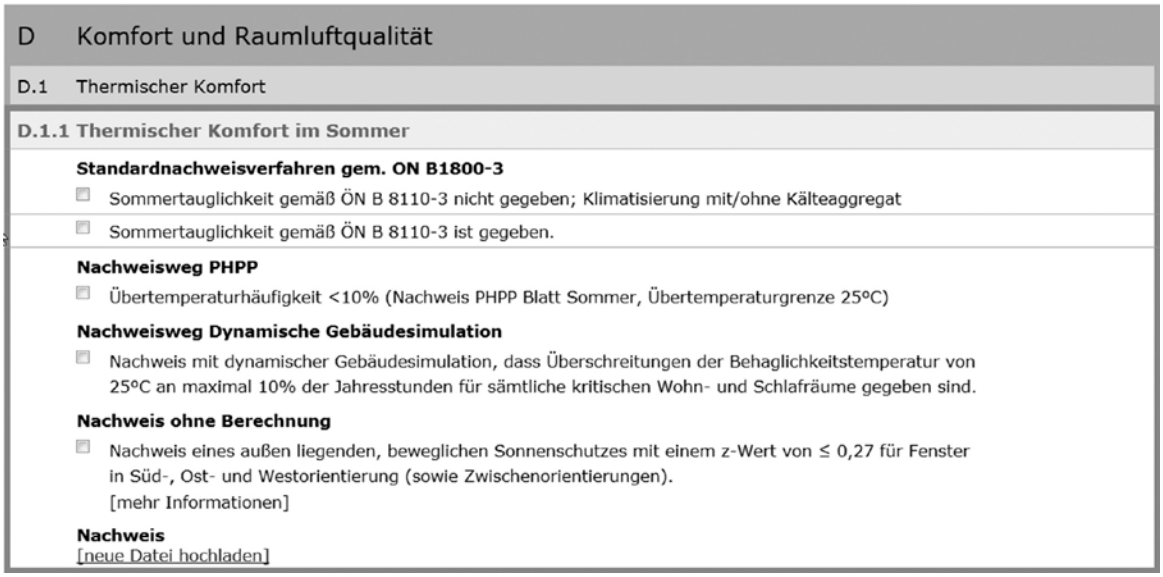
1. Background, purpose, and goal

When traveling through cities, villages, and rural areas with our eyes wide open, we immediately evaluate what we see. We spontaneously judge the buildings we cast our eyes over as beautiful, ugly, fascinating, boring, bizarre or pretentious regardless of their energy credentials.
Energy-efficient construction, Passive House, Solar House and Plus Energy House buildings often do not stand up well to architectural critique. The print media loves to publish attention-grabbing quotes by architects in keeping with the premise that bad news is good news, such as: "Thermal insulation - the burka for the home" (Frankfurter Allgemeine Zeitung, November 14, 2010).
"Every building represents destruction. Destroy intelligently" (Architect Luigi Snozzi). Architecture does not take place in a vacuum. Just as a sculptor can create a piece of art from lump of stone, an architect can also create beautiful buildings with low energy demand

2. Method, evaluation, and judging

Professor and architect Roland Gnaiger and Wolfgang Neumann, the creator of the Energy Conservation Trade Show and the initiator of the Energy Globe Award, sat down together in around 2002. The result of this meeting was the Great Austrian Solar Architecture Award in 2003.
The Austrian Ministry of Agriculture, Forestry, Environment and Water Management is conferring the Austrian State Award for Architecture and Sustainability for the third time. The award recognizes projects with both excellent architectural value and outstanding ecological, energy, social and economic sustainability. Roland Gnaiger from the University of Art and Design Linz, who oversees the prize, developed the first state award in 2006 on behalf of the Ministry and then

worked with ÖGUT to organize its creation. Robert Lechner, the managing director of the Austrian Ecology Institute, then came on board to help develop the parameters for this prize.
Roland Gnaiger stresses that he felt it particularly important that the prize contain the word “and”. In other words, it should be called the State Award for Architecture and Sustainability rather than the State Award for Sustainable Architecture. This means that a building must have exceptional architecture and sustainability to be eligible for the prize.



Method, evaluation, and judging

Jury decisions had to be unanimous to ensure assessment of equivalence. A building cannot receive the prize if it is a real treat architecturally speaking, but its sustainability, its ability to benefit future generations, is anything short of excellent. The opposite is also true: a building with all of the energy-efficiency and environmental credentials in the world cannot receive a state award if the jury deems its architectural features to be average. This is the first special element of the prize.

The process has three stages: an invitation for submissions, an initial round and judging. While the preliminary review of architectural features can focus solely on whether formal criteria have been met, buildings undergo rigorous scrutiny of their sustainability credentials at this stage. A web portal set up for the State Award for Architecture and Sustainability documented the entries. The content of this web portal leans heavily on klima:aktiv’s evaluation structure:

- Building data and general information
- A Planning and implementation (max. 130 points)
- B Energy and supply (max. 600 points)
- C Building materials and construction (max. 150 points)
- D Comfort and indoor air quality (max. 120 points)

Buildings can achieve up to a maximum of 1,000 points from all four categories. Each category or sector is subdivided into up to three levels, for example:

The preliminary review entails the labor-intensive task of checking that the information contained in all entries is complete and accurate.

A total of 99 buildings were put forward for the prize. The caliber of entries for the 2012 State Award for Architecture and Sustainability was much higher than in years past. At its first meeting, the jury narrowed the field down from 99 entries to 14 buildings that members visited in person during a three-day trip. This elaborate trip is needed because the jury is sometimes only able to confirm the building's quality by looking at it in person from the inside and out.
Another meeting at the end of the trip selected the five award recipients from the nine buildings nominated for the prize.

The results of the jury trip were stunning. All projects were of the highest quality, yet a decision still had to be made. In his summary, Roland Gnaiger writes: "This group's contributions are so important because they provide definitive proof that architectural and aesthetic needs can be integrated seamlessly with ecological, social and economic responsibility. Paul Valéry got to the heart of the matter in his wonderful dialog "Eupalinos or the Architect". His Socrates says, "This type of artist has no need for modesty. They have discovered the means to mix necessity and artifice inextricably.""

While few and no famous prize-winning architects had designed buildings put forward for the award just a few years ago, a surprisingly large number were in the running for the 2012 State Award for Architecture and Sustainability. This a good sign that excellent architecture does not fly in the face of sustainability, ecology and solar power. In this vein, Otto Kapfinger, one of Austria's most well-known and acclaimed architecture critics, remarked that "the three school projects in the final round by themselves are far superior to what we normally see in branding architecture in terms of their functionality, room quality and detail while meeting the highest ecological and energy standards." When analyzing a building's architecture and sustainability, a choice does not have to be made between one or the other; a building can perform well in both areas.
Another interesting feature is that several solid-construction buildings (of course, with highly efficient insulation and other Passive House Standard elements) were among the entries, unlike in years past.

The winners of the State Award for Architecture and Sustainability are outlined over the next few pages.

Figure 1: Salzkammergut Agricultural Education Center, Altmünster - STATE AWARD WINNER

This education center including a boarding school is a new build extension including an existing wood-framed wing with a usable area of around 10,000 m².
Key figures: 3.7 kWh/(m²a) (Austrian Institute for Building Technology, national calculation method)
Building owner: Landes-Immobilien GmbH Oberösterreich
Architect: Fink Thurnher Architekten
Professional planning: DI Dr. Lothar Künz ZT GmbH (construction physics); E-Plus GmbH (building services)
Special features: untreated wood used in the interior, which accommodates 250 students Redesigning, retrofitting, and adding a floor to a 50-year-old school building

Figure 2: Linz General Special School – STATE AWARD WINNER

Key figures: Heating demand: 3.12 kWh/(m²a) (Austrian Institute for Building Technology)
Building owner: Immobilien Linz GmbH & Co KG
Architect: grundstein Architektur
Professional planning: IBO (construction physics); Ing. Grillberger GmbH & Co KG (building systems)
Special features: Fully accessible to the disabled; solid construction with wood elements and a wood-concrete composite ceiling system; made entirely out of CFC-free and PVC-free materials

Figures 3 and 4: NÖ Haus Office Building in Krems - STATE AWARD WINNER

10,000 m² usable area, solid construction with insulation composite system built to Passive House Standard
Key figures: 2.6 kWh/(m²a) (Austrian Institute for Building Technology)
Building owner: NÖ Landesimmobilien GmbH
Architects: ARGE NÖHK: AllesWirdGut Architektur ZT GmbH, feld72 Architekten ZT GmbH, FCP – Fritsch, Chiari & Partner ZT GmbH
Professional planning: DI Walter Prause (construction physics), TB ZFG-Projekt GmbH (building services) and bauXund Forschung und Beratung GmbH (building ecology)
Special features: A redensification project in the historic town center, PVC-free, bicycle racks and showers, extensive green roofs, use of ground water to flush toilets

Figure 5: Wohnhaus U31 - STATE AWARD WINNER

New residential build with solid construction containing 46 apartments and commercial space
Key figures: 6.0 kWh/(m²a) (Austrian Institute for Building Technology); 14.2 kWh/(m²a) (PHPP)
Building owner: Heindl Holding GmbH
Architect: querkraft Architects ZT GmbH
Professional planning: Schöberl&Pöll GmbH (construction physics); BPS Engineering (building services)
Special features: Community rooms

Figures 6 and 7: Residential complex in Graz's trade fair district - STATE AWARD WINNER

A solid-construction residential building with 196 apartments and commercial space in the first floor
Key figures: Heating demand: 9.0 kWh/(m²a) (Austrian Institute for Building Technology)
Building owner: ENW – Gemeinnützige Wohnungsgesellschaft mbH
Architects: DI Markus Pernthaler Architekt ZT GmbH
Professional planning: Vatter & Partner ZT GmbH (construction physics), RFG Engineering GmbH (building services), and bauXund Forschung und Beratung GmbH (building ecology)
Special features: Stands to hold 547 bicycles, swimming pool and sauna on the roof, and 700 m² solar array

3. Outlook

The 2012 Austrian State Award for Architecture and Sustainability demonstrates that architecture can go hand in hand with sustainability. But opponents still argue that this is not the case, as changing direction is inherently difficult, especially in a sector dealing with immobile goods. Understandably, architects lament the increasing burden they face when planning buildings. New and sometimes incomprehensible standards and laws are coming to bear, along with more and more building contractors who are no longer tradespeople and cannot be due to massive pressure on prices.
Despite all of these hurdles, the buildings recognized with the State Award for Architecture and Sustainability show that we can achieve and build what is desirable. These architectural lighthouses can no longer be ignored; they serve as benchmarks for other projects. As a result, they will also influence everyday architecture, which shapes our perception of building culture.

4. More information

There are all projects presented with detailed explanations on the website:

Die Klimaschutzinitiative
des Lebensministeriums

klima:aktiv Bauen und Sanieren

behaglich, gesund und energiebewusst!

klima:aktiv Bauen und Sanieren steht für
Energieeffizienz, ökologische Qualität, Komfort und Ausführungsqualität. Egal ob Neubau oder Gebäudesanierung, klima:aktiv Bauen und Sanieren hilft Ihnen, die richtigen Entscheidungen zu treffen. Welche Maßnahmen lohnen sich? Welcher Energieträger ist in welcher Situation sinnvoll? Welche Förderungen gibt es?

Gebäude in klima:aktiv Qualität garantieren Ihnen

- niedrigen Energieverbrauch und niedrigste CO_2-Emissionen
- beste Raumluftqualität
- optimalen Nutzungskomfort und eine ökologische Bauweise
- hohe Planungs- und Ausführungsqualität
- Wirtschaftlichkeit und hohen Wiederverkaufswert der Immobilie

„klima:aktiv Bauen und Sanieren" ist Teil der Klimaschutzinitiative klima:aktiv des Bundesministeriums für Land- und Forstwirtschaft, Umwelt und Wasserwirtschaft.

Building and Refurbishment

Comfortable, healthy and energy-conscious

klima:aktiv Building and Refurbishment stands for energy efficiency, ecological quality, comfort and high quality of execution. No matter, whether we are talking about a newly constructed building or the renovation of a building, **klima:**aktiv Building and Refurbishment helps you to take the right decisions. Which measures are worthwhile? Which energy source is useful in which situation? Which funding schemes are available?

klima:aktiv Building and Refurbishment is part of the climate protection initiative of the Federal Ministry of Agriculture, Forestry, Environment and Water Management.

Sustainability Report 2012

What we strive for

Sustainability Goals

Employees	Deadline	Performance 2012	2011	Remarks
Reduce the frequency of accidents to < 10 per million hours worked by 2015	2015	**12**	17	We have made substantial progress in this area since the implementation of the safety initiative in 2010
Increase the data collection on respirable crystalline silica to > 95% of all ceramic plants by 2020	2020	**84%**	na	We will continuously expand data collection on respirable crystalline silica
Increase the share of women in senior management to 20% by 2020	2020	**8%**	8%	Preferential treatment of women when qualifications are equal; low number of new appointments in 2012 due to restructuring measures
Increase the share of women in administration to > 45% by 2020	2020	**44.3%**	43.7%	
Increase the share of women in sales to 30% by 2020	2020	**24.3%**	24.2%	
Environmental Protection in Production				
Reduce specific energy consumption in ceramic production 20% below 2010 level by 2020	2020	**-9%**	-5%	The Environmental Action Plan defines measures to reach our goals in the ceramic production; however, the targets are very ambitious, since we have already reduced these figures significantly during the past 10 to 15 years
Reduce specific CO_2 emissions from ceramic production 20% below 2010 level by 2020	2020	**-1%**	0%	
Reduce the share of water drawn from public supply networks to 40% by 2020	2020	**45%**	48%	We have already reduced the share of water drawn from public supply networks in 2012 and are confident to reach this goal
Sustainable Products				
Increase the share of revenues generated by innovative products to 30% in 2015	2015	**23.4%**	23.3%	We have set an ambitious goal and are constantly working to bring innovative products to our markets
Corporate Social Responsibility				
Expand WISBA to 12 countries by 2015	2015	**na**	na	We created WISBA in 2012; four countries will participate in 2013; the concept will be rolled out step by step
Stakeholder Management				
Introduce a stakeholder dialogue in 90% of our ceramic production network by 2020	2020	**na**	na	We set this goal in 2012 and will start to implement measures in 2013

WISBA … Wienerberger Sustainable Building Academy

1) The data were adjusted to reflect a change in accounting policies.
2) excluding North America (analysis limited by special local legal regulations)
na … not available (data has not been collected)

We have set goals for these key data that we want to reach by 2015 or 2020.
A summary of all goals can be found on the previous page.
The individual goals are described in detail in the respective chapter of the report.

Because coming generations will benefit even more from our sustainable business approach.

A good working environment is the foundation for our future.

We challenge and encourage our employees. To make sure we can expect top performance, we invest in a safe and motivating working environment. We have significantly reduced the number of work accidents since 2010 and, with 12 accidents per million hours worked in 2012, moved closer to our goal of less than 10 accidents by 2015.

As an employer in many, in part structurally weak regions, we want to offer stable employment relationships. The long service length of 12.9 years and a low number of days lost through work stoppages speak a clear language.

A long life requires amazingly little energy.

A house made of Wienerberger building materials is an investment for coming generations. The core of our sustainability strategy is the long service life of our products. At the same time, we implement measures to reduce the environmental impact of our production processes. Our activities are focused not only on reducing energy consumption, but also on improving our ecological footprint by using fewer raw materials and increasing the use of recycled products.

We don't think about tomorrow.
We're already there.

The sustainability of our products is underscored by their long service life. Outstanding technical properties are another exceptional feature: ceramic building materials are free of pollutants. They not only provide good thermal insulation, but also protection against noise and fire, and create a healthy, comfortable indoor climate. With continuous innovation, we make sure our pipes can meet any challenge – above all in the areas of health and supply security.

Success can't always be measured in numbers.

We believe we can help best in areas related to our core expertise. That's why we are active, above all, in two main areas. First, in the construction of housing for the needy and help in the event of disasters near our plants. And second, in cooperation with the Vienna University of Economics and Business, we give young, talented men and women an opportunity to obtain additional technical training in sustainable construction.

Every bridge we build brings us closer together.

We are convinced that sustainable management creates added value for all our stakeholders. In order to establish and maintain positive relations with our investors, the media, suppliers and other stakeholders, we follow a policy of transparent communications and active dialogue. Invitations to our plants and the regular exchange of information provide a platform for interaction with neighboring residents in many countries. We want to be a fair neighbor who not only meets but also exceeds legal regulations to provide quality living for local residents.

Introduction by the Chief Executive Officer

Dear Ladies and Gentlemen,

The mega-challenges of the future require responsible action

Climate change, limited resources, population growth, rising poverty, migration, demographic change, urbanization, the loss of biodiversity – the list of global, often interconnected challenges is long.

Climate protection and climate change as central concerns

The frequently discussed climate change is attributable primarily to the sharp rise in CO_2 emissions from the burning of fossil fuels such as crude oil and natural gas. In order to limit global warming to a tolerable level, we must reduce CO_2 emissions, use energy more efficiently and convert to non-fossil energy sources – and all that as quickly and completely as possible.

Nearly zero-energy standard mandatory in the EU starting in 2021

The energy consumption of buildings plays a major role in this process. The building sector in the EU is currently responsible for roughly 40% of total energy consumption. As a result, the EU issued a directive that requires all buildings built after January 1, 2021 to meet "nearly zero-energy" standards [1)].

e4-Brickhouse 2020 already meets this standard today

Our e4-Brickhouse 2020 already meets these requirements today. It can save 4,200 tons of CO_2 per year compared with a conventional single family house because it produces more energy than it uses. In order to verify this claim, the Austrian Institute of Technology (AIT) will monitor the first e4-Brickhouse 2020 up to 2014. This house was built in the Lower Austrian town of Zwettl by a family of four, who moved in during the past year.

Healthy living (e.g. interior air) as a key issue for the future of housing

In addition to the energy efficiency of buildings, I see healthy living as one of the most important issues for the future of modern housing. People in the western industrial countries spend roughly 90% of their time indoors – and the quality of the interior air generally leaves a lot to be desired: pollutants, dry air, dust and mold not only have a negative influence on the indoor climate, but also represent a major health risk. Today, asthma is the most frequently diagnosed disease among children in Europe. It is no coincidence that bricks have been used as a building material for thousands of years – their outstanding properties create an optimal quality of living for residents. Bricks are absolutely free of pollutants. They are also permeable, which means they equalize the humidity in the room and, in this way, create a healthy indoor climate. Bricks also help to save energy, both in heating and cooling, because of their natural air conditioning properties. The accumulation capacity of bricks evens out temperature fluctuations by absorbing heat during the daytime and releasing it in the night, or vice versa. Bricks are therefore one of the best building materials for the creation of a pleasant and comfortable atmosphere.

