Table of Contents

Forewords

Forewords 1

A1 - Legal and economic frame conditions for ecological high quality refurbishment

TOPIC A1 14

Comparison between energy usage and thermal comfort of typical masonry houses in Ireland before and after receiving retrofit 15

Jamie Goggins

Collaboration Models for Industrialised Renovation Methods and Prefabrication - Experience and Outlook on Organizational and Legal Frame Conditions 27

Sonja Geier

Cost optimal building standards – evidence based! The case of Austria 39

Walter Huettler, Johannes Rammerstorfer

Comprehensive Assessment for the Refurbishment of Chinese Existing Building 50

Lei Fan, Yuanfeng Wang

A2 - Life cycle perspectives in a high refurbishment - Part 1

TOPIC A2 59

Critical Issues in Application of New European Standard EN15978 in building refurbishments 60

Stepan Mancik, Julie Hodkova, Antonin Lupisek

Environmental and economical assessment of refurbishment concepts 69

Tarja Häkkinen

LCA and LCC based Energy Optimization of Building Renovation Strategies 77

Francesco Pittau, Enrico De Angelis, Giorgio Pansa, Nadia Villa, Antonio La Torre, Caterina Porcino

NZE-renovation of houses: Life cycle costs & environmental impact 87

Jeroen Vrijders, Lisa Wastiels

Retrofitting solid wall buildings: carbon costs and savings 95

Alice Moncaster

A3 - Life cycle perspectives in a high quality refurbishment - Part 2

TOPIC A3 102

Life Cycle in Timber Façade Systems – Robust Design Patterns 103

Stephan Ott, Stefan Winter

Naturwall: active timber wall for renovation of existent buildings 114

Antonio Spinelli, Guido Callegari, Chiara Rizzi

Finding the Balance between Measures Reducing Energy Demand and Measures Based on Renewable Energy Sources in Building Renovation 122

Walter Ott

Management and financial tools for housing regeneration 131

Paola Piermattei

Catalogue of passive house details for refurbishments 139

Thomas Zelger

A4 - Technologies and aspects of high quality refurbishment in nonresidential constructions

TOPIC A4 151

Requirements and solutions for high performance school renovations 152

Armin Knotzer

Indoor Environment Quality in Riga City Kindergarten Buildings: Actual Data, Problems and Solutions 159

Eriks Krumins

Re-Commissioning Services: Immediate Savings and Triggering Building Refurbishment Measures in Non-Residential Buildings 166

Boris Papousek

Risk Assessment for Energy Efficient Refurbishment of 19th Century Townhouses Using Interior Insulation 173

Paul Wegerer

Analysis of the thermal behaviour of historical box type windows for renovation concepts with CFD 181

Daniel Brandl

A5 - Opportunities and potentials for an energy efficient modernisation of syndicates of municipalities

TOPIC A5 195

Selection of refurbishment construction solutions to improve the IEQ and Sustainability of a building 196

Sandra Monteiro da Silva, Manuela Almeida

The uncertainty of the energy demand in existing Mediterranean urban blocks 204

Joana Ortiz

PV integration in the open urban space redevelopment of historical villages in Italy 213

Pierluigi Bonomo

Energy efficient roofs retrofit for communist prefab concrete blocks 223

Catalina Bocan

Methodology for improving and testing the quality of renovation actions: a case study application(modified according to reviewer's suggestion) 232

Jacopo Gaspari, Andrea Boeri, Danila Longo

A6 - Demonstration projects considering new technologies and innovative concepts in rehabilitaion of large-volume buildings

TOPIC A6 240

Comparative analysis for the refurbishment of the high-rise concrete building stock based on life cycle assessment scenarios 241

Sára Hrabovszky-Horváth, Zsuzsa Szalay, Tamás Csoknyai

"Johann Böhmstrasse": Renovation concept towards energy plus standard with prefabricated active roof and facade elements, integrated home automation and grid interaction 251

Tobias Weiss

Block of Flats from 1958, Rejuvenated with Wood 256

Florian Lichtblau

Renovation to plus- energy- standard schools – Rainbach im Mühlkreis/Austria 261

Ingrid Domenig-Meisinger, Albert Böhm

E-Office: a prime example for energy efficiency 269

Urs Harnik-Lauris

B1 - Best Practice in Sustainable Buildings

TOPIC B1 277

Best case plus-energy renovation of a residential building in Kapfenberg assessed with the ÖGNB Austrian Building Certification Scheme and klima:aktiv building standard 278

Alexander Passer, Susanne Geissler

Certification System for Research and Laboratory Buildings – The Case Study MED CAMPUS Graz 293

Alexander Passer, Helmuth Kreiner

B2 - Evaluation of Embodied Energy and Carbon Dioxide Emmissions for Building Constructon (Annex 57)

TOPIC B2 294

IEA ECBCS, ANNEX 57 - EVALUATION OF EMBODIED ENERGY AND CARBON DIOXIDE EMISSIONS FOR BUILDING CONSTRUCTION 295

Tatsuo Oka

Key contributors to embodied carbon and energy of four Brazilian case studies 303

Maristela Silva, Vanessa Gomes, Marcella Saade

Embodied energy and CO2 emission associated with building construction by using I/O based database and process based database in Japan 311

Noriyoshi Yokoo, Toru Terashima, Tatsuo Oka

B3 - Facade

TOPIC B3 317

Leichtbau 3.0: Material, Structure, Energy 318

Oliver Englhardt

Energy performance of windows in various building types 320

Adrian Trzaski

The pitfalls of building integrated photovoltaic. 328

Dieter Moor

Novel type of façade-window solar thermal collector 334

Ilija Nasov, Anka Trajkovska Petkoska

Development of innovative building skins in the context sustainability assessment 342

Alexander Passer, Gernot Fischer, Thomas Mach, Helmuth Kreiner

B4 - Best Practice

TOPIC B4 359

Environmental performance of energy efficient residential building – a case study of Lithuania 360

Violeta Motuziene, Tatjana Vilutiene, Artur Rogoza

Reality check of a brick made plus energy dwelling 368

Tim Selke

LCA of a Net Zero Energy Office Building - The New Technology Park of Bolzano 376

Marina Fusco, Ulrich Filippi Oberegger, Roberto Lollini, Giulia Paoletti

Integration of sustainability targets in the planning process and their consequences project results – case study of the MED CAMPUS Graz 384

Heinrich Schober, Alexander Passer

Plus Energy Building in Estonia 403

Georg W. Reinberg, Tönu Mauring

B5 - Database & Tools

TOPIC B5 414

Towards a new generation of building LCA tools adapted to the building design process and to the user needs 415

Sebastien Lasvaux

The use of Generic LCIA Databases in the Process of Building Sustainability Assessment – the case of SBToolPT® 427

Ricardo Mateus, Luís Bragança

Adapting existing life cycle inventory of building products for the brazilian context 435

Luciana Oliveira, Sébastien LASVAUX, Endrit HOXHA, Julien Hans

LCC and LCA of dynamic building elements in the context of social housing 446

Damien Trigaux, Frank De Troyer, Karen Allacker, Anne Paduart, Wim Debacker, Niels De Temmerman

B6 - Certification sheems

TOPIC B6 457

Guidelines and Indicators for Sustainable Mega-Event-Buildings 458

Natalie Essig

A free building assessment tool facilitates change in the construction sector towards environmental, economic and social sustainability 465

Susanne Geissler

Schools go green - extension of the BNB-Certification methodology for educational buildings 469

Carl-Alexander Graubner, Carmen Schneider

Challenges of LCA in a European context – Findings from the research projects OPEN HOUSE and EeBGuide 475

Johannes Gantner, Sebastien Lasvaux, Katrin Lenz, Julia Böttge, Sarah Schneider, Sarah Homolka

Practical Aids, Instruments and Tools of the Assessment System for Sustainable Building (BNB) 485

Andreas Rietz, Heidemarie Schütz

C1 - Building Information Modelling

TOPIC C1 489

An Integrated BIM LCA framework for the assessment of Chinese urban residential buildings 490

Wei Yang, Shanshan Wang

Life Cycle Sustainable Assessment and BIM 498

Bruno Fiès, Thomas Lützkendorf, Maria Balouktsi

The sustainability effects of Product/Service-System design validated through Life Cycle Assessment 509

Leise Dreijer, Morten Birkved, Thomas Howard, Niki Bey

An LCA Study on a Concrete Structure by Variations of Compressive Strength of Concrete to define the characteristics of GHGs emission 521

Chae Chang-U, Suhyun Cho, Sunghee Kim, Jiyeon Park

C2 - Smart Cities - Part 1

TOPIC C2 529

Environmental sustainability assessment of urban systems applying coupled urban metabolism and life cycle assessment 530

Morten Birkved, Benjamin Goldstein

Modelling the transformation of the residential buildung stock - a case study for the city of St. Gall 542

Susanne Kytzia

Norwegian Smart Cities - Towards cross-scale indicators 555

Rolf Andrè Bohne

Efficiency Optimization of a real Settlement 565

Azra Korjenic

SMART ENERGY DEMOnstration: First research results of an Austrian SMART CITY 571

Alois Kraussler

C3 - Smart Cities - Part 2

TOPIC C3 579

KomMod as a tool to support municipalities on their way to becoming Smart Energy Cities 580

Jan-Bleicke Eggers, Gerhard Stryi-Hipp

Project –“Morgenstadt: City Insights” - Analysis of Interactions Between Key Factors 592

Elvira Ockel

Towards Sustainable Knowledge Ecosystem with Open Data, Co-creation and User Empowerment 601

Jessica Karhu, Suvi Nenonen

Intensity and Spatial Influence of Urban Parks: A case study in Sao Paulo, Brazil 609

Paula Shinzato

Leadproject ECR Energy City Graz-Reininghaus □ □ Framework Plan Energy Graz-Reininghaus 617

Ernst Rainer, Kersten Hofbauer, Hans Schnitzer, Thomas Mach, Alexander Passer, Peter Maydl, Lothar Fickert, Helmuth Kreiner

C4 - Green Products - Part 1

Social performance assessment of buildings according to the European standard prEN 16309 629

Wibke Tritthart, Chris Hamans

TOPIC C4 641

Using life cycle based environmental assessment in developing innovative multi-functional glass-polymer windows 642