1) Directive 2010/31/EU from May 19, 2010 on the energy performance of buildings

Heimo Scheuch, Chief Executive Officer of Wienerberger AG

Special pipe system to prevent flooding in cities

The consequences of climate change and the resulting heavier rainfall over shorter periods of time represent a new challenge, above all for urban areas. Flooding has become a growing problem because sufficient drainage areas are frequently not available and sewage systems are not designed to handle the higher water volumes. With our innovative Raineo^{TM} pipe system, we have developed a solution for this problem.

Long service life of our products brings responsibility for continued development and innovation

Our products have a proven service life of more than 100 years. This creates value for generations, but also brings a great deal of responsibility. Therefore, one of our main goals is to anticipate trends and developments to offer our customers innovative and affordable solutions for residential construction, infrastructure and renovation that guarantee long-term comfort, health and security. Innovation is one of the guiding principles of our strategy to generate organic growth and create maximum value for all our stakeholders, above all our customers. This is our course for the future. Our goal is to increase the share of innovative products from the current level of 23% to 30% of revenues by 2015.

First-time announcement of sustainability goals in this report to improve transparency

Sustainable management has been a key part of the Wienerberger corporate culture for many years and is integrated in all areas of the company. In order to make our activities even more transparent, we have decided to announce our sustainability goals for various areas for the first time in this report and will report to you on our progress in the future. I invite you to form your own opinion of our efforts in sustainability management and to join us on a sustainable course into the future.

Yours

Wienerberger at a Glance

The Wienerberger History

From an Austrian brick manufacturer …

Wienerberger was founded in 1819 by Alois Miesbach on the Wienerberg in Vienna. This Austrian brick manufacturer became one of the first companies to trade on the Vienna Stock Exchange with its initial public offering in 1869. In spite of this listing, Wienerberger remained a local company for over one hundred years. The first internationalization step was taken in 1986 with the acquisition of the German Oltmanns Group and continued with successful expansion into Eastern Europe, France and the Benelux countries during the 1990s. The ***founding of Pipelife*** (plastic pipes) as joint venture with a Belgian partner and the development of the Group's ceramic pipe and concrete paver activities also occurred during this time.

… through a number of expansion steps …

Further growth steps in Europe were followed by Wienerberger's development into a ***global player*** with the takeover of General Shale in the USA during 1999. Another key strategic milestone was set in 2003 with the Group's ***entry into the roofing systems market through the acquisition of Koramic*** and the steady expansion of this business in the following years.

… and restructuring measures …

After many years of strong, expansive growth, Wienerberger was hit hard by the global economic crisis in 2009 because of its heavy dependence on cyclical new residential construction. ***Heimo Scheuch*** took over as ***chief executive officer*** of the Wienerberger Group in summer 2009 and implemented an extensive restructuring program through the end of 2010 that adjusted corporate structures to reflect the difficult market conditions. The end of the restructuring process was followed by a strategic reorientation, which focused the company on financial discipline and organic growth through innovative and premium products. The expansion steps after 2009 were directed, above all, to less cyclical business areas like roof tiles and pipe systems in order to ensure the sustainable generation of stable earnings.

Company Profile

… to an international system provider of building materials

With the full takeover of the plastic pipe producer Pipelife in 2012, Wienerberger completed its transformation into an international supplier of building material systems. Business activities are now aggregated in two divisions: Bricks & Tiles and Pipes & Pavers. The Bricks & Tiles Division covers the clay block, facing brick and clay roof tile product groups. Wienerberger is the world's largest producer of clay blocks, number one in facing bricks in Europe and the USA and the market leader for clay roof tiles in Europe. The Pipes & Pavers Division includes our activities in the areas of plastic pipes, ceramic pipes and concrete pavers. Wienerberger is one of the leading suppliers of plastic pipes, ceramic pipes and concrete pavers (only in Central-East Europe) in Europe.

Clay blocks:	**No. 1 worldwide**
Facing bricks:	**No. 1 in Europe, co-leader in the USA**
Clay roof tiles:	**No. 1 in Europe**
Plastic pipes:	**Leading position in Europe**
Ceramic pipes:	**No. 1 in Europe**
Concrete pavers:	**No. 1 in Central-East Europe**

Strategy and Business Model

Sustainable creation of added value as top corporate goal

The goal of our business model is to create and maintain a sustainable increase in the value of the company in accordance with ecological, social and economic principles. Accordingly, we want to create added value for all our stakeholders.

Completion of strategic reorientation from an expansion-driven to a market-oriented company

For Wienerberger, the years since the crisis have been characterized, above all, by a difficult new residential construction market and an internal focus on cash generation. Extensive restructuring measures were implemented in 2009 as a reaction to the global financial crisis, which cut fixed costs by approx. € 200 million, substantially reduced working capital and gradually decreased the company's debt. The restructuring phase was followed by a strategic reorientation from a primarily expansion-driven to a market-oriented company with a focus on organic growth. Our customers are the focal point of our actions – we want to create added value for them with innovative, high-quality and application-oriented system solutions. Comprehensive advising and service for our customers, starting with the project planning stage, are an important part of our improved sales activities. The strategy for our core business is designed to establish and extend leading positions in all markets in which we are present.

Strategic expansion through development of pipe systems

In order to reduce Wienerberger's dependence on new residential construction over the medium-term, we have been working for several years to expand the core business through a stronger concentration on renovation and infrastructure. Our activities in the area of pipe systems should be seen in this connection. We acquired Steinzeug-Keramo, the market leader for ceramic pipes in Europe, during 2010. In 2012 the Wienerberger Group completed its transformation to an international system provider of building materials with the full takeover of Pipelife, one of the leading European producers of plastic pipes. Both companies were acquired at comparatively low multiples and create substantial added value with a CFROI that clearly exceeds the internal hurdle rate of 11.5%. The expansion of the core business has reduced the dependence on cyclical new residential construction from approx. 70% to roughly 60% of revenues. It has also broadened Wienerberger's strategic base and extended the potential for sustainable growth over the medium- and long-term.

Financial discipline is a top strategic priority for Wienerberger

Our strategic focus will remain on financial discipline as well as the protection of a strong capital structure based on our internal goal to hold the ratio of net debt to operating EBITDA below 2.5 years. The issue of an additional bond in April 2013 with a volume of € 300 million increased our liquidity reserves and further optimized the term structure of liabilities. The maintenance and protection of a strong capital structure remains a central goal for Wienerberger, which we will continue to pursue through the proactive management of liquidity and the term structure of liabilities.

Wienerberger Group: EBITDA potential of € 600 million

Wienerberger's activities cover ***solutions for walls and roofs*** (clay blocks, facing bricks and clay roof tiles) as well as ***pipe systems & paver solutions*** (plastic pipes, ceramic pipes and concrete pavers). These businesses are managed by region based on the following divisions: ***Bricks & Tiles Europe***, ***Pipes & Pavers Europe*** and ***North America***. The Wienerberger Group has a medium- to long-term EBITDA potential of approx. € 600 million across all divisions, once the new residential construction market recovers.

The Year 2012 in Review

Increase in operating results through expansion of pipe operations in a difficult market environment

Wienerberger increased revenues by 23% and operating EBITDA by 2% during 2012 in a difficult market environment. The Group's results were influenced by three major developments: an earnings decline in the European brick business due to weaker residential construction across Europe, a substantial positive contribution from the acquisition of Pipelife in May 2012 and moderate recovery on the US new residential construction market with a resulting improvement in revenues and earnings in the North America Division. The Bricks & Tiles Europe Division recorded a decline in revenues and earnings for the year because the European construction industry was again faced with the negative effects of the euro and sovereign debt crisis and new residential construction subsequently fell below the 2009 crisis year in a number of key markets. These developments were met with a restructuring program that involves non-recurring costs of approx. € 43 million, but will bring sustainable costs savings of € 50 million by year-end 2014. The costs for the restructuring program and other non-cash effective one-time expenses resulted in a loss of € 40.5 million for the year.

Return of 20% on free cash flow

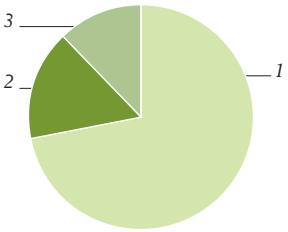
Wienerberger again demonstrated its cash flow-generating strength in 2012, despite the difficult market environment, and increased free cash flow by 21% to € 164 million. That represents a free cash flow return of 20% at year-end. The Group's strong capital structure was underscored by a ratio of net debt to operating EBITDA that equaled 2.2 years at year-end 2012. As a result a € 0.12 dividend per share for the 2012 financial year was paid to shareholders.

Pipelife acquisition main reason for increase in workforce

The average number of employees in the Wienerberger Group rose to 13,060 during the reporting year. This development resulted, above all, from the initial consolidation of Pipelife as of May 31, 2012. The Pipelife acquisition and compensation increases explain the rise in wages, salaries and employee benefits.

Dividend and coupon on hybrid bond lead to payments of € 46.3 million

A dividend of € 0.12 per share, or a total of € 13.8 million, was paid in 2012 from profit recorded for the 2011 financial year. As in the previous years, the payment of the hybrid coupon amounted to € 32.5 million. Net debt rose from € 358.8 million at year-end 2011 to € 602.0 million as of December 31, 2012, in particular due to the Pipelife acquisition, but gearing equaled a comparatively low 26% at the end of 2012.



Payments of € 33.7 million to the public sector

Payments to the public sector, which represent taxes on income and other taxes (excluding deferred taxes) fell slightly to € 33.7 million in 2012 due to the decline in earnings and the resulting lower tax expense.

Cash flows to stakeholders *in € mill.*	2010 [1]	2011 [1]	2012	Change in %
Revenues and other operating income	1,731.3	1,971.8	2,407.3	+22
Operating costs [2]	-1,040.1	-1,179.0	-1,518.7	+29
Employee wages, salaries and benefits [3]	-469.4	-525.4	-592.5	+13
Payments to providers of capital (owners) [4]	-32.5	-44.2	-46.3	+5
Payments to providers of capital (creditors)	-43.8	-39.5	-52.1	+32
Payments to public authorities [5]	-24.4	-35.7	-33.7	-6

1) The data were adjusted to reflect a change in accounting policies
2) Production costs plus selling, administrative and other operating expenses; excluding wages, salaries, benefits, depreciation and amortization as well as non-income based taxes
3) Excluding temporary personnel and company automobiles; including employee-related restructuring costs
4) The hybrid coupon and dividend are shown in the year in which payment was made
5) Excluding deferred taxes

Public financial subsidies
in %

1 Investments in environmental protection and occupational safety 72%
2 Product research and development 16%
3 Other 12%

The Wienerberger Group received public financial subsidies of € 3.2 million in 2012 (individual amounts over € 50,000 are recorded). The major payments represent investments in environmental protection and occupational safety (€ 2.3 million), product research and development (€ 0.5 million) and other financial subsidies (€ 0.4 million).

Corporate Governance at Wienerberger

Implementation of strict principles for good management and transparency

For many years Wienerberger has followed a strategy that is designed to maximize cash flows in order to create and maintain a sustainable increase in shareholder value. Strict principles of good management and transparency as well as the continuous development of an efficient control system form the basis for meeting this goal.

Compliance code to prevent insider trading and code of conduct for lobbying activities

We give the highest priority to providing all shareholders with the same comprehensive information. To prevent insider trading, we have released a compliance guideline that implements the provisions of the Issuer Compliance Code published by the Austrian Financial Market Authority. A compliance officer monitors the observance of these rules. A code of conduct based on the Austrian Lobbying Act covers all corporate bodies and the employees of Austrian companies in which Wienerberger AG holds a controlling interest. This code defines the principles for lobbying activities and can be reviewed on the Wienerberger website (www.wienerberger.com).

Wienerberger is the leader for transparency

Wienerberger was one of the first companies in Austria to announce its support for this code and to commit to compliance with its rules. Wienerberger met all rules and recommendations of the code (in the version dated July 2012) in 2012. The corporate governance report is integrated in the 2012 annual report (pages 20 to 37).

Additional information on corporate governance at Wienerberger is provided in the 2012 annual report, which is also published on the company's website (annualreport.wienerberger.com).

Sustainable Development at Wienerberger

Wienerberger Principles of Sustainability

Business as an integral part of society

Wienerberger views business as an integral part of society. Its duty is to serve people and create value for everyone. Wienerberger takes its role as a responsible member of society seriously. We define responsibility as ethical actions, honest communications, active participation in the transparent development of our economic environment, personal accountability and actions that confirm our standing as a reliable and valuable member of society.

Sustainable products are the focal point of the sustainability strategy

Sustainability represents an integral part of the Wienerberger corporate culture and the corporate strategy. We view sustainable management as a process that creates lasting added value for all our stakeholders. Our sustainable products and system solutions form the focal point of our sustainability strategy. Wienerberger produces and sells a wide variety of building material products and solutions that are used for very different applications. One of our most important goals is to create added value for our customers with our products and solutions with their long service life, technical properties, low impact on the environment over the entire lifecycle and economy. In general, we see sustainability as a function between the service life of a product and its impact on the environment during production, transport, installation, use and disposal:

The sustainability of a product increases with its service life. Increasing the service life of a product reduces the use of resources and the effects on the environment over the entire lifecycle. In this same way, a reduction in the use of resources based on a constant lifecycle makes products more sustainable.

The Sustainable Management Cycle

Sustainability is an integrated process

At Wienerberger, sustainability is embedded in all stages of the value creation process. We see sustainability as an integrated process that creates lasting value for all our stakeholders.

Sustainability begins with our ***employees***. We place high value on their health, advancement and development because our success is based on the commitment of a workforce that believes in sustainability and acts as entrepreneurs. Our focus for ***production*** lies on the best possible conservation of resources and the recycling of materials. We produce innovative, long-lasting ***products and system solutions*** for residential construction and infrastructure that create sustainable value for the people who use them every day. In accordance with our donation guideline, we provide in-kind support for the needy with our products and also give young people an opportunity for training in sustainable construction. These measures demonstrate our commitment to sustainability and to ***society*** and, in the end, create sustainable added value for our ***stakeholders*** – which completes the cycle.

1. Development of employees

Employees are the basis of our success

Our employees are the basis of our future success. We therefore place a special focus on these men and women, and encourage the creation of internal networks and cooperation throughout the Wienerberger Group. In accordance with our corporate values, we offer a healthy, safe and motivating working environment. Our goal is to develop the potential of our employees

and, subsequently, to fill most of our management positions internally. A corporate culture that encourages openness and respectful interaction serves as a reference point for our employees, also with respect to their targeted personal development.

2. Environmental protection in production

Resource conservation and recycling as central principles for production

Environmental protection in production is a top priority for Wienerberger. The use of reusable raw materials and recycling are the central principles of our sustainable production. Another important focal point of our activities is the greatest possible conservation of resources. That means improving the energy and resource efficiency of production processes through optimized technologies and, in that way, and through the use of renewable energy carriers reducing CO_2 emissions. We are also working to reduce the weight of our products and evaluating the use of secondary raw materials.

3. Sustainable products

Long-lasting and innovative products create sustainable value

The value of a building or a pipe system is dependent on numerous factors, not least on the products used. A central principle of product development at Wienerberger is the creation of sustainable value for people with long-lasting and innovative system solutions. Wienerberger brick products form an integral part of sustainable building concepts. They guarantee a high quality of living and make an active contribution to climate protection. In the area of pipes and pavers we offer system solutions for today's challenges, including the demands on water management resulting from climate change and increasing urbanization.

4. Responsibility for society

We are committed to social responsibility

"Building with a clear conscience" – Our belief in sustainability is also reflected in our goal to accept responsibility for society. The protection of human rights and compliance with all relevant national and international legal regulations as well as open and transparent communications with politics and public authorities also represent an integral part of our commitment to social responsibility. Our donation guideline provides a framework for the targeted, in-kind support we provide to the needy in the form of products or training programs. We believe we can help best in areas related to our core expertise, namely in the provision of building material solutions and know-how for sustainable construction.

5. Added value for our stakeholders

Our most important goal: the creation of added value for all our stakeholders

Our foremost goal is to generate added value for all our stakeholders through future-oriented, proactive behavior. We create a healthy living environment and provide security of supply for our customers with our long-lasting and innovative products, a solid investment for our shareholders and an attractive workplace for our employees. Wienerberger engages in an active dialogue with all its stakeholders and is well aware of its responsibility to shareholders.

Processes and Instruments of Sustainable Development

Sustainability report as part of a continuous process

The Wienerberger sustainability report transforms our commitment into an obligation. It is based on the standards defined by the Global Reporting Initiative (GRI) and represents an integral part of a continuous process. All levels of management and our employees have taken on shared responsibility for the implementation of measures to support a continuous improvement in sustainability at Wienerberger. This sustainability report provides information on the current status and further measures in the areas of employees, environmental protection in production, sustainable products, social responsibility and stakeholder management. It not only represents a collection of interesting facts and figures, but also serves as an instrument to monitor the progress of our sustainable development.

Transparent communication of goals for the first time

The Sustainable Development Steering Committee (SDSC) was founded in 2009 to define Wienerberger's sustainability strategy, key indicators according to GRI and goals for sustainable development. The SDSC meets regularly or as required to discuss progress on the sustainability process and options for further actions. It also defines goals and measures for implementation throughout the Group. In order to make our commitment to these goals transparent, we are publishing them for the first time in this sustainability report. The following chapters provide information on our goals in the respective areas.

CEO monitors sustainable development

This sustainability report was released by the SDSC. The Chief Executive Officer of Wienerberger AG, Heimo Scheuch, is a member of the Sustainable Development Steering Committee. He monitors the company's sustainable development on a regular basis and ensures that sustainability always has top priority for the company.

Sustainability management is anchored in the organization

In recent years our approach to sustainability management has become substantially more professional and more firmly anchored in the company. Responsibilities for sustainability have also been clearly defined. In addition to a Group-wide sustainability officer who reports directly to the Chief Executive Officer of Wienerberger AG, each of our country organizations and subsidiaries has designated a person who is responsible for sustainability and the implementation of the respective Group guidelines and programs.