Karen Allacker, Maria Calero, Fabrice Mathieux, Catia Baldassarri, Ya Roderick

Carbon footprint of green roofs in Singapore 650

Nalanie Mithraratne

Life-Cycle Energy Performance of Semi-Transparent Building-Integrated Photovoltaic (BIPV) Windows in Tropical Singapore 659

Poh Khai Ng, Nalanie Mithraratne

Medium-rise structural timber apartments; Luxury or long-term carbon storage solution? 668

Douglas Thomas, Grace Ding, Keith Crews

Optimization of wood based structural elements concepts for increased resource efficiency 676

Alireza Fadai, Wolfgang Winter

C5 - Green Products - Part 2

TOPIC C5 684

Environmental improvement of building insulating cladding system 685

Paola Garbagnoli, Marta Musitelli, Maria Vittoria Diamanti, Barbara Del Curto, MariaPia Pedeferri

The environmental footprint of plastic pipe systems within the built environment 693

Sandor Aranyi, Carolin Spirinckx, Zoran Davidovski, Karolien Peeters

Symbio2 - An Integrated system for the production of microalgae in the urban environment in symbiosis with building systems and their envelope. 702

Alistair Law

A proposal for the information needed with respect to BRCW7: Sustainable use of natural resources 711

Tom Harrison

C6 - Green Products - Part 3

TOPIC C6 721

A Comparative Analysis of Life Cycle Impact Assessment Methods for Building Materials 722

Saniye Karaman Oztas, C.Zeynep Oguz, Leyla Tanacan

Product Design Aspects of Agro-fibres Biocomposites for Architectural Applications 730

Hanaa Dahy

Challenging ETICS 741

Wolfgang Winter, Ingo Curt Riemenschneider, Markus Mosing, Heinz Ferk

Measuring the Ug-value of window glazing 753

Helmut Weinläder, Sven Hippeli

Identification of building materials influence on robustness and uncertainty of single houses LCA 760

Endrit Hoxha

D1 - Energy

TOPIC D1 771

Assessment of the relevance of “embodied energy” in the building stock of the city of Zurich 772

Holger Wallbaum, Martin Jakob, Gregor Martius, York Ostermeyer

The Energy Sufficiency Path: Basics for Residential Buildings 773

Annette Aumann, Katrin Pfäffli, Heinrich Gugerli

Residential High-Rises without the usage of Air-Conditioning in Tropical and Subtropical Regions 781

Ferdinand Oswald

Criteria for low energy buildings 792

Jerzy Kwiatkowski, Aleksander Panek

Where is the embodied CO2 of buildings mainly located? Analysis of different types of constructions and various views of the results 800

Viola John, Guillaume Habert

D2 - Renewables

TOPIC D2 808

Zero Carbon Village Energy self-sufficiency, Modular Prefabrication and Sustainable Building Materials 809

Robert Wimmer, Sören Eikemeier

Wood in Carbon Efficient Constructions 816

Franz Dolezal, Hildegund Mötzl, Oskar Mair am Tinkhof, Christina Spitzbart

Greenhouse gas emission from construction process of multi-story wooden buildings 827

Atsushi Takano, Francesco Pittau, Annette Hafner, Stephan Ott

Recycling and End-of-Life scenarios for timber structures 835

Annette Hafner, Stephan Ott, Stefan Winter

Regulation of displacement ventilation systems combined with surface heating/cooling in passive house office model rooms 846

Tobias Waltjen, Bernhard Lipp, Thomas Zelger, Markus Rösler, Ralf Gritzki

D3 - Integrated Design Process

TOPIC D3 856

Sustainability in Competitions: New German Federal System to verify the Qualities of Sustainability in Planning Competitions (SNAP) 857

Merten Welsch

Debating economic performance aspects of buildings in the context of sustainability assessments 864

Thomas Lützkendorf, David Lorenz, Peter Michl

Interaction between sustainability and quality in buildings - Systemic approach for sustainability issues 877

Annette Hafner

The impact of sustainability issues on real estate project development processes 887

Wilhelm Brugger, Werner Gächter, Arnold Tautschnig

Nearly zero energy target integration in public design tenders 896

Giulia Paoletti, Annamaria Belleri, Roberto Lollini, Hannes Mahlknecht

D4 - Sustainable Assessment

TOPIC D4 904

Realising Blue Buildings? - Life Cycle Management as an integrated management philosophy for blue building projects 905

Rainer Stempkowski

Benchmarking of DGNB-Certified Buildings in Austria 915

Roman Smutny, Alexander Passer

SB13 Graz - Extended Abstract Achieve Sustainability in Laboratory Buildings on different Ways – Building, Equipment and User Behavior 925

Egbert Dittrich

Time Valued Life Cycle Greenhouse Gas Emissions from Buildings 927

Howard Darby, Abbas Elmualim, Fergal Kelly

The influence of structural design on the sustainability assessment of building constructions 939

Julia Maydl

D5 - Blue Buildings

TOPIC D5 948

Development of LCA Tool for Use in Initial Stage of Housing Design Based on Endpoint Modeling of Residents Part. 1 Examination of Assessment Framework 949

Azusa Takayama, Koichi ASANO, Ken-ichi HASEGAWA, Hideto KANNO, Ryo MURATA, Yuki TENMA, Naoshi KANEKO