Internal audit as control function

The SDSC uses Wienerberger's internal audit department to review major aspects of the sustainability program. This department, which reports directly to the Managing Board, evaluates the company's operating processes each year based on an audit plan and a risk assessment. Monitoring the internal control system in the accounting process is one of the most important responsibilities of internal audit. Another duty is the review of compliance with legal regulations and internal guidelines, for example the guidelines on business gifts and competition law. Internal audit also evaluates compliance with Wienerberger safety standards for employees and with selected areas of the Austrian Corporate Governance Code, whereby the latter is mainly a focus of activities by the external auditor.

2001

Commitment to a Social Charter for compliance with the applicable agreements and recommendations of the International Labor Organization (ILO) in Geneva

2003

Commitment to the UN Global Compact – a United Nations initiative established in 1999 to promote ethical behavior among companies (good corporate citizenship)

2004

Extensive discussions of sustainability by Wienerberger management together with external advisors; definition of the Wienerberger mission statement by 80 managers from all country organizations

2005

Communication of the Wienerberger mission statement to all employees and implementation in all country organizations

2006

Wienerberger is a founding member of the Austrian UN Global Compact network respACT Austria

2009

Founding of the Wienerberger Sustainable Development Steering Committee to define Wienerberger's sustainability strategy, key indicators and targeted goals for sustainable development

2010

Publication of the first Wienerberger Sustainability Report and implementation of the defined measures, for example the Environmental Action Plan and Safety Initiative 2010

2011

Integration of local sustainability managers into a network to better anchor sustainability issues in the Wienerberger country organizations

2012

Communication of goals for defined sustainability indicators

Employees

Principles of Sustainable Human Resources Management

Sustainable human resources management for diversity and equal opportunity, safety and health, training and a motivating working environment

Our employees are the basis of our success and a key factor for the successful development of our company. Wienerberger is well aware of its responsibility to its employees and takes this responsibility seriously. We are committed to sustainable human resources management that creates the necessary requirements and conditions for our employees in the areas of diversity and equal opportunity, occupational safety and health, training and a motivating working environment. Our human resources management is based on the following sustainability principles, which apply without limitation throughout the entire Group:

– *Equal opportunity independent of age, gender, culture, religion and origin*
– *Healthy and safe workplaces*
– *Advancement and development of each employee*
– *High readiness to act and personal responsibility*
– *Entrepreneurial thinking and actions*

Wienerberger Social Charter guarantees fair working conditions

With the signing of a social charter in 2001, Wienerberger formally confirmed its intention to work toward employment and working conditions in all Group companies that meet or exceed national law or collective bargaining agreements. The company is also committed to compliance with the recommendations of the International Labor Organization (ILO), which include the prohibition of child labor and discrimination, respect for the freedom of association and the right to collective negotiations as well as the provision of safe working conditions.

Corporate culture as success factor

The Wienerberger corporate culture influences the actions and behavior of our employees. Our common goal is to provide people with a better quality of life through our outstanding, sustainable building material and infrastructure solutions. Expertise, passion, integrity and respect, customer orientation, entrepreneurship, quality and responsibility are the seven key factors for Wienerberger's business success.

"ideas & more" to better utilize our employees' potential

We see the know-how of our employees as one of the most important sources of innovation and the further development of existing products. In order to better utilize this potential, we have anchored the subject in business and work processes. The "ideas & more" internet platform was launched to give employees an opportunity to support the development process by submitting their suggestions for improvement and their ideas for innovation.

Processes and Instruments for Sustainable Human Resources Management

Employee development and support as central responsibility of human resources

The focal point of human resources management at Wienerberger is the support and development of all employees in line with the Group's strategic goals. The responsibilities of human resources include employee recruiting, international know-how transfer and exchange, talent management and succession planning, training and education platforms, appropriate compensation and bonus systems, occupational safety, internal communication and industrial relations as well as the socially responsible reduction of jobs in connection with restructuring programs. In all these areas, human resources also serves as a contact partner and advisor for employees.

Succession planning as part of annual management review

Strategic succession planning represents a central challenge for sustainable human resources management. An annual management review focuses on the evaluation of senior managers and succession planning for senior management positions. Wienerberger maintains a management database to provide fast access to records on the training, professional experience, salary structure and service contracts of the respective employees. This database, which covered roughly 90 men and women in 2012, supports structured and transparent career planning.

SHE reporting

The Safety, Health & Education (SHE) reporting system was introduced throughout the Group in 2007. This system collects quarterly data from all local Wienerberger companies on the size of the workforce, occupational safety, days lost through illness as well as training and development. The resulting indicators provide management with the necessary tools for analysis and the development of appropriate measures in the areas of occupational safety, health and training.

Wienerberger safety standards

The improvement of workplace safety in all its plants is an important goal for Wienerberger. In this connection, the following safety standards were implemented in 2009:

1. *Introductory safety training program for all employees*
2. *Appointment of an occupational safety officer*
3. *Increased awareness for occupational safety*
4. *Personal protective equipment for each employee*
5. *Safety introduction and protective equipment for visitors*
6. *Regular safety training programs*
7. *Establishment of a working group in each plant and quarterly safety meetings*
8. *Plant safety audits*
9. *Monitoring of workplace conduct*
10. *Mandatory accident reporting*

Implementation through safety initiative

Wienerberger's safety initiative provides the framework for realizing these goals. The related investments, i.e. the purchase of protection equipment, have already been completed. Employees are now receiving special training to increase their awareness of occupational safety and change their behavior over the long-term to prevent accidents. These training programs are organized by the local companies. Progress in the area of occupational safety is monitored by SHE reporting at the Group level, which allows for the identification and implementation of additional measures as needed.

The following statistics include Steinzeug-Keramo beginning in 2011 and Pipelife for the full 12 months of 2012. A different method was used to calculate the number of employees, and explanations are provided in footnotes at the relevant sections.

Employment Trends

Number of Employees

10% workforce increase in 2012 due to initial consolidation of Pipelife

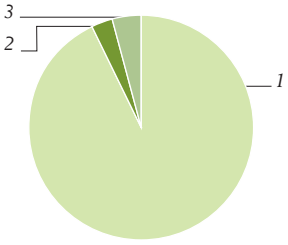
The average number of employees in the Wienerberger Group rose by 10% year-on-year to 13,060 in 2012. The Bricks & Tiles Europe and North America Divisions reported workforce reductions due to the weaker development of business and resulting restructuring measures, while the number of employees doubled in the Pipes & Pavers Europe Division. This strong increase is explained, above all, by the takeover of Pipelife during the reporting period.

Ø Employees by operating segment

Full-time equivalent	2010 [1]	2011	2012 [2]	Chg. in %
Bricks & Tiles Western Europe	6,130	6,420	6,227	-3
Bricks & Tiles Eastern Europe	2,747	2,618	2,516	-4
Bricks & Tiles Europe	8,878	9,038	8,743	-3
Pipes & Pavers Western Europe	33	470	1,604	>100
Pipes & Pavers Eastern Europe	1,029	1,052	1,440	+37
Pipes & Pavers Europe	1,062	1,522	3,044	+100
North America	1,104	1,127	1,064	-6
Holding & Others	252	206	209	+1
Wienerberger Group	**11,296**	**11,893**	**13,060**	**+10**

1) Steinzeug-Keramo is included in the Pipes & Pavers Western Europe Segment beginning in December 2010.
2) Pipelife is included as of June 2012.

Higher number of employees in all functional areas



The Pipelife consolidation led to an increase in the number of employees in all functional areas during 2012. This development was evident, above all, in administration and sales because Pipelife operates through direct sales organizations in a number of countries.

Ø Employees by functional area

Full-time equivalent	2010 [1]	2011	2012 [2]	Chg. in %
Production	7,604	8,048	8,673	+8
Administration	946	980	1,142	+17
Sales [3]	2,746	2,865	3,245	+13
Total	**11,296**	**11,893**	**13,060**	**+10**

1) Steinzeug-Keramo is included in the Pipes & Pavers Western Europe Segment beginning in December 2010.
2) Pipelife is included as of June 2012.
3) Employees in sales, marketing and warehousing

Classification of employees by type of employment *in %*

1 Full-time 93%
2 Part-time 3%
3 Temporary (incl. limited contracts) 4%

Of the total workforce employed by the Wienerberger Group as of December 31, 2012, 93% were full-time and 3% part-time. Temporary employees and persons with limited employment contracts therefore represented 4% of the total.

Employee Turnover

Employee turnover

The restructuring programs implemented in recent years in the Bricks & Tiles segment as a reaction to the difficult market environment have led to repeated, substantial increases in employee turnover. The conclusion of the first measures at year-end 2010 was followed by brief stabilization in the workforce, but the necessary implementation of further restructuring measures in 2012 caused another rise in turnover. In spite of this development, the average length of service equals a relatively long 12.9 years and represents a clear vote of confidence by employees in favor of their employer.

A detailed analysis of employee turnover shows the different effects of the restructuring programs on the individual divisions. The Bricks & Tiles Europe Division reported the largest increase, with turnover rising from 6.6% in 2011 to 10.3% in 2012. This development is explained, above all, by the higher number of employees leaving companies in the Bricks & Tiles Europe Division as a result of the increased restructuring measures. The Pipes & Pavers Europe Division remained stable in year-on-year comparison. The Holding and Others Division was the only segment to report a sharp drop in turnover of 5 percentage points to 9.3% in 2012, which reflected the lack of involvement in restructuring measures. The employee turnover rate for the Wienerberger Group rose from 7.5% to 10.6% in 2012, above all due to the higher turnover in the Bricks & Tiles Europe Division.

Turnover rate by operating segment [1] *in %*	**2010**	**2011**	**2012**
Bricks & Tiles Western Europe	8.1	5.5	7.8
Bricks & Tiles Eastern Europe	20.9	9.1	16.3
Bricks & Tiles Europe	12.0	6.6	10.3
Pipes & Pavers Western Europe	-	1.4	7.5
Pipes & Pavers Eastern Europe	15.2	17.4	14.5
Pipes & Pavers Europe	15.2	11.6	11.4
Holding & Others	13.8	14.3	9.3
Total, excluding North America	**12.3**	**7.5**	**10.6**
North America [2]	16.3	26.7	26.1

1) Turnover rate: ratio of persons leaving the Wienerberger Group (termination by the employee or employer as well as mutually agreed terminations) to the average number of employees in permanent employment; excluding temporary workers as well as workers with limited contracts; persons who retire or are on official leave are not included.
2) Analysis limited by special local legal regulations

1,295 employees left the company in 2012

A total of 1,295 employees left the Wienerberger Group in 2012, whereby the restructuring program led to the reduction of 492 jobs. The remaining 803 employees included 669 men and 134 women (excl. the North America Division). A classification by age shows the following results: 180 of these employees were under 30 years of age; the largest decline (-454) was recorded in the age group of 30 to 50 years; and 169 employees over 50 years left the company.

Diversity and Equal Opportunity

The principles of sustainable human resources management at Wienerberger ensure that all employees have the same rights and opportunities independent of age, gender, culture, religion, origin and political views. Wienerberger does not tolerate any form of discrimination whatsoever. Since the start of data collection by HR local management on possible discrimination, no such incidents were reported.

No reports of discrimination since start of data collection

Gender

Wienerberger traditionally has a high share of male employees because of its concentration on production (heavy industry). Special efforts are therefore in progress to increase the share of women, above all in non-production areas, e.g. administration, sales and management. One of the implemented measures involves preferential treatment for women in new appointments when candidates' qualifications are identical. The share of women in **senior management** for the Wienerberger Group currently equals 8%, and **the goal is to increase this indicator to 20% by 2020.** The share of women rose slightly in all functions during 2012 to 13.7% at year-end (2011: 12.6%). **We want to increase the share of women to more than 45% in administrative functions and to 30% in sales functions by 2020.**

Share of women rose slightly in 2012

Share of women by function [1] *in %*	**31.12.2010**	**31.12.2011**	**31.12.2012**
Production	4.5	4.1	4.3
Administration	47.4	43.7	44.3
Sales [2]	24.2	24.2	24.3
Total	**13.3**	**12.6**	**13.7**

1) Temporary employees and persons with limited employment contracts are not included.
2) Employees in sales, marketing and warehousing

Age

The long average length of service with the company is also reflected in the age structure of our workforce. In 2012 58% of the employees were between 30 and 50 years old, 11% were younger than 30 years and 31% over 50 years. These indicators have not changed significantly in recent years. We are particularly interested in the training and education of young people. In Bricks & Tiles Germany we increased the number of apprenticeships by nearly 20% in 2012 and are planning a further increase in 2013.

58% of employees are between 30 and 50 years old

Cultural Diversity

Corporate cultural identity strengthened by regional appointments

As a multinational corporation, Wienerberger believes in respect for local cultures and the support of diversity. We see regionally recruited teams as an important success factor, not least because of the local nature of our products and markets. Our human resources planning is therefore directed to the employment of local workers, plant supervisors and managers to ensure that the Group viewpoint also includes a focus on the local markets and regions. Job rotations strengthen the internationality of Group management and allow for better insight and new perspectives in many areas. This cultural diversity and these decentralized structures have a positive influence on Wienerberger's corporate cultural identity.

Occupational Safety and Health

Safety initiative focused on increased awareness and change in behavior

Wienerberger acknowledges its responsibility to provide safe working conditions and to protect the health of employees. A safety initiative was launched in 2010 to ensure the implementation of uniform safety standards throughout the Group in order to significantly reduce the number of accidents. In a number of companies, the program was initially connected with investments in protective equipment. The completion of this first important step has been followed by measures to create a greater awareness for safety among all employees and, through a change in working habits over the long-term, prevent accidents. As part of this process, the safety targets defined by the Group were broken down to the plant level in the individual regions. Specific safety targets are defined for each plant and must be reached within a defined time period. These goals are set in agreement with the respective plant managers and represent an element of variable remuneration. In addition to the legal regulations applicable in some countries, the Wienerberger safety standards call for the installation of an occupational safety committee, the assignment of responsibilities and the introduction of comprehensive training. A toolbox of successfully implemented, best practice examples is available to help the plant managers select the optimal measures to reach their goals.

Occupational safety has top priority for Wienerberger. As part of our safety initiative, we continuously train our employees to create a greater awareness for this important issue.

CHRISTOF DOMENIG *(Deputy CEO Bricks & Tiles Europe Division)*

SHE reporting records all accidents that lead to the loss of at least one working day. The most common cause of accidents is carelessness. Since the issue of safety was handled differently throughout the Group prior to the start of the safety initiative, activities were initially directed to the countries and regions with the greatest potential for improvement. The commitment of local management supported the fast implementation of recommended measures and led, in part, to a significant reduction in accidents, especially in Italy, Bulgaria and Romania. Both the frequency and severity of accidents have declined significantly in all divisions since 2010. We have made substantial progress in the area of occupational safety over recent years, but have still not reached our goal to completely avoid accidents. **In a first step, we want to reduce the frequency of accidents to less than 10 per million hours worked by 2015.**

Decline in accident frequency from 20 in 2010 to 12 incidents per million hours worked in 2012

Accident frequency by operating segment [1]	2010	2011	2012
Bricks & Tiles Western Europe	27	22	17
Bricks & Tiles Eastern Europe	15	11	8
Bricks & Tiles Europe	23	19	14
Pipes & Pavers Western Europe	-	29	17
Pipes & Pavers Eastern Europe	20	13	7
Pipes & Pavers Europe	20	17	10
North America	4	4	3
Holding & Others	8	10	4
Wienerberger Group	**20**	**17**	**12**

1) Accident frequency: number of work accidents / number of hours worked x 1,000,000; including temporary employees and persons with limited employment contracts

The Bricks & Tiles operations in Italy reduced the accident frequency from 52 in 2011 to 9 for the reporting year. This outstanding development resulted from the implementation of a strict safety management system. After an in-depth risk assessment, the initial problems were solved with safety investments, the posting of safety instructions in all production areas and intensive training courses on occupational safety. All Italian plants received the internationally recognized OHSAS 18001 certification in May 2012. Plans call for the immediate analysis of all future accidents in a personal discussion to prevent further incidents.

Bricks & Tiles Italy cuts accident frequency from 52 to 9

The severity of accidents, which is measured as the number of days lost per million hours worked, fell sharply from 470 in 2011 to 308 in 2012 for the entire Wienerberger Group. Only the North America Division recorded a slight year-on-year increase due to two severe accidents that resulted from carelessness. Despite these positive developments at the Group level, two tragic fatal accidents unfortunately occurred during the reporting year. Industrial accidents at a brick plant in Belgium and a concrete paver plant in Romania resulted in the death of two employees. We immediately investigated the reasons and made the information available to all plants to prevent similar accidents in the future.

Decline in accident-related days lost from 470 to 308 per million hours worked

Accident severity by operating segment [1]	2010	2011	2012
Bricks & Tiles Western Europe	555	472	396
Bricks & Tiles Eastern Europe	588	584	385
Bricks & Tiles Europe	566	507	393
Pipes & Pavers Western Europe	-	427	402
Pipes & Pavers Eastern Europe	481	699	148
Pipes & Pavers Europe	481	632	240
North America	95	76	100
Holding & Others	330	103	4
Wienerberger Group	**496**	**470**	**308**

1) Severity of accidents: accident-related days lost / number of hours worked x 1,000,000; including temporary employees and persons with limited employment contracts

STOP™, an accident prevention instrument for Pipelife plants

Pipelife has followed a zero accident strategy for many years. One of the most important measures to reach this goal is STOP™ (Safety Training Observation Program), a program that supports accident prevention. Employees use STOP cards to identify hazards and report occupational safety issues to the responsible managers. The entire workforce is therefore actively involved in eliminating potential dangers. These measures are intended to sustainably improve working conditions and reduce the frequency of accidents, while also creating a better awareness among employees for safe behavior.

Future project "Safety at Semmelrock"

Semmelrock announced plans to launch a new safety program "Safety at Semmelrock" in mid-2013. Work on the first goals started before the official kick-off and includes, above all, the implementation of the AIRS reporting system ("Accident Investigation Report Semmelrock") to centrally document, analyze and administer all accidents and incidents in the future.

Annual safety coaching and training at Steinzeug-Keramo

Steinzeug-Keramo has reduced accidents with annual safety training programs that are specifically designed for each workplace as well as an additional offering of courses on occupational safety and accident prevention.

Health protection measures

The Wienerberger Group offers regular physical examinations and vaccination campaigns to prevent illness. Employees can call on company medical staff and arrange for ergonomic workplace analyses. Support for fitness is also important. For example, events and outings for employees in Austria are frequently connected with sporting activities. Other measures include reduced fees for health club memberships and special exercise courses to prevent vertebral problems.

Average of 10.6 sick-leave days per employee

The average number of sick-leave days equaled 10.6 days per employee in 2012. This indicator remained within the range of 9.9 and 11.4 days that is based on the data collected since 2007.

Sick-leave days per employee by operating segment [1]	2010	2011	2012
Bricks & Tiles Western Europe	10.3	10.9	11.2
Bricks & Tiles Eastern Europe	10.1	9.0	9.2
Bricks & Tiles Europe	10.3	10.3	10.6
Pipes & Pavers Western Europe	-	9.4	10.0
Pipes & Pavers Eastern Europe	8.0	10.5	11.9
Pipes & Pavers Europe	8.0	10.1	11.0
Holding & Others	3.8	3.8	3.6
Total, excluding North America	**9.9**	**10.1**	**10.6**
North America [2]	2.2	2.6	3.0

1) Including temporary employees as well as persons with limited employment contracts
2) Analysis limited by special local legal regulations (on sick-leave days)

Protection against Respirable Crystalline Silica

Protection against respirable crystalline silica

In the Wienerberger Group, only the employees in the ceramic plants are exposed to respirable crystalline silica. The protection of these employees has top priority, whereby our goals are to minimize the respirable crystalline silica emissions from brick production and create an increased awareness of the need for careful handling. The central office at the EU level is the European social dialogue between employees and employers under the direction of the European Commission, in which Wienerberger has been active for many years.

NEPSI (Negotiation Platform on Silica) used for EU surveys

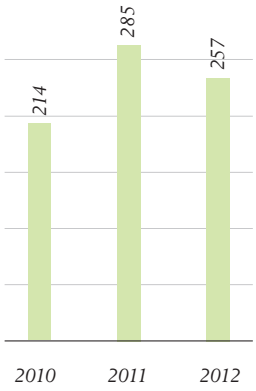
The EU has collected comprehensive data on respirable crystalline silica from the involved branches in all member states since 2008. This survey is conducted every two years through NEPSI (Negotiation Platform on Silica), a shared online platform. There was no survey conducted in 2012, but the results of the latest survey can be found in our 2011 sustainability update, which is available for download on our homepage. The NEPSI system collects data, among others, on potential dangers to employees, health controls, training, the implementation of organizational measures, the distribution and use of protective equipment (e.g. the mandatory use of protective equipment) and technical measures such as the enclosure of involved production lines. Wienerberger collects relevant data on all involved Group plants that are located in the EU.

Annual internal survey planned in future

The issue of **respirable crystalline silica** emissions not only concerns our plants in the EU but all our production facilities, and we have consequently started to implement the NEPSI standard at other plant locations. Data has been collected to date from 84% of the Wienerberger plants, and **the goal is to reach a coverage rate of over 95% by 2020.** Future plans include the collection of data for the NEPSI survey as well as annual internal surveys through a separate query system. This should further improve transparency at the Group level. As announced in the previous year, the data in next year's sustainability report will also cover Norway, the plants in the USA and Steinzeug-Keramo.

Training and Personnel Development

Training



12.8 training hours per employee

At Wienerberger, we believe in advancing and supporting our employees as well as creating a climate that encourages the cross-border exchange of knowledge. An average of 12.8 hours per employee was spent on training in 2012. This indicator includes both internal and external programs, but excludes on-the-job training. The number of training hours per employee declined in the Bricks & Tiles Europe Division due to the end of the Sales Academy program. In the Holding & Others Division, cost reduction measures led to a decline in the number of training hours. In particular, the use of external training courses was substantially reduced during the reporting year. This cutback is also reflected in the total number of training hours for the Group.

Average training costs of € 257 per employee

The average training costs per employee equaled € 257 in 2012, compared with € 285 in 2011. The decline in this indicator resulted from an increase in the internal training offering as well as a reduction in the total training hours per employee.

Average training costs per employee *in €*

Training hours per employee and operating segment [1]	2010	2011	2012
Bricks & Tiles Western Europe	12.0	18.4	17.6
Bricks & Tiles Eastern Europe	19.2	16.8	14.4
Bricks & Tiles Europe	13.6	17.6	16.8
Pipes & Pavers Western Europe	-	4.8	8.0
Pipes & Pavers Eastern Europe	4.0	7.2	4.8
Pipes & Pavers Europe	4.0	6.4	6.4
North America	2.4	11.2	11.2
Holding & Others	23.2	36.8	14.4
Wienerberger Group	**12.0**	**16.0**	**12.8**

1) Including internal and external training programs; based on headcount

Sales Academy to professionalize marketing and sales activities

In the Bricks & Tiles Division, Wienerberger has developed from an expansion-driven to a market-oriented company in recent years. One of our key corporate goals is to intensify our marketing and sales activities, and thereby strengthen our customer ties. In order to provide the best possible support for making this goal reality, the Sales Academy training offensive was launched in 2010. The program is designed to strengthen and improve selling activities in the local organizations through the creation of a know-how network and the international exchange of ideas.

Engineering Academy: training and international exchange of know-how by engineering personnel

The Bricks & Tiles Division also offers other internal and external training programs that give employees an opportunity to continue their professional and personal development. Of special note is the Wienerberger Engineering Academy, which was established as a permanent facility to provide internal training in various technical areas and thereby create a sustainable competitive advantage in production. The academy offers different programs: basic modules, the Engineering Academy Advanced and the Plant Manager Course. In the basic modules, our experts transfer their international know-how on raw materials, processing, drying and firing technology as well as quality analysis to engineering employees. The Engineering Academy Advanced was developed in 2010 as a platform for the exchange of information between experienced and younger engineers on strategic issues such as plant and process optimization as well as energy and cost efficiency. In the Plant Manager Course, key employees from the production area are provided with general training. The main focal points include process optimization, basic financial management and personal development. The design of the modules for the plant manager course is also based on international know-how exchange and networking.

We believe in the development and advancement of our employees. Through specially designed programs and individual measures, we support targeted development steps.

MAREN FELLNER *(Corporate HR Manager)*

Ready4Excellence: training and international know-how transfer

A number of cross-divisional training measures were also implemented in recent years. Together with parts of the Pipes & Pavers Division, a four-module Ready4Excellence program for international key people was launched in May 2012 with 22 colleagues from 12 Wienerberger countries. This program is designed to communicate content and instruments based on Wienerberger's requirements. Its objective is to support international professionalization – above all with respect to instruments and processes – and ensure targeted support for the implementation of the Wienerberger strategy. Other topics include communications and familiarization with our feedback philosophy to support personal growth and the continuous development of the corporate culture. The knowledge transfer from these modules is not only interesting for Wienerberger employees, but also for non-company persons. For this reason, Wienerberger allocated three places in last year's program to the aid organization Concordia, which provides shelter for homeless children in Romania, Bulgaria and the Republic of Moldavia.

Pipelife Business School, Pipelife University and Pipeschool

The Pipes & Pavers Division also offers training programs that concentrate on specific problems related to plastic pipes. The Pipelife Business School is a one-year training program that covers modules on management, communications, project management, self-management and finance. Selected Pipelife employees are given an opportunity to expand their knowledge in these areas and to apply this know-how in specific projects. In addition, the Pipelife University L6S and the Pipelife Pipeschool are open to all employees. L6S is a training course for employees who are involved in the implementation of Lean Six Sigma. This well-known management system is focused on the delivery of qualitatively faultless products and services that completely and profitably meet customers' needs. The Pipelife Pipeschool is an online learning platform that offers lessons on general Pipelife subjects, Pipelife products, 5S and visual management.

Personnel Development and Succession Planning

Talent management to identify and advance future managers

The structures and processes for professional talent management in the Wienerberger Group were defined during 2012, and the first specific measures have already been implemented. The goal of this program is to identify and develop qualified men and women for positions in key management functions. In this way motivated employees with suitable potential receive an opportunity for further development, while Wienerberger is able to fill management positions internally and also maintain its high management standards. In recent years, many graduates of the previous Ambassador Program have assumed managerial roles or key positions in local companies.

Annual assessment of all employees and support for international mobility

Personnel development also includes annual appraisals of all employees as well as the annual management review. The latter serves to evaluate senior management and supports strategic succession planning for positions at this level. International mobility is promoted by means of corresponding expatriate packages and comprehensive support on relevant issues by the local HR departments and corporate HR.

Satisfied employees as key success factor

The wide range of measures implemented in the areas of training and personnel development plays an important role in establishing and maintaining employee satisfaction. Well-trained and satisfied employees are a key success factor for Wienerberger. Employee satisfaction is also reflected in the relatively high average length of service – 12.9 years – which represents a clear vote of confidence by employees in favor of their employer.

Remuneration

Income that provides a secure livelihood

The Wienerberger Social Charter states that employees are entitled to receive wages, salaries and benefits in line with the normal payment for similar jobs in similar branches or industrial sectors in the region where the work is performed and that this remuneration should be sufficient to provide for a secure livelihood. Our employees are paid at or above the legal minimum wage or the minimum income defined by applicable collective bargaining agreements.

Long-term remuneration model for top management

Management compensation at Wienerberger includes both a fixed and a variable component to increase motivation and strengthen identification with corporate goals. The variable component is based on short-term remuneration as well as medium- to long-term remuneration within the framework defined by the long-term incentive (LTI) program. The short-term variable component for 2013 will be paid out over two years, whereby the second payment is dependent on the attainment of an additional goal. This modus strengthens the link between the short-term bonus and sustainable management. Additional information on the remuneration model is provided in our 2012 annual report (annualreport.wienerberger.com).

Group-wide guideline for design of local incentive systems

A group-wide guideline forms the basis for local incentive systems. Local circumstances (e.g. government minimum support programs) are taken into account and the rules are adapted to meet the respective market conditions. In addition to company pension plans, disability insurance and health insurance, the Wienerberger employees and managers are also covered by travel insurance.

Industrial Relations

Wienerberger Social Charter

The Wienerberger Social Charter was signed in 2001 by the Managing Board of Wienerberger AG and the chairman of the European Employees' Council in Strasburg to formally confirm the company's intent to comply with the relevant agreements and recommendations of the International Labor Organization (ILO). With this charter, Wienerberger demonstrates its global commitment, among others, to human rights, to sufficient remuneration, against excessive working hours, to permanent employment and to respect for the freedom of association and the right to collective negotiations.

Installation of European Employees' Council in 2011

The European Employees' Council was founded in 2011 on the basis of the European Forum, a social partnership board. It addresses European issues such as strategy, investments, reorganization and rationalization measures. The goals of the European Employees' Council are constructive social dialogue and the creation of networks for employees' representation committees. Currently, 10 countries are represented by 26 delegates. The steering committee of the European Employees' Council is headed by Karl Sauer and includes five elected delegates from Austria, the Netherlands, Germany and Poland. The European Employees' Council meets twice and its managing board at least twice per year. Appropriate adjustments to the European Employees' Council are planned to reflect the acquisition of Pipelife.

Improvement of workplaces and health protection

The most important objectives of the European Employees' Council are to improve workplace conditions and health protection. Another concern is to reduce the physical burden for older employees as a result of the increasing retirement age by providing jobs that require less physical labor. This has already been realized at some Wienerberger locations. The European Employees' Council also works to achieve fair and just remuneration.

National employees' councils based on Austrian example

In Austria, for example, employees' councils have been installed at all locations. There are 54 employee representatives. These representatives elect a central council, which consists of four persons and is headed by Karl Sauer. Elections for the employee representatives and the central council are held every four years. The employee representatives hold one conference each year, while the central council meets at least four times or more often as needed. Similar structures can be found in other European countries.

Company agreements, collective agreements or at least legal requirements

Different regulations apply to employees in Europe, including collective bargaining agreements, laws and directives, union contracts and company or individual employment agreements. All employee representatives of Wienerberger AG are located in countries that recognize the right of employees to free assembly and collective negotiations.

Future Measures

Implementation of Group-wide HR standards

Group-wide HR standards will be introduced in order to ensure uniform practices. In addition, talent management and the training programs for sales management will be expanded.

Respirable crystalline silica: internal survey system in addition to NEPSI and integration of further plants

Plans for 2013 include the annual collection of relevant data on respirable crystalline silica with a separate query system to further increase transparency at the Group level. Additionally, as announced in the previous year, the survey on respirable crystalline silica will be expanded for the 2013 sustainability report to cover the plants in Norway and the USA as well as Steinzeug-Keramo.

Further measures to improve workplace safety

Additional measures will also be implemented to improve workplace health and safety. Among others, Semmelrock is expected to launch its new program "Safety at Semmelrock" in mid-2013. Data collection in the plants will then be used to design future measures and start specially designed safety programs.

Specific long-term goals for the future

Wienerberger has set a number of long-term goals in the area of human resources: to increase the share of women by 2020 to 20% in the Group's senior management, to more than 45% in administrative functions and to 30% in sales functions, to reduce the accident frequency to less than 10 per million hours worked by 2015 and to expand data collection on respirable crystalline silica to cover more than 95% of the relevant Group plants by 2020.

Environmental Protection in Production

Principles of Sustainable Production

Production in harmony with the environment

Environmental protection in production is a matter of great importance to Wienerberger. We are well aware that industrial production processes always involve a certain degree of interference with the natural environment. Our goal is to minimize the environmental impact of our production processes. The responsible interaction with clay extraction sites, the best possible conservation of resources and an increase in the share of recycling materials are the central principles of our sustainable production.

Responsible clay extraction and professional restoration of mining sites

The use of recyclable raw materials and ***the responsible interaction with clay extraction sites*:** The methods used by Wienerberger to extract and process clay, the recyclable raw material that is used for our ceramic products, are designed to minimize the impact on the environment and to conserve resources. Responsible interaction with clay mining sites means preventing negative effects on neighboring residents during extraction (in the form of noise or dust) as well as protecting the environment (e.g. by maintaining local biodiversity). The clay reserves in our extraction sites are used to the greatest extent possible. Responsible interaction with clay extraction sites at the end of their useful life means professional restoration – often in cooperation with environmental NGOs like the WWF – or transfer to another use. Specifically designed restoration concepts allow for the ecologically friendly utilization of exhausted clay pits and often help to increase biodiversity.

Resource conservation in the production of ceramic products ...

Greatest possible conservation of resources: The conservation of resources starts at the beginning of the production chain. Our ceramic plants generally process local raw materials like clay, loam and sand. Since the clay pits are usually located close to our production facilities, transport routes tend to be short. The use of these resources is optimized continuously, while product quality is maintained or improved at the same time. These results are achieved, for example, with the use of recycled ceramic materials. Another important resource for the ceramic production process is energy, which generates the high temperatures required for drying and firing. We work to make these processes as environmentally compatible as possible by optimizing our production technology and using renewable energy sources.

... as well as plastic pipes

Resource conservation is also a focal point in the production of our plastic pipes. We work to reduce product weight and increase the share of recycling materials in the mix, while maintaining the same high level of quality. Energy consumption plays a less important role in the production of plastic pipes than in our ceramic business. However, a comparatively large amount of water is required to cool this production machinery. Our goal is to minimize water consumption, above all the amount of water drawn from public supply networks.

Processes and Instruments for Sustainable Production

Research and development

R&D in production is a focus of strategic planning

Research and development (R&D) form an integral part of strategic planning at Wienerberger and represent key activities for the Group. In these areas we work to optimize production processes and to continuously improve and develop our products and system solutions. R&D at Wienerberger is managed centrally in the individual business units, but implemented locally based on close cooperation between the various R&D departments and on-site management and engineers. This ensures the fast and efficient rollout of successful developments throughout the Group. In 2012 R&D expenditures in the Wienerberger Group amounted to € 9.0 million.

Process optimization to improve sustainability of ceramic products

The improvement of production processes represents the main focus of research for our ceramic products. A central engineering department is working, above all, on projects to reduce energy consumption. Drying and firing comprise a significant amount of the energy requirements for our production, and many assignments therefore concentrate on optimization in this area. Other research projects involve resource conservation in production, the responsible processing of raw materials and the use of recycled materials.

Use of recycling materials and reduction in weight of plastic pipes

R&D activities for plastic pipes are located at our research center in the Netherlands, which works together with universities and external experts from various disciplines. Research is concentrated on the refinement of formulas for the raw material mix and the optimization of the production process. Our production-related projects target the increased use of recycled products as raw materials and the reduction of product weight.

Research projects for our concrete pavers are focused on the composition of raw material mixtures and, above all, on the reduction of the cement content.

Environmental Management

Ecologically relevant aspects in QMS

The environmentally relevant aspects of our workplaces, e.g. the management of waste and residual materials or the prevention of noise and dust emissions, were integrated in the existing quality management systems (QMS). The QMSs in nearly all plants are certified according to ISO 9001. The criteria defined in the QMS form the starting point for the demands on production and the related processes. Environmental officers ensure the implementation of the relevant standards. A number of plants have been certified according to ISO 14001, but there are no plans for additional Group-wide certification under ISO 14001 or EMAS. Wienerberger believes the current QMS provides appropriate control and management for processes and their environmental impact.

Technical Controlling System

Production data collected by technical controlling system

A technical controlling system has been implemented in all production areas of the Wienerberger Group. This system collects the production-related data required for controlling activities and internal benchmarking among the plants. Statistics are compiled on production volumes, product quality, machine efficiency, energy consumption and, if relevant, CO_2 emissions. The resulting analyses indicate the effectiveness of measures implemented to reduce the environmental impact of our production processes.

Key Data on Sustainable Production

Energy Consumption

The key data presented in this sustainability report were adjusted to reflect the new corporate structure. The following statistics therefore cover the entire Wienerberger Group, including our pipe activities. This data includes our ceramic pipe activities starting in 2011 and our plastic pipe activities beginning in June 2012.

Energy consumption *in MWh*	**2010**	**2011**	**2012**	**Chg. in %**
Natural gas	6,062,614	6,457,081	5,541,640	-14
Coal	234,629	248,541	186,663	-25
Heating oil	112,178	104,529	90,783	-13
Liquid gas	70,591	75,715	62,338	-18
Electricity	800,985	841,240	863,372	+3
Wienerberger Group	**7,280,997**	**7,727,106**	**6,744,796**	**-13**

Energy consumption declined by 13%

Energy consumption in the Wienerberger Group declined by 13% year-on-year in 2012, despite the initial consolidation of the Pipelife Group. This development resulted, above all, from a decline in natural gas consumption. Natural gas is used primarily in ceramic production to generate the high temperatures required for the firing process. The decline in the use of natural gas during 2012 can be explained by a 9% volume decrease in the Bricks & Tiles Europe Division and an improvement in specific energy consumption in the clay block, clay roof tile and ceramic pipe product groups. We are currently working on projects to identify other energy sources as substitutes for coal and heating oil in order to reduce CO_2 emissions and costs. The slight rise in electricity consumption resulted from the initial consolidation of Pipelife, where the production process is driven almost entirely by electrical energy. Renewable energy sources as a share of total electricity consumption declined from 43% in the prior year to 31% in 2012 due to the inclusion of the pipe business.