Contribution of plastics to the sustainability of buildings 957

Arjen Sevenster

Relevance of the recycling potential (module D) in building LCA: A case study on the retrofitting of a house in Seraing 964

Lisa Wastiels, Laetitia Delem, Johan Van Dessel

Decision making processes in sustainable refurbishment projects for public administration 974

Linus Waltenberger, Bernhard Herzog, Florian Danner

D6 - Life Cycle Assessment

TOPIC D6 981

The need for a comprehensive and consistent approach in life cycle sustainability assessment of buildings 982

Karen Allacker, Rana Pant, Erwin M. Schau

A modular LCA database adapted to different user needs during the building design process 991

Galdric Sibiude, Sébastien Lasvaux, Manuel Bazzana, Alexandra Lebert, Pierre Ravel, Laëtitia Arantes, Thibault Hallouin, Romain Bonnet

System and scenario choices in the life cycle assessment of a building – changing impacts of the environmental profile 1003

Freja Nygaard Rasmussen, Harpa Birgisdottir, Morten Birkved

Trends in Building & Construction Life Cycle Assessment 1013

Bastian Wittstock, Matthias Fischer, Julia Böttge, Johannes Gantner, Elvira Ockel, Anna Braune

Life Cycle Assessments and the Austrian Construction Sector 1021

Florian Gschösser, Alexander Passer, Stefan Marchtrenker

Posters

POSTERS 1033

Renovation strategies for ageing society 1034

Markus Summer, Iva Kovacic, Christoph Achammer

Gender Perspectives on the Design and Optimisation of Highly Energy Efficient Buildings 1046

Siegrun Klug, Susanne Geissler, Edeltraud Haselsteiner, Gabriele Bargehr, Sabine Steinbacher

Cost optimallevels for envelope components in residential building renovation–Rainha Dona Leonor neighborhood case study 1054

Ana Rodrigues, Manuela Almeida, Marco Ferreira, Pedro Silva

Building Envelope Retrofits for Improved Energy Performance and Thermal Comfort in Detached Houses in Serbia 1062

Vladimir Jovanovic

Life cycle assessment of wooden building systems for façade retrofitting 1072

CECILE HUREL

Co-Benefits in Building Retrofit – Methodology proposal, tool development and a case-study demonstration 1080

Marco Ferreira, Manuela Almeida, Dias Nelson, Ana Rodrigues

BIPV-Standard Module for Large-Scale Halls 1088

Claudio Ferrara, Carmen Vicente Iñigo

Prefabricated Retrofit Façade System – a Systemized Building Construction Detailing 1096

Stephan Ott, Stefan Loebus, Stefan Winter

Assessment of Double Skin Façade Technologies for Office Refurbishments in the United Kingdom 1107

Francesco Pomponi, Kenneth Ip, Poorang Piroozfar

Characterization and Classification of the Energy Performance of Facades According to Climate and Location 1119

Marlix Perez Gonzalez, Elena Cuerda, Javier Neila

Characterization and Classification of the Energy Performance of Facades According to Climate and Location 1126

Marlix Perez Gonzalez, Elena Cuerda, Javier Neila

Evaluating the energy savings potential of window refurbishment 1133

Helmut Weinläder, Cornelia Stark, Erik Fischer

Monitoring results of PCM systems for room cooling 1139

Helmut Weinläder, Werner Körner

Cost-effective and high performance renovation of existing residential multi-family buildings in three European countries 1148

Holger Wallbaum, York Ostermeyer, Andrea Chegut, Rolf Bastiaanssen

Innovative modernization of historic buildings – pilot projects in Vienna 1150

Walter Huettler, Johannes Rammerstorfer

Energy Demand Calculations – View from above 1159

Jan Tywoniak, Jan Antonin, Pavel Kopecky

CESBA – a collective initiative for the new building culture in Europe 1163

Markus Berchtold, Andrea Moro

Human Scientific Contributions to Life Cycle Sustainability 1168

Harald Deinsberger-Deinsweger

OPEN HOUSE: Common European methodology for assessing building sustainability 1180

Daniel Hiniesto, Vincent Peyramale, Rocio Barros, Edith Guedella, Natalie Essig

Development of a Performance Based Evaluation Method for Carbon Management of Existing Buildings in Egypt 1188

Khaled Tarabieh, Mirette Khorshed

Better understanding and modelling of user behavior in (nearly) zero energy buildings 1198

Wibke Tritthart, Jürgen Suschek-Berger, Anita Thaler, Magdalena Wicher

Timber in the City 1200

Milena Stavric, Stefan Zedlacher

Criteria of Mobility for Sustainable Buildings 1207

Herbert C. Leindecker, Isabella Dornigg

Hiqh Performance Buildings Quality Assessment 1217

Herbert C. Leindecker, Susanne Luger

Assessment of an Office Building in Serbia by New Proposed Methodology - „OPEN HOUSE“ 1225

Djordje Djordjevic, Biljana Avramovic

Case study: Green family house in Slovenia, from planning until certification 1232

Matjaž Nekrep Perc, Benedikt BoršiĊ

Improving comfort condition in the building 1243

Abdolsalam Ebrahimpour, Yousef Karimi Vahed

Integration of Zero Energy Standards into Student Accommodation: Demonstrated through a Case Study of Lancaster University Residences in the UK 1251