Index of specific energy consumption	**2010**	**2011**	**2012**	**Chg. 2011 in %**	**Chg. 2010 in %**
Wall	100	95	89	-6	-11
Roof	100	93	84	-9	-16
Facade	100	96	98	+2	-2
Ceramic pipes	100	90	82	-9	-18
Ceramic Segments	**100**	**95**	**91**	**-4**	**-9**
Plastic pipes	100	100	98	-2	-2
Concrete pavers	100	108	96	-12	-4
Wienerberger Group	**100**	**97**	**92**	**-5**	**-8**

The specific energy consumption in the above table represents a historical comparison of the individual product groups and therefore differs from the consolidation range of the Wienerberger Group. This sustainability report uses 2010 as the basis for the specific energy consumption index (based on kWh/ton), which forms the starting point for the following goal.

By 2020 we want to reduce the specific energy consumption in ceramic production by 20% below the 2010 level. This is a very ambitious target, since we have already reduced energy consumption significantly during the past 10 to 15 years. We have made sound progress in clay block, roof tile and ceramic pipe production in recent years, but our efforts in the facade brick area are just beginning.

CO_2 Emissions

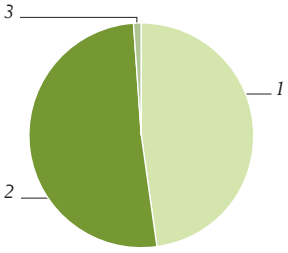
Data collection on CO_2 emissions is based on the method defined by the European Union Emissions Trading Scheme (ETS system), which only records direct CO_2 emissions. Accordingly, only the CO_2 emissions from our ceramic production (bricks and ceramic pipes) are relevant. The CO_2 emissions from primary energy sources change in line with energy consumption, while the emissions from the production process result from raw materials and in the case of clay blocks from the use of pore-forming agents. Electrical energy is used in the production of plastic pipes and concrete pavers, and the related CO_2 emissions are attributable to the electric power producer.

CO_2 emissions *in tons*	**2010**	**2011**	**2012**	**Chg. in %**
From primary energy sources	939,826	960,269	829,176	-14
From the production process	561,545	688,421	562,455	-18
Total – within the ETS [1)]	**1,501,371**	**1,648,690**	**1,391,631**	**-16**
Plants outside the ETS [2)]	**400,356**	**461,343**	**442,442**	**-4**
From biogenic added materials [3)]	305,870	310,492	280,098	-10

1) Source: Community Independent Transaction Log (CITL)
2) Calculated in accordance with national rules (Switzerland) or based on EU standard emission factors. Only the CO_2 emissions from the firing of primary energy sources are included for the plants in the USA.
3) Volumes from Wienerberger CO_2 monitoring in accordance with national rules

The following data on specific CO_2 emissions (based on kg CO_2/ton) represents a historical comparison of the individual product groups. The slight increase in CO_2 emissions for clay blocks is related to raw material process emissions, which are nearly impossible to reduce, and to a shift in the product mix to high thermal insulating blocks, which require more pore-forming agents.

However, our goal is to reduce the specific CO_2 emissions from ceramic production 20% below the 2010 level by 2020. This is also a very ambitious target because we have already reduced CO_2 emissions significantly during the past 10 to 15 years.



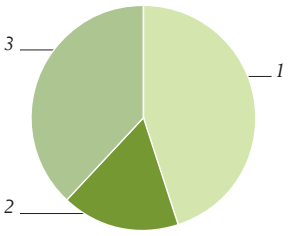
Index of specific CO_2 emissions	2010	2011	2012	Chg. 2011 in %	Chg. 2010 in %
Wall	100	101	101	0	+1
Roof	100	95	85	-10	-15
Facade	100	100	102	+1	+2
Ceramic pipes	100	91	87	-4	-13
Wienerberger Group	**100**	**100**	**99**	**-1**	**-1**

Waste

Statistics for 2012 show 133,600 tons of waste for Wienerberger. The year-on-year increase (the prior year data were adjusted to reflect the inclusion of Steinzeug-Keramo) is attributable to the initial consolidation of Pipelife. Most of this (nearly 100 %) is non-hazardous waste that is collected and recycled or disposed. The only hazardous waste includes relatively small amounts of workshop waste (oily rags) and oil separator contents (from refueling stations).

Waste *in tons*	2010	2011	2012
Wienerberger Group	116,894	132,433	133,600

Total waste 2012
in %



1 Non-hazardous, recyclable 48%
2 Non-hazardous, deposited 51%
3 Hazardous 1%

Water Consumption

Statistics on the specific water consumption in m³/ton for each product group are presented for the first time in this sustainability report. Water consumption plays a limited role in the production of ceramic products, but comparatively large amounts of water are required to cool plastic pipes after extrusion. The specific water consumption was reduced substantially in 2012, above all for plastic pipes and concrete pavers.

Specific water consumption *in m³/ton*	2010	2011	2012	Chg. in %
Brick products	0.163	0.183	0.180	-2
Ceramic pipes	0.225	0.241	0.242	0
Plastic pipes	4.830	4.673	4.476	-4
Concrete pavers	0.056	0.057	0.047	-17

Water usage by source
in %

1 Water from public networks 45%
2 Water from plant wells 17%
3 Water from ponds (rainwater) 38%

The total water consumption in the Wienerberger Group rose by 21% to 3.2 million m³ in 2012 due to the initial consolidation of Pipelife. We attempt to use water that comes primarily from our own wells or ponds (rainwater). In 2012 the volume of water drawn from public supply networks decreased to 45% due to the initial consolidation of plastic pipe activities. **In order to make our efforts measurable, our goal is to reduce the share of water drawn from public supply networks to 40% by 2020.**

Water consumption		2010	2011	2012	Chg. in %
Wienerberger Group	*in mill. m³*	2.2	2.7	3.2	+21
From public supply networks	*in %*	54	48	45	-

Ceramic Production

Responsible clay extraction and professional restoration of mining sites

Resource conservation starts at the beginning of the ceramic production chain. The most important raw material for our ceramic products (clay blocks, facing bricks, roof tiles and ceramic pipes) is the recyclable raw material clay. Wienerberger places high value on protecting endangered animal and plant species as well as rare, sensible ecosystems. The greatest possible conservation of resources in clay extraction is just as important as the expert restoration of former clay mining sites. There are generally several possible alternatives for the restoration of clay pits, e.g. conversion for agricultural use, residential or commercial construction, nature conservation or use as recreational areas. Wienerberger works to return former clay mining sites to nature wherever possible, since these restored areas often become substitute habitats for protected animal and plant species that would otherwise be lost.

Short transport routes from clay pits to plants

Since the clay pits are usually located close to our production facilities, transport routes tend to be short. After extraction, the clay is prepared through a grinding and milling process. Water, sand and, for some products, pore-forming agents (e.g. sawdust, paper fiber) are then added. Wienerberger has issued a group-wide guideline for the use of additives. It ensures that our plants only use additives that meet local environmental requirements and applicable health and legal regulations.

Drying and firing process

After brief storage in a mud house, the clay is ready for shaping. It is pressed through dies into the desired shape by extruders or compressed into forms. The cut products are then transported on palettes to the dryer. The drying process removes the moisture from the soft products and prepares them for firing. Depending on the type of the product, the drying period lasts between four and 45 hours. The moisture content drops to below 2% during this time. After drying the products are transferred to a kiln, where they are fired at a temperature of 800 to 1,200°C over a period of six to 36 hours. The drying and firing time can be longer for technically demanding products. Firing gives the products a permanent strength and makes them permanently nonflammable and fire-safe. In packaging our products, we use particularly thin foils. Transport routes to our customers are short because of our regional, decentralized plant network, which also reduces the impact of our business on the environment.

Energy Consumption and CO_2 Emissions

Thermal energy is used for drying and firing

Most of the energy used in ceramic production is thermal energy (natural and liquid gas, oil or coal). This energy is used mainly to heat the tunnel kilns, whereby the heat released during the cooling process is recovered and returned to the drying process. Electrical energy plays only a limited role in ceramic production (e.g. to mix and prepare the raw materials, for extrusion and grinding and in transportation).

Pilot projects for substitution of fossil energy sources

Energy consumption was lower in 2012, in part because of the decline in production volumes. However, we also implemented a number of measures to optimize the dryer-kiln-heat system and thereby reduced the specific energy consumption for clay block, roof tile and ceramic pipe production. We are also working to substitute alternative fuels for fossil energy sources. A biogas plant was built near one of our ceramic pipe plants, which is fueled with biomass from the surrounding area. This biogas is used to operate a combined heat and power station, and the residual heat is used to dry the clay pipes. At our plant in India, we converted part of our energy sources to biomass during the reporting year, and in Italy and Germany we are using electrical energy generated by our own photovoltaic equipment. In Switzerland and the USA we are gradually replacing heating oil and coal with natural gas, which produces significantly lower CO_2 emissions and is also less expensive.

Environmental Action Plan defines measures to reduce energy consumption

We have defined our goals for energy-efficient, environmentally compatible and resource-conserving production in an Environmental Action Plan (EAP). In particular, it includes our goal to achieve a 20% reduction in specific energy consumption and specific CO_2 emissions in ceramic production by 2020. The core of the EAP is formed by a package of measures to optimize the drying and firing process, optimize the dryer-kiln-heat system, recover heat through the installation of heat exchangers, improve and target thermal insulation, reduce the water content of clay, cut production weight, optimize the raw material mixture, increase the use of biogenic fuels and use stretch foils in packaging. A program to implement these measures was launched at nine plants in Belgium, Germany, the Netherlands and Poland during 2010. The EAP has since been rolled out to 51 plants and will be introduced at other Wienerberger locations in the future. We also invest continuously in technological optimization measures to make our production process as environmentally compatible as possible, above all through the use of renewable energy.

> Our measures to reduce the use of energy in ceramic production, above all through the optimization of the dryer-kiln-heat system, have already produced the first positive results and we now intend to implement this program at other plants in the future.
>
> **JOSEF BIRNGRUBER** *(Head of Process Technology in the Bricks & Tiles Europe Division)*

Goal: 20% reduction in indicators by 2020

Over the coming years these measures should help us to reach our ambitious goals – to achieve a 20% reduction in specific energy consumption and specific CO_2 emissions in ceramic production below the 2010 level by 2020.

Waste and Recycling

Nearly all ceramic production waste is non-hazardous

Nearly all the waste resulting from ceramic production is non-hazardous. It is separated, collected and recycled or disposed. Hazardous waste appears in only very small quantities, e.g. as workshop waste (oily rags).

Recycling materials are added to raw materials mixture

Internal production scrap such as broken or imperfect products can be reprocessed and recycled and is therefore not classified as waste. External recycling materials are used as additives for certain product groups and are generally processed together with the raw material mixture during preparation. Typical recycling materials from biogenic sources include sawdust, hay, sunflower seed shells and paper fiber, which are used to create the pores in clay blocks. In the production of ceramic pipes, we also use rock grain from gravel production and ceramic scrap from the production of clinkers, roof tiles, tiles and other ceramic products that cannot be recycled in these areas.

We now use up to 40% ceramic recycling products in our raw material mixture for specific ceramic pipes. That makes an important contribution to resource efficiency.

GERNOT SCHÖBITZ *(CEO Steinzeug-Keramo)*

Clean separation of materials and awareness in construction industry are required for recycling

External recycling materials can only be used if they are separated correctly when buildings are demolished. Wienerberger works to increase the awareness of construction personnel for recycling and plays an active role in designing a legal and normative framework that will make the use of recycled building materials easier and more economically feasible in the future. Our work is also focused on the recycling of construction rubble as an input for brick production, but also to develop new opportunities for its use (e.g. in landscaping).

Water Consumption

Recycling of water

The use of fresh water and wastewater plays a limited role in the production of ceramic products – clay blocks, roof tiles, facing bricks and ceramic pipes. Many of the Wienerberger plants recycle their process wastewater. This water drains into a collecting tank, is subsequently processed and then reused for clay preparation. Evaporation loss is replaced from public water lines or plant wells. In 2012 the specific water consumption declined slightly in brick production and remained constant for ceramic pipes.

Plastic Pipe Production

PVC, PP and PE as raw material granulates

In the plastic pipe business, our most important raw materials include PVC, PP and PE granulates. We only use materials that do not represent a risk for the environment during the production, use or disposal of the pipes. No plasticizers are used. As a member of local initiatives like Responsible Care in Austria, we regularly evaluate the health, environmental and safety impact of our raw materials and products.

Materials are heated, then shaped with an extruder

The plastic raw materials are first mixed together to create the properties for a specific product group and then heated. The melting process requires a temperature of approx. 200°C, depending on the raw material mixture. The heating takes place directly in an extruder, which presses the hot moldable plastic mass through a die to shape the pipes. In the so-called casing head, a calibrator ensures the desired diameter, which can range from several millimeters up to 2.5 meters. The accessories for our pipes are shaped in forms after the raw materials are heated.

Cooling in water bath and final cutting of pipes

After shaping, the pipes are cooled and hardened in a water bath. The continuous pipe string is then cut to the desired length, whereby a length of up to 600 meters can be produced for certain applications. The pipes are then packed and delivered to the customer. A decentralized network of 27 plastic pipe plants in 27 countries positions us close to our customers and normally provides for short transport routes.

Energy Consumption and CO_2 Emissions

No direct CO_2 emissions from plastic pipe production

Electricity is the main energy source for the production of plastic pipes. It is used to operate the machinery and equipment and heat the granulates. There are no direct CO_2 emissions from plastic pipe production, which is the reason our plastic pipe activities are not registered in the European Emissions Trading System. In 2012 we reduced the specific energy consumption in plastic pipes by 2% with the regular monitoring of energy consumption and optimization measures. At our plant in Turkey, transparent spaces were installed in the roof of the production hall. The resulting inflow of daylight generally eliminates the need for artificial light during the daytime.

Waste and Recycling

Waste plays only a limited role

Waste plays only a limited role in the production of plastic pipes. More than 50% of this waste is recyclable, and is collected and reused.

Goal: Increase in the share of recycling materials

A major goal in the plastic pipe area is to increase the share of recycling products in the raw materials mix. Our research center in the Netherlands is working on projects to increase the use of secondary raw materials, while maintaining the same high product quality. The share of recycling materials per produced ton rose by 11% to approx. 60 kg in 2012.

Pipelife is collection point for recycling materials in Austria

Recycling materials from external sources must first be collected and prepared. Through its membership in national associations, Pipelife plays an active role in creating a greater awareness for the importance of recycling. The Pipelife plants in Austria, for example, serve as collecting points for used pipes and fittings. The Austrian plastic pipe industry set a new record by collecting approx. 1,500 tons of used pipes. That represents CO_2 savings of roughly 9.2 million automobile kilometers.

Water Consumption

Cooling in closed water cycles

Water plays an important role in the production of plastic pipes because it is used to cool the hot extruded products. Our plants generally use closed water cycles and heat exchangers, which prevent the cooling water from becoming contaminated. At a plant in Ireland, our location allows us to use river water in a closed cycle to cool the pipes. This water is returned to the river after the cooling process without any problem.

Water is sourced mainly from company wells and ponds

Pipelife uses water from its own wells or ponds (rainwater) whenever possible. Roughly 80% of the water used in production comes from these sources. In 2012 continuous optimization measures in the water cycle supported a 4% reduction in specific water consumption.

We monitor our water consumption continuously and took a number of steps in 2012 to further reduce the use of external water supplies.

ZORAN DAVIDOVSKI *(Vice President Marketing, Innovation & Sustainability at Pipelife)*

Concrete Paver Production

Cement, sand, rock grain and water are most important raw materials

Concrete is a moldable building product that is made of several basic natural raw materials: cement, sand, rock grain and water. Semmelrock purchases these raw materials from local producers based on pre-defined quality standards.

Pavers are dried at room temperature

The first step in the production of concrete pavers is the mixing of the raw materials. Our research and development activities for the production area are focused on reducing the cement content. After mixing, the concrete is shaped by pressing or pouring. The products are then dried at room temperature over a period of roughly 24 hours. Certain products receive special surface treatment before or after the drying process, such as washing, grinding, sanding or sealing. The finished products are then packaged and delivered to our customers.

Energy Consumption and CO_2 Emissions

No direct CO_2 emissions

The production process for our concrete pavers requires comparatively low amounts of energy to drive the machinery. Electricity, which does not cause any direct CO_2 emissions, is the only energy source used.

Waste and Recycling

Most waste is non-hazardous

Scrap from the production of concrete pavers is returned to production. Broken or imperfect items can normally not be recycled. However, nearly all the waste from concrete paver production is non-hazardous and can be recycled or disposed.

Water Consumption

Water used as raw material and for surface treatment

In the production of concrete pavers, water is used as a raw material and in special surface treatments (e.g. the washing of slabs). Semmelrock recycles part of the washing water into production to minimize wastewater. Most of the plants have implemented a water management system, and our plans call for the step-by-step implementation of water management systems in all plants.

Future Measures

Stronger integration of energy reporting

Plans for 2013 call for the even stronger integration of energy reporting in the SAP system to increase the automated collection of data.

Continued roll-out of measures to improve energy efficiency in ceramic production

In the ceramics area, we will continue to roll out the measures defined in the Environmental Action Plan to reduce energy consumption and CO_2 emissions. The facing brick product group will represent a special focal point for the coming years. We want to make our production processes even more energy-efficient and increase resource conservation in the future.

Cradle to cradle certification for ceramic pipes

All ceramic pipe products will be certified according to the cradle to cradle concept in 2013. This underscores the continuous improvement of our production processes in the interest of sustainability.

Numerous smaller measures for plastic pipes

Numerous smaller measures will be implemented in the plastic pipe area over the coming years, for example to gradually reduce energy consumption by insulating casing heads and thereby preventing heat loss. We will also continue to invest in technological improvements that lead to an increase in energy efficiency.

Sustainable Products

Principles of Sustainable Products

Creation of sustainable value with high-quality building material solutions

A central principle of product development at Wienerberger is the creation of sustainable value for our customers with long-lasting and innovative system solutions. We view sustainability as a function of the service life of a product and its impact on the environment during production, transport, installation, use and disposal. Wienerberger brick products form an integral part of sustainable building concepts. They guarantee a high quality of living and make an active contribution to climate protection. In the area of pipes and pavers we offer system solutions for today's challenges, including the demands on water management resulting from climate change or increasing urbanization.