Hasim Altan

A Study on Assessment Methodology to Measure Carbon Reduction Potentials of Recycling Building Materials considering Avoided Impacts 1261

Sunghee Kim

Using MFA for the performance economy : a case study of industrial storage 1269

Thomas Peverelli, Célian Colon, Thomas Peverelli, Samuel Causse

Identification of climate neutral buildings using LCA – Case studies from the project ÖKOPLUS-KOMPLEX 1278

Gerfried Jungmeier, Gerfried Jungmeier, Stefan Gunczy, Karl-Peter Felberbauer, Rudolf Stiglbrunner, David Tudiwer, Reinhard Padinger

Sustainability issues in the valuation process of project developements 1282

Georg Fröch, Arnold Tautschnig, Christoph Achammer

Non-state market driven governance in the Green Building sector 1293

Sabine Sedlacek, Hannes Hippacher

Proposition of socioeconomic logical attributes to aid decision making processes in Brazilian construction sector: complementing LCA results 1299

Marcella Saade, Maristela Silva, Vanessa Gomes

Indicators to Support Sustainability and Performance-Based Selection of Structural Frame Alternatives in Concrete: Validation at Typical Floor and Superstructure Levels 1307

flavia oliveira, Maristela Silva, Vanessa Gomes

Performance of Domed Roofs using a New Computer Model 1315

Giamal Mashina

Embodied energy and CO2 emission associated with building construction by using I/O based database and process based database in Japan 1322

Noriyoshi Yokoo, Toru Terashima, Tatsuo Oka

Combining Concepts of Energetic, Environmental and Economic Life Cycle Balance towards an Integrated Life Cycle Approach 1328

Susanne Geissler, Christina Ipser, Ulrike Radosch, Helmut Floegl, Hildegund Mötzl

Can form follow energy? – Critical factors in modelling for computational design optimization 1335

Sven Schneider

The Energy Performance of Commercial Building FacadesiIn Saudi Arabia 1343

Mohammed Essam Shaawat, Salah Alghamdi, Noman Ashraf

Assessing the severity of workmanship defects using thermography and 2-D and 3-D heat transfer models 1351

Tim Taylor, John Counsell, Steve Gill, Gerraint Oakley

Water and Energy Recycling in a Residential Passive House 1362

Erwin Nolde

ELIH-MED - Energy Efficiency in Low Income Housing in the Mediterranean area 1370

Anna Moreno

Life Cycle Assessment for sustainable buildings during the planning phase 1378

Anton Zuser, Barbara Jörg, Maria Popp, Bernhard Herzog, Thomas Belazzi

In situ U-value measurements for today’s Cypriot Houses 1385

Flouris Xeni

Life Cycle Costing of innovative energy storage systems in buildings 1396

Julia Böttge, Sarah Homolka

Real-time Energy Simulation for Advanced Building Control 1404

Karsten Menzel

Energy Efficiency Using Integrated ICT Systems: Business Challenges and Opportunities 1413

Gaby Abdalla

Comparison of sustainable office facade renovations in the Netherlands 1415

Michiel Ritzen, Roland Rovers

The CO2 footprint of plastic pipe systems 1430

Carolin Spirinkx

Cooling concept of the new R&D building of the ZAE Bayern using several thermal energy storage technologies 1439

Felix Klinker, Christina Konstantinidou, Helmut Weinläder, Harald Mehling, Dietrich Büttner, Stephan Weismann, Hans-Peter Ebert, Eberhard Lävemann, Werner Jensch, Thilo Ebert

Refurbishment of a Viennese residential estate to future building standards with integrated PV 1448

Christoph Neururer

LifeCycle Tower - The Natural Change in Urban Architecture 1456

Michael Zangerl, Jakob Bonomo

Concrete Repair Mortar Made of a Waste from Oil Refining Industry 1464

Carla COSTA, Maria Sofia RIBEIRO, Nuno BRITO

Biobased Sandwich System for Applications in Architecture 1472

Preface

Climate change, increasing energy demand and resource scarcity not only require a change in infrastructure and industry but also in buildings and cities with smart technologies and systems.

Research and innovation crucially contribute to sustainable and energy-efficient buildings and cities. In the course of the research programme “Building of tomorrow” in the last years my resort has supported many concepts and key technologies for buildings. International co-operations made it possible to successfully disseminate Austrian research results. Today Austria plays an international pioneer role in energy-efficient building.

The new research programme „City of tomorrow“ aims to face coming challenges by funding technological research and development projects of systems and services for the city of the future.

I am therefore very pleased to introduce here at the Sustainable Building Conference 2013 this new research programme to an international audience for the first time. Dedicated to essential questions reaching from renovating buildings and quarters to smart cities, the conference is an excellent platform to present Austrian technologies and know-how in the realms of buildings and cities.

With this in mind I wish those attending the international conference stimulant and exciting discussions!

Doris Bures
Bundesministerin
für Verkehr, Innovation und Technologie

Preface Minister

The klima:aktiv building standard is Austria´s most prominent quality label for buildings

Sustainable building and renovation are essential instruments of climate protection and represent an important step towards energy autonomy. About one third of our energy consumption results from private and public buildings and from service buildings. Due to space heating and their demand for electricity buildings cause a substantial part of the greenhouse gas emissions.The klima:aktiv building standard is Austria´s most prominent quality label for buildings

Sustainable building and renovation are essential instruments of climate protection and represent an important step towards energy autonomy. About one third of our energy consumption results from private and public buildings and from service buildings. Due to space heating and their demand for electricity buildings cause a substantial part of the greenhouse gas emissions. With comprehensive thermal retrofitting, greater energy efficiency in new buildings and an increase in the share of renewable energy we can protect our climate for the long term. Austria possesses extremely extensive know-how in the fields of environmentally benign and energy-efficient construction and heating technologies. Our country is a frontrunner in the passive house technology and all over the EU one out of three solar energy systems is already from Austria. We must exploit this immense potential.

My ambition is to achieve energy autonomy, meaning that, on balance, Austria produces enough energy from renewable sources to be self-sufficient. To attain this goal until 2050 I am strongly promoting a shift of our system towards renewable energy and higher energy efficiency. With my climate protection initiative klima:aktiv, the subsidisation priorities in the climate and energy fund, the promotion of environmental projects in Austria and vigorous action to foster thermal refurbishment, the Ministry of Life offers concrete advice and financial

support. These investments have also significant economic impacts in Austria: They bring about economic recovery and growth and provide new green jobs.

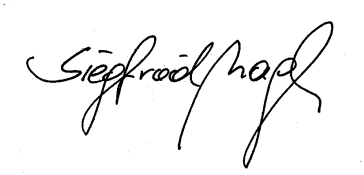
The klima:aktiv programme "bauen und sanieren" for building and renovation aims at making energy-efficient building and comprehensive thermal-energetic refurbishment an issue of public interest. The klima:aktiv building standard of the Ministry of Life is the most prominent Austrian quality label for residential buildings and service buildings. It is awarded to buildings which satisfy very demanding energetic and ecological requirements. Energy-saving and energy-efficient building is an essential criterion which we have to fulfil to achieve energy autarky. A construction sector which is oriented towards sustainability has positive impacts not only on the environment: With new green jobs it provides promising perspectives on the job market and induces economic advancement.

The Sustainable Building Conference 2013 in Graz comprises highest standards concerning "blue buildings", "green products" and "smart cities". We are convinced that the klima:active building standard will contribute to the high quality of this international conference.

I wish the Sustainable Building Conference 2013 a sustainable success and lots of interesting discussions and insights.

Nikolaus Berlakovich
Minister of the Environment

Ladies and Gentlemen,
dear participants of the “Sustainable building Conference 2013”



A cordial welcome to Graz, the World Cultural Heritage City, the City of Human Rights and the City of Design!
All three titles have one thing in common: They are all connected to UNESCO.
If we leave out the U-N and O, then it is about Education, Science, and Culture.
We like to think that our city is built on these three pillars, but one pillar is missing here and that is commerce and industry.
But, as you know, this fourth pillar results from promoting the first three.Knowledge is power. Research and the resulting competitive edge form the basis for surviving in today’s global competition.
The ever growing body of knowledge, which is making it more and more difficult to gain an insight into and an overview of specialized fields, means that working in networks is indispensable. These networks between universities provide the foundation for world-class research.

However, networks are a significant factor for progress and development on all levels—both for individuals as well as projects and businesses.

The worldwide growing urban centres need new and creative solutions for ecological and sustainable house building, as well as plant manufacturing. We need also sustainable energy supply, short distances between accommodations, offices, kindergartens, schools and shop centres etc. and we need smart solutions for the traffic.

Therefore, I would like to wish your conference a successful outcome and hope to be able to welcome you again soon in our city!

Yours sincerely,

Mayor Siegfried Nagl
City of Graz

Dear SB 13 participants,

As director of the executive department for urban planning, development and construction of the City of Graz it is a great pleasure to be able to welcome you to Graz, where sustainability in building has long been an important topic. We understand the importance of communicating with other cities and other regions in order to be able to compare the best examples, both in research and in practice. This enables us to discuss their relevance for each city and therefore find optimal solutions. Everyone benefits from being involved in this sort of international cooperation.
The City of Graz has already achieved international recognition for its efforts to find sustainable solutions. This has been made possible through cooperation with numerous experienced partners such as the University of Technology in Graz, Province of Styria and also with outstanding companies working within the research and energy sector. For this reason our concept for a Smart City, the sole flagship project in Austria, has been awarded with a financial sponsorship from the federal running into millions.
This means that we are now able to begin the detailed planning phase of building a sustainable, futureproof, energy self-sufficient district which will be built on an old industrial brownfield near to the main train station in Graz.

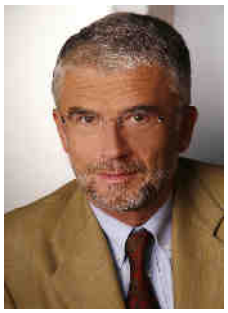
Concerning the project “Energy City Graz-Reininghaus”, an overall energy concept including energy networks will enable sustainability for this district. The first steps of the implementation can already be seen.

At SB 13 internationally renowned experts will highlight all aspects of sustainable construction in numerous talks and lectures. The topics range from sustainable, energy self-sufficient urban technologies and the building of new, futureproof buildings to environmentally friendly building materials and sustainable renovation as well as the development of whole districts in such a way that resources are conserved and the observation of the entire lifecycle of buildings.