Energy efficiency and climate protection, raw material efficiency, healthy living, safety and economy as central demands on modern brick construction

Wienerberger's innovative products and system solutions for bricks meet the wide variety of challenges presented by modern, sustainable construction. As a recyclable product made of clay and based on its long service life of up to 100 years, the brick – whether in the form of clay blocks, roof tiles or facing bricks – meets today's demands for ecological, economical and social sustainability like no other building product. In the area of energy efficiency and climate protection, our high thermal insulating clay blocks help building users to reduce energy costs and CO_2 emissions. Complete housing concepts also optimize energy efficiency over the entire product life cycle. Our high thermal insulating clay blocks filled with mineral wool or perlite already meet all EU requirements for 2020. We are continuously increasing the raw material efficiency of our products by optimizing their design to reduce the weight and the amount of materials required, while maintaining or improving the static and thermal insulating properties. Another focal point in this respect is the reduction of energy consumption in production. The high accumulation capacity of brick walls keeps rooms cool in the summer and pleasantly warm in the winter. Our bricks attain excellent values for interior air quality and a healthy room climate, and create lasting value in the form of high-quality, healthy homes. Another closely related subject is safety, an area where our products stand out by providing high protection against fire and earthquakes. In order to combine maximum quality and affordability, a special focus of our efforts is continuous improvement in the economy of our brick solutions. We work to reduce laying time and simplify construction with product innovation and systems. For example, our Dryfix® aerosol glue reduces construction time by up to 50% compared with conventional masonry methods.

Housing is a very long-term investment. For that reason, we should base construction on building materials with a long service life like our ceramic products. An analysis of housing in Belgium shows that over 20% of all brick homes are more than 100 years old.

ANITA ORY *(Sustainability Manager in Belgium)*

Outstanding mechanical properties, high resistance to chemicals and protection against corrosion make plastic pipes long-lasting and economical

At Pipelife, our specialist for plastic pipe systems, the R&D and marketing departments work closely together to meet customers' needs with fast reaction times and short development periods. Our lightweight, flexible and easy to install pipes can be used in a wide variety of solutions for fresh water and wastewater management, residential construction, industrial facilities and public supply infrastructure. Outstanding mechanical properties like high pressure resistance, particularly smooth surfaces and high resistance to many chemicals make these products especially long-lasting and economical. They are also absolutely corrosion-free. With solutions for water management (fresh water, wastewater and irrigation systems), energy supply, electrical wiring and telecommunications, Pipelife products and system solutions represent an integral part of the answers to the megatrends of the coming decades.

Sustainable concrete paver products

Concrete pavers made by Semmelrock create lasting value with their variety, high resistance, durability and wide range of applications. Concrete is a moldable building material that is made of natural raw materials – cement, sand, rock grain and water.

Ceramic pipe systems are suitable for trenchless installation and environmentally friendly

Steinzeug-Keramo ceramic pipes also meet important demands for ecological and economical sustainability. Vitrified clay pipes have a service life of more than 100 years, are virtually maintenance-free, retain their shape and are highly resistant to corrosive chemicals because of their glaze. Vitrified clay pipes do not cause any reaction between the building section and the surrounding earth or ground water, can be installed in an environmentally-friendly manner without trenches and are completely recyclable. Therefore, the use of ceramic pipe systems is extremely eco-friendly and economical.

System solutions for energy-efficient construction as competitive advantage

The many diverse demands on modern buildings from users, developers and regulatory requirements such as the Energy Performance of Buildings Directive (EPBD) have made the systems approach a key focal point of construction. Integrated system solutions can optimally combine and utilize the outstanding properties of individual products in the Wienerberger portfolio with products from partners in building technology. **Our goal is to increase the share of Group revenues generated by innovative and sustainable products from 20% in 2010 to 30% in 2015.** The share of revenues from the sale of premium products increased slightly in the Bricks & Tiles segment in 2012. On the Group level this key figure remained constant at 23.4% due to the initial consolidation of Pipelife, which shows a long-time share of revenue by innovative products of 20%.

Processes and Instruments for Sustainable Product Development

Research & Development

Market-oriented product development is focus of R&D

Research and development (R&D) form an integral part of strategic planning at Wienerberger and represent key activities for the Group. In these areas we work to continuously improve and develop our products and system solutions in all our application areas – from energy-efficient building concepts to environmentally compatible pavers and supply and sewerage systems. We want to protect and further expand our market positions through product innovation and move closer to the decision-makers in the construction process to support the timely exchange of information. Our research centers maintain an ongoing dialogue with universities and experts in various disciplines. Product development at Wienerberger is managed centrally in the individual business units, but is always market-oriented and therefore implemented in the individual countries. In addition to legal requirements and standards at the European or national level, a new product must harmonize with local building traditions. Product development must recognize cultural factors as well as the local cost structure of comparable construction methods and systems.

Innovation as Result of Research and Development

Product development and innovations for bricks

Wienerberger operates three research centers for Bricks & Tiles that are specialized by product group: clay blocks, facing bricks and clay roof tiles. Our product management experts work closely with the various marketing and sales departments to ensure that new developments always meet the needs of our customers. One of the R&D focal points in 2012 was to minimize thermal conductivity and optimize the thermal insulating properties of clay blocks. These activities led to the creation of the new mineral wool-filled PTH 30 W.i. Objekt, which was developed especially for multi-story buildings. It combines low wall thickness to maximize usable space and high compressive strength with excellent thermal insulation. Wienerberger is also pursuing a “light brick” strategy for infill masonry. These clay blocks have 25% less weight, which reduces raw material, transport and energy costs and also increases the living space. Light bricks are used to fill the space between the load-bearing sections of a building and create a pleasant and healthy interior room climate.

Goal for new roof tiles: optimal resource efficiency

Resource efficiency represents the focus of product development for roof tiles. In 2012 Wienerberger introduced a so-called FEM (finite element method) calculation for the optimization of the geometry of roof tiles. Two models were successfully used in Switzerland during 2012, and a third model is currently being implemented. The goal is a 10% reduction in the weight of the roof tile with constant bending load bearing capacity, which will decrease raw material requirements and energy consumption and also optimize the transport weight.

Facade developments focused on solutions for renovation and space optimization

Development projects for TERCA facade solutions were concentrated primarily on renovation in 2012. The responsible revitalization of existing buildings and the optimization of energy efficiency are two important goals in this area. The development of the Eco-brick® or SlimBrick® product lines provides two-layer wall systems with higher thermal insulation and a maintenance-free service life for the facade over many decades. Ceramic facade boards for rear-ventilated facades from the ArGeTon® product line can be combined with a variety of other building materials and are particularly well-suited for multi-story residential construction. The special development ArGeLite® saves space and reduces the use of raw materials.

Product development and innovation for plastic pipes

R&D activities for plastic pipes are located at our research center in the Netherlands, which works together with universities and external experts from various disciplines. Research is concentrated on the development of new products as well as the refinement of formulas for the raw material mix. One recent development by Pipelife is the Halovolt Low Friction EMC, an electrical installation pipe that minimizes electromagnetic radiation in the immediate surroundings. This solution sets a new environmentally friendly and healthy standard for public and private buildings. Pipelife is also a leader in the development and production of oversized pipes (LLLD pipes) with a length of up to 600 meters and a diameter of up to 2.5 meters for industrial applications. Special products in the Soluforce Heavy line are used in high pressure applications by the oil and gas industry. Steel wire reinforcement and high corrosion resistance make these pipes long-lasting, more resource-efficient and economical. The special plastic liner can also withstand a wide variety of aggressive chemicals and handle the safe collection and drainage of toxic waste water.

Ceramic jacking pipes allow for trenchless installation

The optimization of technical properties represents the focal point of R&D for ceramic pipes. One result is the development of ceramic jacking pipes that are suitable for trenchless installation. The pipes are inserted into a starting shaft and then pushed to the target shaft by means of a tunneling machine. This procedure allows the pipes to be installed with only minimal earth movements and without disturbing the existing infrastructure. Steinzeug-Keramo set a milestone in 2012 by installing the first ceramic jacking pipe in a curve drive for a project in Singapore. This technique can also be used to replace existing pipelines without digging new trenches.

Development of surface structures to extend service life and improve economy

Research projects for concrete pavers are directed to improving the surface designs and developing new technologies for the surface structure to extend the service life and increase product economy. Semmelrock Premium Protect®, a special surface shield, seals the stones and thereby provides for long-lasting color protection and easy maintenance, even on areas that are exposed to heavy soiling. Einstein®, an innovative jointing system, was developed to meet the high demands on heavily trafficked areas. This fully interlocking system with integrated protection against shifting prevents the paved areas from displacing, tilting or warping, even under high stress.

Our innovative surface treatments create modern and attractive paver solutions, and also extend the service life of our products.

ROBERT F. HOLZER *(CEO Semmelrock)*

Wienerberger System Solutions

Combining the outstanding properties of individual products into specially designed system solutions for the many diverse demands on modern construction is one of the central challenges for Wienerberger as an application-oriented and innovative building materials producer.

e4-Brickhouse 2020

The e4-Brickhouse: a leading and comprehensive concept for the affordable home of the future

The building concept for the e4-Brickhouse 2020, which includes all Wienerberger product groups, illustrates the principle of a complete system solution. In the Lower Austrian town of Zwettl, Wienerberger is demonstrating this principle in practice. A family of four moved into the first e4-Brickhouse 2020 during 2012 – a home that already meets all requirements of the Energy Performance of Buildings Directive 2020, which requires all buildings constructed after 2020 to have a positive energy balance.

The e4-Brickhouse has a positive CO_2 and energy balance

The e4-Brickhouse 2020 produces more energy than it uses during a year, which results in a positive CO_2 and energy balance. Experts have calculated that 33,600 kg of CO_2 can be saved with this house by 2020. The heart of the e4-Brickhouse 2020 is a thermal building shell made of high thermal insulating POROTHERM W.i. bricks that are filled with mineral wool and, in monolithic construction, can reach a U-value of ≤ 0.13 W/m^{2}K on the exterior wall (including plaster). The plane ground bricks are laid with the time-saving Dryfix® system, an aerosol masonry glue that makes fast masonry work possible at temperatures down to -5°C. The wall temperation heating system developed together with Pipelife creates a pleasant room climate and leads to lower energy consumption by reducing heating requirements (see below). The exterior walls are covered with TERCA facade bricks and ArGeTon® brick slabs. Semmelrock supplied the concrete pavers for the outside areas. The products from our Koramic line create a long-lasting, attractive appearance of the roof and additionally cover more than 100% of the electricity requirements with photovoltaic equipment from our offering of complete solutions.

Brick Wall Temperation

Energy savings and a healthier room climate with brick wall temperation

The high accumulation capacity of brick walls keeps rooms cool in the summer and pleasantly warm in the winter. As a system solution combining plastic pipes and clay blocks the brick wall temperation manages and increases this effect. The brick wall is thermally activated by an integrated pipe system. The air temperature can be reduced by increasing the surface temperature of the wall, without impairing the perceived room temperature. This can result in energy savings of up to 20% compared with convector heating. The lower interior air temperature increases the humidity in the room and reduces dust convection, which has a positive influence on the health of the building users. Three pilot projects were realized with this newly developed wall heating system in 2012, one of which is the e4-Brickhouse 2020.

Raineo™ ends Flooding in Inner City Areas

System solution to prevent flooding in inner city areas

Climate change and the increasing development of green areas have led to a growing incidence of flooding in inner city areas. With Raineo™, Pipelife has developed an extremely efficient system to solve this problem. It is installed underground and creates the necessary space for rainwater to drain off quickly. The system covers collection, preparation, storage and recycling or the diversion and disposal of the water. The heart of the system is the so-called "Stormbox", a large plastic box that is installed under built-up areas to collect excess water. When the rain is heavy, the water overload flows into the box and, in this way, the system prevents flooding.

Our Raineo™ water management system provides solutions to meet the challenges of climate change and helps to mitigate and prevent flooding in urban areas.

NIELS RUNE SOLGAARD-NIELSEN *(CEO Pipelife)*

The Energy-Independent House

Prof. Timo Leukefeld
on the energy-independent house
made of Wienerberger bricks:

"The Helma energy-independent house is a possible answer to the question of how we want to live in the future. It uses the free, crisis-proof 'raw material sun' to generate electricity and heat and also support our mobility. The result is complete energy independence – with no need for fossil fuels or electricity from public supply networks. That is what I call modern high-tech."

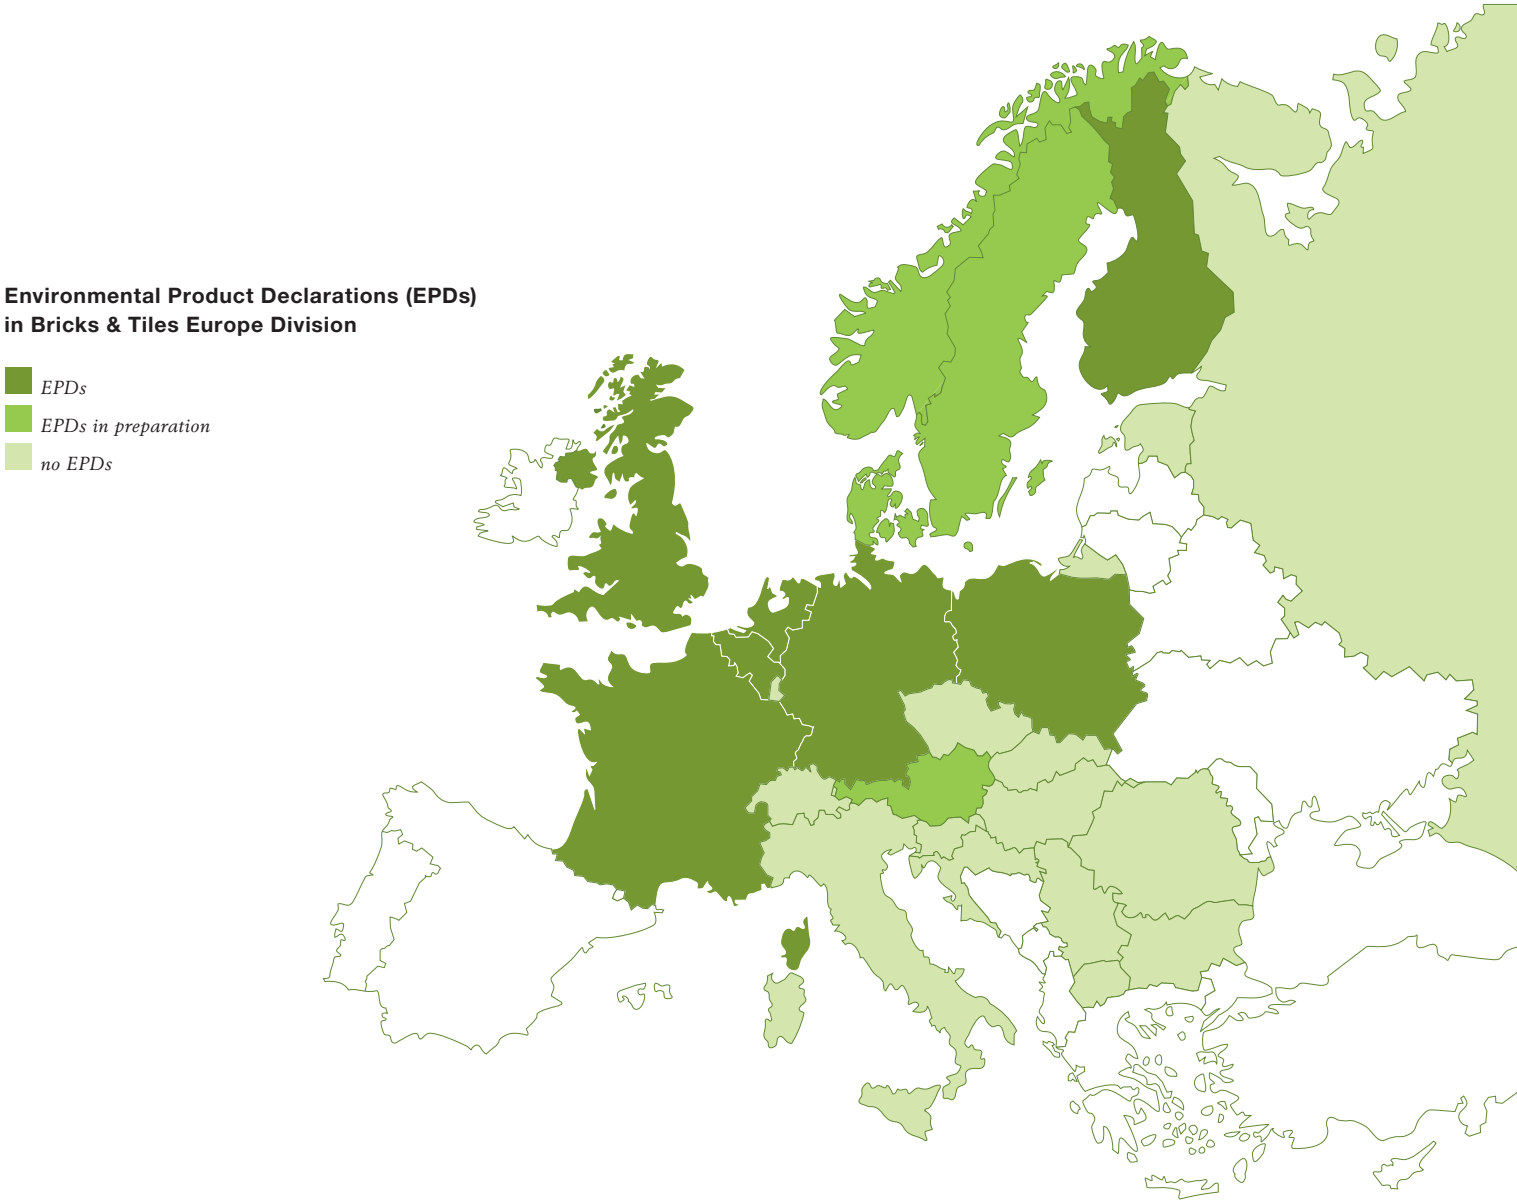
Technical concept:

The energy-independent house with monolithic brick walls by Wienerberger provides a possible answer to the future of housing design and concepts that include complete energy self-sufficiency (i.e. no connections to the public supply network are required). These energy-efficient houses use solar energy to generate electricity and heat and power motor vehicles. Although the amount of available solar energy can fluctuate considerably from day to day, this energy (solar electricity and solar heat) can be stored to ensure long-term supplies. That provides sufficient energy for heating, household electricity and powering an e-car over an entire year, which also leads to a substantial reduction in costs.