The fact that young researchers have been invited to come and present new research methods shows that we do not want to simply be satisfied with that which we are building now, but that we want to focus on the future. I have high hopes that the International Sustainable Building Conference 2013 in Graz will represent an important milestone in the development of sustainable building!

I wish you every success and best wishes for a sustainable future!

DI Mag. Bertram Werle
Director of the executive department for urban planning, development and construction
City of Graz



As most visible elements of our built environment, buildings satisfy a deep rooted human need for protection, comfort and well-being. Be it on the workplace, at home, or the public sphere, constructions most strongly determine our quality of life.
But construction and operation of buildings also form part of highest primary resource consumption, energy intakes and environmental pollutants. With 30 to 40 % of pollution and energy consumption within the industrialized world being associated with our buildings, quality and efficiency improvements can provide profound contributions to a more balanced and ecologically sound society.
Therefore all constructive disciplines, civil engineers, architects, infrastructure planners- as well as socio-cultural scientists and political representatives need to be interlinked in order to make a difference by implementing new and innovative technologies. With life cycles that last over decades, generations and often centuries, application of newest technologies and standards is paramount when it comes to ecologically sound and economically efficient buildings.

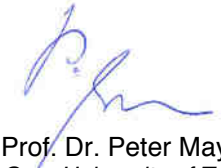
Being a powerhouse of sustainability, Graz University of Technology is the perfect place to host this “International Sustainable Building Conference”. Through our Field of Expertise “Sustainable Systems”, as well as via the “European sustainable energy innovation alliance” (esaia), we form part of a highly dynamic global sustainability network. Your conference participation most clearly displays the successful path this institution has taken. The coming days will provide you with ambitious intellectual, scientific as well as social inputs. All this is needed to help implement long lasting solutions – and develop new ideas – on how to reduce our primary and secondary resource consumption in building and construction. I hope that after the coming days you will associate Graz with visions, ideas and solutions on how to make our planet a better place!

Yours

Harald Kainz
Graz University of Technology

Foreword

Meanwhile sustainable development has got to a place in the building and construction sector. Therefore it is time to transpose the paradigm change into practice on an overall basis. Whereas in Austria energy efficiency, use of renewable energy or reduction of greenhouse gas emissions were synonyms for sustainable construction we can notice today an increasing acceptance of the holistic approach, the necessity of considering ecology, economy and sociocultural aspects in the building sector simultaneously over the entire life cycle.



The European Commission enforced this development by releasing numerous strategies, directives and regulations such as e.g. the Energy Performance of Buildings Directive, the Lead Market Initiative Sustainable Construction or the new Construction Products regulation with the new Basic Requirement 7 (*Sustainable Use of Natural Resources*). Parallel to these mandatory regulations, a suite of standards (e.g. European standards for sustainable construction) and non-mandatory building certificates particularly in the area of office and retail buildings emerged. This intensive supply of information, however, leads to many more questions from clients and practitioners, especially on how buildings can be constructed and maintained in a sustainable way.

With these facts in mind, we highly appreciate the initiative of CIB, UNEP, iiSBE and FIDIC of having established the series of SB conferences and are very happy to host the last one of the central European SB conferences in 2013 here in Graz.

One of the most important starting points is the sustainable handling of the existing building stock therefore the SB conference in Graz addresses not only new buildings but also restoration and refurbishment. Hence, we combined the SB13 Graz conference with the ökosan conference, which is normally hosted by AEE INTEC (Institute for Sustainable Technologies). Ökosan is a symposium on ecologically sound refurbishment technologies and best practice examples and together with AEE INTEC we have a strong partner, which offers the possibility to merge theory and practice.

Graz University of Technology and particularly the Faculty of Civil Engineering Sciences acted always as an interface in technology transfer between all stakeholders. Therefore, we do hope to contribute with this conference to a knowledge transfer in the scientific community, but especially with commercial partners from industry, planners and public authorities, in order to realise a sustainably sound built environment without overflow of rules and regulations. Standards and assessment tools should be accepted as support and assistance, not as a restraint.

We are looking forward to your vital participation in the sessions and workshops and wish you a pleasant stay in the green heart of Austria.

Prof. Dr. Peter Maydl
Graz University of Technology

Ass.Prof. Dr. Alexander Passer
Graz University of Technology

Dr. Karl Höfler
AEE INTEC

Dear Participants of the “Sustainable Building Conference 2013”,

The global issues we are all currently facing are multiple. A central one is certainly the continuously rising global demand for sustainable solutions and the building sector is playing a key role in this area.
The supply of future oriented building material solutions and optimized production processes of building materials are consequently the core of the Wienerberger sustainability strategy.
Our target is the delivery of building concepts for tomorrow today. Our long-lasting, resource-conserving building materials as well as our energy-efficient house concepts help our customers make a substantial contribution to environmental protection. Our e4-Brickhouse 2020 for example has a positive energy and CO_2 balance and in this way makes an active contribution to climate protection.