The brick is a proven, successful wall building material for energy-independent houses. This is demonstrated by various features, above all thermal storage capacity. Since temperature fluctuations are only transferred to the living areas over a longer period of time, a brick wall is a natural balancing accumulator and therefore the ideal building material for an energy-independent house. In addition, a modern brick provides perfect insulation. The need for heating is reduced considerably: the house stays warm in the winter and cool in the summer. The remaining energy requirements are minimal and can be covered by solar equipment combined with a long-term heat storage system. Solar heat and bricks in this combination produce the most effective houses currently on the market in Europe and could serve as a guiding vision for the European homes of 2020. These energy-independent buildings achieve ratings nearly 80% below the standard passive house for primary energy consumption, CO_2 emissions and annual heating costs.

Koramic Complete Solutions for Roofs

Koramic complete solutions for roofs



The system approach represents the focal point for R&D on roof tiles. Together with our durable, colorfast and stable clay roof tiles, we also offer a complete line of accessories. This underscores Wienerberger's positioning as a complete supplier for roofs and a competent partner for the planning phase. Wienerberger expanded its product line in 2012 to include a Koramic system solution with optimized thermal insulation that is marketed together with the necessary components such as insulation elements and coordinated accessories. We also expanded our offering as a one-stop shop with a service to calculate the energy performance of our roof solutions. Starting in Germany, this service will be successively rolled out in other Wienerberger countries. Climate change and the resulting extreme weather conditions have also led to increasing demands on the resistance of roofs. Wienerberger has met this challenge with the patented *sturm*FIX system, which uses special fixation hooks to protect roof tiles from even the strongest storms.

Ecobalance and Development of Environmental Product Declarations

Long-standing, active role in preparation of ecobalances and EPDs, and European harmonization of standards

The preparation of ecobalances and environmental product declarations (EPDs) for all product lines has been a focus of activities at Wienerberger for many years. The European Construction Products Directive (CPR) and the work of the European Committee for Standardization (CEN TC 350) will make these declarations mandatory for all building materials producers over the coming years. In Belgium, the respective regulations will take effect on January 1, 2014. EPDs from a number of brick producers have been published in recent years. This generally took place at the association level in France, Germany, Belgium and England. The Belgian brick industry developed an EPD system as part of a research project, which defines the criteria for EPDs, and EPDs for all product lines have been issued in the Belgian product line. The brick industry in Austria decided to prepare differentiated branch EPDs by product category, i.e. for clay blocks, facing bricks and roof tiles. This project will be completed in the near future. With these measures, a large part of Wienerberger's brick product line is directly covered by EPDs or included in branch solutions. Wienerberger is a leader on this issue in the above-mentioned countries and, through the positions of the Wienerberger Managing Board and employees in the Tiles and Bricks Europe association (TBE), works actively on the preparation of ecobalances and EPDs as well as the harmonization of national rules throughout Europe.

Environmental Product Declarations (EPDs) in Bricks & Tiles Europe Division

Project to develop ecobalance database for all plants launched in 2012

Wienerberger started a pilot project in 2010 to collect ecobalance data on all its roof tile plants and completed this work in 2011. These ecobalances form the basis for the preparation of EPDs. In 2012 we started a project to create a Wienerberger database for the collection of ecobalance data in all our plants. This will move us closer to meeting our goal – the preparation of EPDs for all product groups – and we can then use this comprehensive database to demonstrate our compliance with national or European regulations.

Cradle to cradle certification

The cradle to cradle concept (C2C) is modeled on nature's processes. It is designed to create waste-free systems by not disposing of products as waste after their use, but returning them to continuous production cycles for new products. This concept is also based on the use of renewable energy and the support of diversity. Certification and the related continuous development of products and production processes in the sense of sustainable environmental protection anchor the cradle to cradle principle in companies. Steinzeug-Keramo has already received C2C certification for part of its product line and is now working to achieve certification for the remaining

products. In the Bricks & Tiles Europe Division, all clay block products in Belgium have been certified under C2C since 2012, and preparations are now in progress for the certification of selected roof tile and facing brick products.

TEPPFA leader in the preparation of EPDs for functional areas

In the plastic pipe industry, the focus is on the preparation of environmental product declarations by the producers' association. The European Plastic Pipes and Fittings Association (TEPPFA) is using life cycle assessments (LCAs) to develop environmental product declarations for functional areas based on ISO 14025. One example of a functional area for heating is the total amount of plastic pipes and fittings required to heat a 100 m² housing unit. TEPPFA members can reference the EPDs for these functional areas. Nineteen environmental product declarations have been completed and the preparation of further EPDs is scheduled for 2013. Niels Rune Solgaard-Nielsen, the CEO of Pipelife, is actively involved in the rapid, goal-oriented implementation in his role as president of TEPPFA.

Future Measures

Our future measures for sustainable products are focused on the (further) development of system solutions, including an improvement in economy and efficiency, as well as the development of solutions for modern, energy-efficient and urbane construction. Wienerberger will also collect ecobalance data from all its plants and work on the preparation of EPDs for the entire product line, and make an important contribution to the harmonization of standards throughout Europe.

Expansion of one-stop shop concept and development of solutions for multi-story housing

In our brick business, we want to further expand the one-stop shop approach that has already proven successful in the roof segment. We will also continue our work on projects that combine the outstanding properties of Wienerberger products into system solutions with concepts like the e4-Brickhouse, also with the inclusion of external partners from branches such as heating and ventilation technology. Our goal is to provide solutions from a single hand that not only comply with all relevant building regulations, but also meet our customers' demands for healthy living, comfort and affordability in construction and use. We are therefore focusing on system solutions that help to reduce construction time and optimize construction logistics. Another central objective is the expansion of our offering for multi-story residential construction. Our efforts in this area will concentrate on our slim infill clay blocks for load-bearing exterior walls and our special lightweight bricks for infill masonry and innovative facade solutions.

Product certification and improvement in economy and service life as focus for Pipes & Pavers

Steinzeug-Keramo will complete the certification of its ceramic products according to the cradle to cradle principle in 2013. In addition to ongoing R&D projects to further generate 20% of revenues from innovative products, Pipelife is working on the collection of ecobalance data and the preparation of EPDs. Activities at Semmelrock involve the improvement of economy through innovative laying systems as well as the extension of the product lifecycle through an increase in durability, color retention and surface stability.

Goal: 30% of revenues from innovative products by 2015

In 2012 23.4% of Group revenues were generated by innovative products and system solutions. Our goal is to increase this indicator to 30% by 2015.

Corporate Social Responsibility

Wienerberger Principles of Corporate Social Responsibility

The economy as an integral part of society

Wienerberger views the economy as an integral part of society. Its duty is to serve people and create value for all. Wienerberger takes its role as a responsible member of society seriously. We define responsibility as ethical actions, honest communications, active participation in the transparent development of our economic environment, personal accountability and actions that confirm our standing as a reliable and valuable member of society.

Defense of human rights

Within its respective sphere of influence, Wienerberger guarantees ***protection for basic human rights***. The company has signed a social charter in which it commits, among others, to supporting the freedom of association and collective negotiations at all locations as well as preventing child labor and forced labor. Our corporate guidelines call for sanctions in the event of violations.

Support for social institutions

Support for social organizations on a local basis is a central principle of corporate social responsibility for Wienerberger. Our donation guideline confirms our intention to provide targeted, in-kind support to the needy in the form of our products and to help young people through training programs in sustainable construction.

Compliance with all applicable national and international laws

A commitment to ***compliance with all applicable national and international legal regulations*** is also an important part of corporate social responsibility at Wienerberger. Legal compliance at all organizational levels creates the basis for good management. Wienerberger ensures that both international and national laws and standards are followed in all its business operations and places a special focus on the prevention of illegal and anti-competitive behavior.

Active participation in political decision-making

As a member of numerous national and European platforms and technical committees, Wienerberger plays an active role in the political decision-making process. Wienerberger is an established, reliable stakeholder and building materials expert that views ***open and transparent communications with politics and public authorities*** as part of its corporate social responsibility. The company works to create a sustainable economic environment that unifies economic, ecological and social interests.

Energy Efficiency and Climate Protection

Climate change as a central challenge for society

The man-made climate change has already started and will represent one of the central social challenges of the future. The creation of a competitive, resource- and energy-efficient economy is one of Wienerberger's stated goals. With our energy-saving building material and infrastructure solutions and our energy-efficient building concepts, we are supporting the transition to a low carbon society. We believe future-oriented building materials must make an important contribution to slowing climate change.

Wienerberger products support climate protection

"Building with a clear conscience" is one of our guiding principles and underscores our commitment to sustainability. We want to create the greatest possible benefits for society with our building material solutions and our expertise. Our long-lasting, resource-conserving building materials help our customers make a contribution to environmental protection. Wienerberger is also committed to the development of energy-efficient house concepts. In these projects, we always consider the total energy efficiency of a building – from production to construction, use and recycling. Our e4-Brickhouse 2020 has both a positive energy and a positive CO_2 balance and, in this way, makes an active contribution to climate protection.

Our innovative pipe systems are an integral part of future-oriented solutions for water management – they allow for the efficient collection of rainwater and wastewater, and also support water transportation, recycling and disposal. These pipe systems help to optimize the water cycle and improve resource efficiency, while also ensuring long-term security of supply.

Regional Employer

Important employer, also in structurally weak regions

Its large network of local production facilities makes Wienerberger an important employer in many, in part structurally weak, regions. We see the creation and preservation of jobs as an important corporate social function. At our plants we work to develop and maintain the best possible understanding with municipal authorities, interest groups, neighboring residents and NGOs. Our activities are focused on mutual understanding, the regular exchange of ideas and respect. We have installed local steering committees at a number of our plants to help us meet this goal.

With the signing of a social charter, Wienerberger formally confirmed its intention to comply with the recommendations of the International Labor Organization. We are committed to safe and appropriate working conditions, fair compensation and our employees' right to the freedom of association and collective negotiations. Approx. 80% of all Wienerberger employees are covered by a collective agreement. Our efforts to ensure fair working conditions are appreciated by our employees and reflected in a low strike rate. The number of work stoppages totaled 402 man-days in 2012, which represents 0.01% based on the total number of hours worked in the Wienerberger Group. Moreover, most of these strike days were protests against general political decisions at the regional level and not directed against Wienerberger.

Wienerberger Donation Guideline

Our goal: to provide the best possible benefits for society with our products

We want to use our products and expertise as a supplier of building material solutions to create the greatest possible benefits for society in every country where we are present. Our donation guideline provides a framework for the targeted, in-kind support we provide to the needy with our products. We also offer additional training programs in sustainable construction for architecture and civil engineering students. We believe we can help best in areas related to our core expertise, namely in the provision of building material solutions and know-how for sustainable construction.

Cooperation with Habitat for Humanity

In connection with its new donation guideline, Wienerberger entered into a three-year agreement with Habitat for Humanity to support the construction of housing in Romania and Bulgaria. Habitat for Humanity is an international organization that is dedicated to providing poor and disadvantaged people throughout the world with safe and affordable housing. This three-year cooperation program was launched with the "Big Build 2012" in Craiova, Romania, from October 1 to 5, 2012. Together with the involved families, volunteers from all over the world built five brick homes in five days.

We believe affordable housing
is a basic human right.
I am therefore particularly pleased
that we are able to build homes for the needy
together with Habitat for Humanity.

GERHARD KOCH *(Head of European Affairs & Sustainability Management)*

Development of WISBA training program

The principles underlying the donation guideline formed the basis for the development of a specialized training concept in 2012, which led to the creation of the Wienerberger Sustainable Building Academy (WISBA). This European training program is focused on sustainable construction and was created together with Vienna University of Economics and Business and in cooperation with technical colleges. WISBA is directed to master's degree students in architecture or civil engineering, who can demonstrate a significant interest and special achievements in sustainable construction. Wienerberger supports this target group by financing the international training, which can be credited in full to the respective degree program (5 ECTS points). The participants also have an opportunity for practical training at Wienerberger. The first course will start during the autumn semester 2013/14 with students from Austria, Germany and Poland. **Plans call for the expansion of WISBA to 12 countries by 2015.**

Selected Charitable Projects

Unbureaucratic help in disaster situations

We regularly support and promote a variety of social projects in nearly all countries where Wienerberger is present. In addition to the planning and realization of charitable projects together with aid organizations, we believe it is important to provide fast and unbureaucratic relief in emergencies. We help where we can make a real contribution and are certain this help will arrive at the right place.

Pipelife: around the world with 27 aid projects

As part of its long-standing partnership with the Austrian Red Cross, Pipelife launched a new campaign in 2012: for 27 months, the company will support 27 humanitarian projects in the 27 countries where it is active. The kick-off for this campaign was a unique training program carried out in cooperation with the Red Cross in Austria and the UK, which also received financial support from the European Community Humanitarian Office (ECHO). The program's goal is to improve the skills of development aid workers to react quickly and correctly in disaster situations and thereby ensure supply security, above all for water. This project "Prepare to Respond" has held courses in a variety of humanitarian fields, including water, hygiene and sanitation equipment.

Support for young masons' competition in Austria

Wienerberger also supports professional training for young men and women in sustainable construction. We supplied the products for an apprentice masons' competition in Austria, and the winner of the national contest will take part in the World Skills 2013 in Leipzig. This initiative will help make the masonry profession more attractive for future generations.

Affordable housing in India

Affordable housing for the people living near our plant has been an important issue ever since our market entry in India. Together with an external partner, we carried out a study on the needs of the local population in 2012. We then developed a concept for affordable housing that provides sufficient living space for a family. In a next step we want to work together with NGOs to support residents in their search for financing.

Compliance

Measures to ensure legally compliant behavior

The term "compliance", which originated in Anglo-American law, is understood to cover all measures required to ensure adherence to the relevant legal regulations and prohibitions by a company and its employees. A commitment to compliance with all applicable national and international legal standards represents a central principle for the Wienerberger Group. Individual legal issues are so important that Wienerberger has issued separate guidelines in these areas and places a special focus on compliance. These areas include the prevention of corruption and compliance with competition law as well as compliance with national guidelines and regulations, which are described in the following sections.

Prevention of Corruption

Difference between business gifts and corrupt behavior

Wienerberger is committed to free and fair competition, and rejects any form of corruption. However, the differentiation between well-meant business gifts and corrupt behavior is often difficult to determine in individual cases. This applies, above all, to procurement and sales because of the increased contact between the respective staffs and public authorities or private business partners.

Guideline on business gifts

In order to inform employees of legally compliant behavior, Wienerberger issued a group guideline that covers business gifts. This guideline is intended to serve as guidance for employees by defining the cases in which the granting or accepting of business gifts could pose a problem under criminal law. It defines the term "business gifts" and differentiates this term from other types of presents. The guideline also distinguishes between gifts to persons in the public sector and the private sphere, and provides standards for acceptable behavior. In conclusion, the guideline defines cases in which the granting or acceptance of business gifts must be reported to the Managing Board or company management.

Instructions for managing directors

In connection with the implementation of this guideline, the top managers and managing directors of the country organizations (approx. 40 persons) were instructed on the correct procedures for dealing with business gifts. This included instructions to ensure full compliance with the guideline in every company. Local management is responsible for passing this information on to employees through special training courses, which are regularly monitored by the corporate headquarters.

Internal audit as control function

The duties of internal audit also include reviewing compliance with legal regulations and internal guidelines. Audits were conducted in 35 companies during 2012, which focused on organization, procurement, materials management, sales and personnel as well as corruption and antitrust law. The audited companies represent roughly half the operating units in the Wienerberger Group. These reviews confirmed that all internal guidelines had been implemented in all companies and that employees had been instructed accordingly. Any deviations were reported to the Managing Board and the Audit Committee, and appropriate corrective measures, such as the improvement of documentation processes, were developed together with the responsible management.

Dual controls for business transactions

Another important instrument for the prevention of corruption is the principle of dual controls for signatures in business transactions with third parties. This principle calls for signatures by two authorized persons in the local unit when rights and obligations are created, amended or cancelled. Group guidelines also include this rule, which supports the prevention of corruption on an international basis.

Sanctions for violations

Legally compliant behavior is expected from all Wienerberger employees, and any violations represent a breach of the obligations under labor law. If the suspicion of a violation is confirmed, it will lead to consequences under labor and civil law that reflect the scope of damages to the Group. In 2012 no charges were filed against Wienerberger based on a suspicion of corruption and no criminal penalties were paid for related violations.

Prevention of Anti-competitive Behavior

Fair competition as basis for our business

Competition law ensures compliance with free and fair competition. Management is convinced that business policies based on free competition are in the best interest of the company and also in the best interest of shareholders and employees.

Antitrust compliance program

The Wienerberger Group introduced an antitrust compliance program many years ago. This guideline forms the basis for increasing the awareness of our employees for compliance with antitrust regulations. The rules of conduct defined in the guideline provide guidance for dealing with sensitive subjects in the area of competition law and must be strictly observed. Special rules regulate contacts with competitors and deal with issues such as market allocation, the exchange of information, the design of prices and delivery conditions and other possible forms of cooperation. The interaction with customers, sales partner and suppliers is, among others, regulated with respect to the determination of resale prices and related restrictions as well as exclusivity agreements. The guideline also contains regulations concerning intellectual property rights and merger controls.

Control through internal audit

Regular training sessions are scheduled for employees as part of the antitrust compliance program. Local management is responsible for organizing these programs and selecting the employees. The realization of the training sessions and compliance with the guideline are monitored by internal audit.

Pending antitrust proceedings in Germany, searches in the offices of plastic pipe producers

Due to the position of the Wienerberger Group in individual markets, the pricing policies of our subsidiaries are actively monitored by antitrust authorities. Antitrust proceedings are pending in Bricks & Tiles Germany and, in the event of a conviction, could lead to a fine. A provision has already been recognized for a possible antitrust penalty, but we assume Wienerberger was not involved in any illegal actions. In addition, the EU Commission ordered searches at the offices of plastic pipe and fitting producers during June 2012 in connection with alleged agreements in violation of antitrust law, which also included Pipelife. The responsible authorities have not issued any findings to date. It should be noted that price-fixing agreements are not part of Wienerberger business policies; internal guidelines expressly prohibit such activities and call for sanctions in the event of violations.

Compliance with National Guidelines and Regulations

Environmental, health and safety regulations

Wienerberger is subject to extensive and increasingly stringent environmental, health and safety laws in many countries, which can lead to investments for compliance with these regulations. The failure to comply with these regulations could result in administrative fines, the assessment of damages or the suspension of operating permits.

Responsibility with local management

In accordance with the decentralized structure of the Wienerberger Group, local management is responsible for implementing and monitoring the applicable national guidelines and directives. Officers have therefore been appointed at the country level in agreement with the relevant national laws. These persons are responsible for evaluating and reporting on legal compliance to local authorities and to the Wienerberger Managing Board. Internal audit reviews compliance with these processes on a regular basis and reports to the Managing and Supervisory Boards on the results of these audits.

The Political Decision-making Process

Active participation in political decision-making

Wienerberger is a member of numerous European and national professional associations and platforms as well as various technical committees and, in this way, plays an active role in the political decision-making process. One of our most important goals is to address the trends and developments in individual markets, for example growing urbanization, and to provide decision-makers with practicable, sustainable and, above all, affordable solutions for new residential construction, infrastructure and renovation.

Membership in national and European ceramic associations

Through its country organizations in the Bricks & Tiles segment, Wienerberger is a member of numerous national brick associations which, in turn, are organized at the European level into an association called Tiles and Bricks Europe (TBE). Heimo Scheuch serves as president of the TBE, which is located in Brussels, and regularly attends the meetings of the executive committee. In the ceramic pipe segment Gernot Schöbitz, CEO of Steinzeug-Keramo, is president of the European association Feugres. Both TBE and Feugres are active members of the European ceramic association CERAME-UNIE, where Heimo Scheuch serves as vice-president. CERAME-UNIE also organizes the annual European ceramics forum together with representatives of the European Parliament. This forum takes place in the European Parliament and provides a platform for the exchange of information and communication between industry, the European Commission and politics on current economic topics.

Pipelife is a member of the European association TEPPFA

Wienerberger's plastic pipe business is represented in The European Plastic Pipes and Fitting Association (TEPPFA) through Pipelife. In April 2013 Pipelife CEO Niels Rune Solgaard-Nielsen was elected president of TEPPFA. Our membership in this association provides a platform for our active participation in the political decision-making process at the European level, where we support key issues such as recycling, the development of product standards for plastic pipes and the preparation of environmental product declarations.

Semmelrock is represented in VÖB

Semmelrock represents the Wienerberger Group in VÖB, the association of Austrian concrete and prefabricated producers. Semmelrock CEO Robert F. Holzer serves as the vice-president of this organization, which represents the interests of all concrete prefabricated producers in Austria and views itself as a know-how platform and branch speaker. VÖB is a member of the Bureau International du Béton Manufacturé (BIBM), which is active at the European level.

Emission trading system 2013-2020

The most important economic and environmental issues for Wienerberger in 2012 included, among others, the design of the emissions trading system for 2013-2020, the Energy Efficiency Directive and the Construction Products Directive. In 2012 Wienerberger played an active role in the national implementation of the European Energy Performance of Buildings Directive (in particular with regard to the cost optimization of energy-efficient buildings). We are also involved in a number of regional and national construction initiatives.

Future Measures

Continued cooperation with Habitat for Humanity

Wienerberger entered into a three-year cooperation agreement with Habitat for Humanity in connection with our donation guideline. Plans call for the construction of roughly 150 homes for the needy in Romania and Bulgaria during this period.

Start of WISBA in autumn semester 2013/14

The first course of studies in the Wienerberger Sustainability Academy is scheduled to start during the autumn semester 2013/14. It will include 12 students from Austria, Germany and Poland, who will complete an international training program on sustainable construction. We plan to expand WISBA to 12 countries by 2015.

Increase in local steering committees

In order to provide a platform for increased dialogue with the stakeholders near our plants, we want to establish local steering committees at additional locations.

Preparations to preserve carbon leakage status

Through the Tiles and Bricks Europe Association (TBE), the European brick and roof tile industry started preparations at the end of 2012 to preserve carbon leakage status after 2015 and will continue these measures during 2013. Wienerberger also works to standardize the interpretation and implementation of the Construction Products Directive by means of its membership in various European associations.

Stakeholder Management

Principles of Stakeholder Management

Communication is the central principle of responsible interaction with our stakeholders

Creating value in the interest of all stakeholders is one of Wienerberger's central principles. Accordingly, communication forms the focal point of responsible interaction with our stakeholder groups. Our efforts in this area are designed to provide our employees, customers, shareholders, local residents and suppliers as well as politics, the media and NGOs with relevant information, while also maintaining an open, proactive, continuous and transparent dialogue with these groups. This dialogue creates a better mutual understanding for the respective interests, needs and concerns, and creates added value for everyone involved. Our communication instruments include personal meetings as well as regular newsletters, information brochures, internet-based platforms and information events.

Communication with employees

Employees are interested in a motivating, future-oriented and stable employment relationship, opportunities for advancement and active involvement as well as a good working environment that guarantees health, safety, fairness and equal opportunity. These principles and values are an integral element of our corporate culture, which forms the basis for our everyday work. In order to create a motivating environment and encourage individual initiatives, we provide our employees with comprehensive and timely information on corporate goals and strategies as well as important developments and measures. Various internal media are used for this purpose, including a regular CEO letter, iComm (our intranet platform), local employee magazines and internal newsletters from various departments (e.g. engineering and marketing newsletters). Our "ideas & more" innovation platform gives employees an opportunity to contribute ideas and receive a bonus if they are implemented. As part of our health & safety initiative, we also organize regular training courses for employees to further improve occupational safety and promote good health.

Communication with consumers, merchants, developers, planners and masons

Our customers – consumers as well as merchants, building developers, planners and masons – are interested in high-quality, long-lasting and affordable products that provide security and comfort. We maintain a continuous dialogue with our customers to better understand their concerns and develop products that meet their needs. Wienerberger informs customers of the technical, ecological and economic benefits of its products through a wide range of communication measures that include information brochures, presentations at trade fairs, training courses and online tools. Training programs and our service center support our customers in the use of our products and system solutions.

Communication with shareholders, analysts and banks

Capital market participants – shareholders, analysts and banks – are interested, above all, in the sustainable development of the company. Comprehensive and transparent reporting as well as timely communications and regular exchanges with the Managing Board play a central role in supplying the necessary information. The main instruments used for this purpose include the annual and quarterly reports, presentations and press releases on current developments. Road shows, participation in investors' conferences, one-on-one meetings and the annual capital markets day ensure a continuous and active dialogue with all capital market participants.

Fair business relationships with suppliers

Suppliers are interested in fair business relationships. Wienerberger is interested in the long-term, sustainable procurement of the required raw materials, supplies and products. We therefore communicate our expectations for compliance with economic and social standards to our suppliers. Pipelife, for example, has compiled these standards in a code of conduct that must be signed by suppliers before contracts are concluded and followed during the entire business relationship.

Communication with the media

The media expect targeted and up-to-date information on strategic and current issues. Our objective is to achieve fair reporting by the media. In order to ensure optimal cooperation, we provide the media with timely information through press releases and press conferences. Inquiries by journalists are answered as quickly as possible, with personal interviews allowing for the necessary exchange of information.

Communication with politics

Politics establishes the legal framework for society and, as such, defines the general business environment for Wienerberger. The subjects on which the exchange of information with Wienerberger took place in 2012 are described in the section "The Political Decision-making Process" in the chapter "Corporate Social Responsibility" (page 60). Our media contacts include an increasing focus on the need for affordable housing and social housing construction in Europe. We also support public subsidies for renovation and the construction of (water) supply and disposal networks in Western and Eastern Europe.

Communication with other stakeholder groups

Our stakeholders also include local residents, communities and public authorities as well as NGOs. The Bricks & Tiles Europe Division has established local steering committees in several countries, which include Wienerberger management, residents, political representatives and NGOs. Regular meetings allow for the exchange of information and, wherever necessary, the joint development of measures to improve relations. In 2012 we set a goal for our ceramic production network to collect information on current efforts and to **introduce stakeholder dialogues in 90% of our plants by 2020.** Pipelife also places high value on an open and active dialogue with its stakeholder groups. These communications are supported by different types of events, for example family days for the Pipelife Hungary employees and a get-together at the Pipelife Austria plant.

Wienerberger sees these activities not only as a means of creating added value for all stakeholder groups through active dialogue, but also as a win-win situation. Selected examples are provided on the following pages:

Stakeholder Management: Selected Examples

CEO Letter

Heimo Scheuch,
CEO of Wienerberger

I am committed to providing our employees with regular and timely information on the latest developments. During my frequent visits to our Group companies, I try to meet with employees from all areas of the business. Regular emails also give me an opportunity to communicate a wide range of information. Wienerberger was faced with significant challenges in recent years. As a result of the difficult market environment we were forced to implement numerous restructuring measures and make some very hard decisions. However, we attempted to take the necessary personnel steps as carefully and socially responsible as possible. Internal communications were particularly important for me in this situation. I want each of our employees to know the reasons for our decisions as well as the goals we are following and what we want to achieve together during the coming years. Because we can only be successful when we all work together.

Capital Markets Day in Vienna

Willy Van Riet, CFO

This year's capital markets day was held in Vienna. More than 50 investors, analysts and banks used the opportunity to learn about the latest developments at Wienerberger. The focal point for 2012 was the newly created Pipes & Pavers Division, which was introduced by the respective business unit managers. The participants were given an in-depth view of Wienerberger's plastic pipe, ceramic pipe and concrete pavers businesses as well as our corporate strategy. The program closed with a dinner that provided a platform for extensive discussions with our guests as well as a tour of the Pipelife plant on the following day.

Annual summer event at Schlagmann

Johannes Edmüller,
Managing Director of Schlagmann

As thanks for the good cooperation and support, we organize a summer event for our employees and neighbors and highlight a different topic each year. In 2012 we had a particular reason to celebrate: we implemented an energy management system based on DIN EN ISO 50001 standards and received certification during the summer. Martin Zeil, the Economics Minister and Deputy Prime Minister of Bavaria, presented the certificate at the event and, in his speech, praised Schlagmann's efforts as a pioneer in energy policies. The interaction with our guests from politics, the business sector, friends, neighbors and families made this day a real success for me and my staff.

Open house in Hennersdorf

Christian Weinhapl,
Managing Director Austria

The open house at our plant in Hennersdorf on September 22, 2012 drew a large number of guests. Roughly 350 visitors used this invitation to learn more about brick production and our company through various activities. The event provided our employees with an excellent chance to meet different stakeholder groups and give these visitors an overview of their work and production processes. Bricky and Bricka, our mascots, were a particular highlight for the children.

About this Report

Report Profile

Sustainability report on activities in 2012 with three-year statistical trend

This sustainability report covers Wienerberger's activities during 2012, but selected statistics are also provided for 2010 and 2011 to present a three-year trend. The first Wienerberger sustainability report was prepared for 2009. Sustainability reporting at Wienerberger focuses primarily on the ecological and social aspects of the company's activities. Information on Wienerberger's financial development, organizational profile and corporate governance is provided in our 2012 annual report (annualreport.wienerberger.com).

In the future, full report every two years with short report as interim update

Wienerberger also intends to issue regular reports on its sustainable development in the future. However, we have decided to only publish a complete sustainability report every two years because our sustainability principles cover the long-term and therefore generally remain constant. In the interim periods, we will issue an update that presents the latest facts and figures as well as our progress in specific areas.

Reporting threshold: full coverage of investments

The contents of this sustainability report are based on the fully consolidated subsidiaries in the wall, roof, facade, ceramic pipe, plastic pipe and concrete paver product groups. This reporting structure reflects the consolidation range of the Wienerberger Group and therefore includes our pipe activities for the first time (Pipelife plastic pipe and Steinzeug-Keramo ceramic pipes). Steinzeug-Keramo is included beginning in 2011 (the prior year data were adjusted retroactively). Data on Pipelife are presented in the chapter "Environmental Protection in Production" as of June 2012 (for seven months) and in the chapter "Employees" for the full 12 months of 2012. Any deviations from this procedure are explained in the respective sections. The data in the chapter "Environmental Protection in Production" only cover our production facilities, while the remaining statistics relate to all locations in the Wienerberger Group. Detailed information on the consolidation range and the segmentation of the Wienerberger Group is provided in our annual report.

Core issues and key indicators defined by SDSC

Recommendations for the subject areas and indicators to be included in this report were made by the respective Wienerberger working groups and the sustainability officer. The Wienerberger Sustainable Development Steering Committee (SDSC) under the direction of Heimo Scheuch (CEO) was responsible for the final selection. This sustainability report was prepared in agreement with the requirements of the Global Reporting Initiative (GRI).

External validation by independent auditor

The data presented in this report are based primarily on internal statistics. Selected information was validated by an independent external auditor, whereby the 2012 audit concentrated on a review of the content and statistics on energy consumption and emissions as well as occupational safety and health. The integration of data from Pipelife represented a particular focal point in this respect. The audit also covered the underlying sustainability management and the processes used to collect data and implement the sustainability strategy. This sustainability report reaches the GRI B+ level.

Report on the independent limited assurance engagement in accordance with KFS/PG 13

To Wienerberger AG, Austria

In accordance with our agreed terms of engagement, we performed procedures to obtain limited assurance on selected information of the Sustainability-Report 2012 of Wienerberger AG. This engagement is subject to the "General Conditions of Contract for the Public Accounting Professions" (AAB 2011) as amended February 21, 2011, issued by the Austrian Chamber of Public Accountants and Tax Advisors. Our liability towards the Company and also towards third parties is limited in accordance with section 8 of the AAB 2011.

We draw attention to the fact that the English translation of this Report on the independent limited assurance engagement is presented for the convenience of the reader only and that the German wording is the only legally binding version.

Responsibility of the management

The preparation of the Sustainability-Report 2012 in accordance with the criteria set out in the Sustainability Reporting Guidelines Vol. 3 of the Global Reporting Initiative ("GRI criteria")

- Materiality
- Stakeholder inclusiveness
- Sustainability context
- Completeness
- Balance
- Clarity
- Accuracy
- Timeliness
- Comparability
- Reliability

is the responsibility of the management of Wienerberger AG. This responsibility includes the selection and application of appropriate methods for preparing the Sustainability-Report 2012, making assumptions and estimates of individual sustainability disclosures that are plausible under the given circumstances, as well as designing, implementing and maintaining systems and processes where relevant for the preparation of the Sustainability-Report 2012.

Limitation of the scope of the engagement

Our responsibility is to give an assessment, based on our work, on whether anything has come to our attention that causes us to believe that the quantitative disclosures in chapter "Environmental Protection in Production" on the issues of "Energy Consumption and Emissions" (pp. 35 to 37), as well as in chapter "Employees" on the issues "Occupational Safety and Health" (pp. 24 to 27) of the Sustainability-Report 2012 have not been prepared in accordance with the GRI criteria as set out in the Sustainability Reporting Guidelines Vol. 3. Our review was limited to the key performance indicators in the cited areas of focus.

We also performed the Global Reporting Initiative (GRI) Application Level Check to comprehend the application level declared by Wienerberger AG.

Responsibility of the independent auditor

We have performed our engagement in accordance with Expert Opinion KFS/PG 13 for assurance engagements. This standard requires us to comply with our professional standards and to plan and perform the engagement in a way that enables us to draw conclusions in accordance with KFS/PG 13.

Engagement approach

In a limited assurance engagement, the work performed is less extensive than in a reasonable assurance engagement and, therefore, less assurance is obtained. We performed our work, using appropriate random samples, based on our due judgment and to the extent required to obtain limited assurance. In the course of our engagement, we therefore obtained relevant evidence based on risk and materiality assessments in order to obtain this limited assurance on the compliance of the disclosures according to the scope of the engagement with the GRI criteria mentioned above. In doing so, our work performed at the headquarters of Wienerberger AG in Vienna, Austria, particularly included the following:

- Inspection of relevant documentation of the process for preparing the Sustainability-Report 2012, as well as of existing documents and systems on the sustainability management and their sample testing
- Interviewing employees materially involved in the preparation of the report contents from the departments Corporate Controlling, Corporate Engineering, Human Resource Management and European Affairs of Wienerberger AG in Vienna as well as the sustainability coordinators of the entities Pipelife and Steinzeug-Keramo
- Sample comparison for a selection of disclosures included in the Sustainability-Report 2012 according to the scope of the engagement with records provided by country organizations and recorded centrally, as well as any side calculations
- Reviewing the declaration of Wienerberger AG on the compliance with Level B+ of the GRI G3 guidelines

Conclusion

Based on our work, nothing has come to our attention that causes us to believe that the quantitative disclosures in chapter "Environmental Protection in Production" on the issues of "Energy Consumption and Emissions" (pp. 35 to 37), as well as in chapter "Employees" on the issues "Occupational Safety and Health" (pp. 24 to 27) of the Sustainability-Report 2012, in all material respects, have not been prepared in accordance with the criteria materiality, stakeholder inclusiveness, sustainability context, completeness, balance, clarity, accuracy, timeliness, comparability and reliability of the Sustainability Reporting Guidelines Vol. 3 of GRI.

Based on our work, nothing has come to our attention that causes us to believe that the Sustainability-Report 2012 of Wienerberger AG does not meet the requirements according to GRI Application Level B+.

Sustainability
gets everywhere

ÖGNI
AUSTRIAN SUSTAINABLE BUILDING COUNCIL

Sustainability doesn't end in the bank foyer. Austrian banks like ÖGNI members as the Raiffeisen regional bank of Styria and Real Treuhand rely on sustainable construction and management. They take responsibility.

3P.for.happiness

The Austrian Sustainable Building Council (ÖGNI) has been founded in 2009 of 125 founding members, including Prof. Peter Maydl and Alexander Passer of Graz University of Technology.

ÖGNI pursues the aim of a **paradigm shift towards Sustainability** in Austria's building and real estate industry.

ÖGNI develops content such as guidelines or codices, **certifies companies** in their ethical behavior and honors lighthouse projects of sustainable building with the international **DGNB certificate**.

Sustainability is practiced in a comprehensive way, applying the 3-P approach: **persons, processes** and **products** (real estate).

ÖGNB

Österreichische Gesellschaft
für Nachhaltiges Bauen

The Austrian Sustainable Building Council (ÖGNB) was initiated and founded in Austria in January 2009, by a number of renowned and independent institutions in the field of sustainable building.

Membership is open to all who are interested, to institutions and businesses seeking to participate actively in supporting the Austrian building industry in compliance with sustainable building.

Testing the TQB tool

For testing purposes, please find the TQB assessment tool for both residential buildings and office buildings on www.oegnb.net. Please note that buildings cannot be saved on this site.

To make full use of the service including transfer of proof for the building assessment, you need to register as Austrian Sustainable Building Council consultant. Registration is free.