Wienerberger sees also an important potential in the education of young people in the field of sustainable building solutions. Therefore, Wienerberger provides an international education program dedicated to Masters Students of Architecture, Civil and Environmental Engineering who are outstandingly motivated in the field of sustainable building and wish to extend their knowledge and experience in this area. Within the first round of the Wienerberger’ s Sustainable Building Academy (WISBA 2013/2014) we invite 12 students from three different countries for a fully financed one semester training together with experts from science and economics in the field of sustainable building. We start the program of WISBA 2013/2014 in cooperation with the Sustainable Building Conference 2013 in Graz because it guarantees our scholarship recipients the scientific exchange on a high level with the most important experts in Europe. The 3-day kick-off event of WISBA will then be followed by four international workshops during the next months and a final conference in spring 2014.

Sustainable management has been a key part of the Wienerberger corporate culture for many years and is fully integrated in all areas of the company. In order to make our sustainable management activities even more transparent, we have decided to announce our sustainability goals for various areas in the sustainability report 2012 and will report regarding our progress in the future. I invite you to form your own opinion of our efforts with respect to sustainability management and to join us on a sustainable course into the future. For the Sustainable Building Conference 2013 in Graz I wish you all interesting discussions and a promising outcome.

Yours,

Heimo Scheuch, CEO

Legal and economic frame conditions for ecological high quality refurbishment

Chair: Robert Schwertner
FFG – Austrian Research Promotion Agency, Austria

Comparison between energy usage and thermal comfort of typical masonry houses in Ireland before and after receiving retrofit

Dr Jamie Goggins
Lecturer
National University of Ireland, Galway
Jamie.Goggins@nuigalway.ie

Mr Alan Armstrong, National University of Ireland, Galway, Ireland a.armstrong1@nuigalway.ie
Ms Helena McElmeel, Helena McElmeel Architects, Ireland, helena@mcelmeel.ie

Short Summary

This research project examines the efficacy of typical insulation and building fabric upgrade works of residential buildings in reducing energy and greenhouse gas emissions, as well as their affect on the perceived thermal comfort of the occupants. This is achieved by monitoring 19 houses in Ireland and assessing the internal environment, energy consumption, comfort and occupant behaviour, before and after typical residential insulation improvements. A full economic and environmental lifecycle analysis is conducted, which considers both the energy consumption and carbon emissions embodied in the retrofit works together with those associated with the operation of the home. The houses are typical masonry construction used in Ireland. The retrofit provisions included pumping the cavity walls with insulation and increasing the level of insulation in the attic above the ceiling joists. The heating systems in the homes are a central heating system using an oil-fired condensing boiling and a solid fuel open fire in the sitting room. The mix of fuel type employed varied in the different houses. So did the level of satisfaction expressed by the occupants in relation to the thermal comfort conditions before and after the upgrade works? As expected, the upgrade of insulation of the houses lead to increased internal temperature, but also in most instances an expected decrease in overall energy consumption over the lifecycle of the building. However, deeper retrofitting is required on houses in Ireland if the Sustainability Energy Authority of Ireland's target to reduce CO_2 emissions of buildings by 90% by 2050 is achieved. This is a similar target set by the European Commission for reductions in emissions associated with buildings in Europe.

Keywords: Lifecycle assessment; Retrofit; Embodied energy; Embodied carbon; Residential buildings.

1. Introduction

As Ireland aims at limiting greenhouse gas (GHG) emissions to 113% of 1990 levels through Kyoto Protocol commitments by 2020 [1], national GHG emissions associated with the residential built environment will have a significant role to play. Due to recent deceleration in new EU construction activity [2], it is widely expected that national retrofitting strategies of existing housing stock will require significant investment if legal binding targets are to be successfully achieved, especially in Ireland where a significant portion of Ireland's total housing units were completed in the last decade (see Figure 1). Considering the majority of existing housing units will still be active in 60 years time, a lifecycle perspective strongly suggests domestic energy performance retrofitting or refurbishment schemes will be vital in achieving energy efficiency targets [3]. Hence, the

importance of a lifecycle analysis study, in terms of energy and carbon, for retrofitting projects is authenticated. Over a 60 year lifespan it is important perceived operational energy savings of retrofit options are not outweighed by indirect embodied properties of installed materials or services. Studies have highlighted challenges associated with examining retrofit options in Ireland over a lifecycle period [4, 5].

93% of Irish housing units granted planning permission between 1977 and 2011 have initial energy performance requirements compliant to 2005 Irish building energy performance regulations [6] or earlier from collected Central Statistics Office (CSO) data [7], equating to an equivalent Building Energy Rating (BER) [8] of 'B3' or lower upon construction assuming no subsequent renovations or retrofitting. A BER is an independent national certification system used in Ireland to assess how energy efficient a home is. An alphabetical rating scale from 'A-G' is utilised with an A rated home being the most energy efficient [8]. A BER is based on the characteristics of major components of the dwelling (wall, roof and floor dimensions, window and door sizes and orientations) as well as the construction type and levels of insulation, ventilation and air tightness features, the systems for heat supply (including renewable energy), distribution and control, and the type of lighting. It covers annual energy use for space heating, water heating, ventilation, lighting and associated pumps and fans, calculated on the basis of a notional standard family with a standard pattern of occupancy [8]. It is important to note that a BER is only an indication of the energy performance of a house. For example, a rating of B3 equates to a primary energy usage of between 125 and 150 kWh/m^2/yr. Hence, logical conclusions suggest retrofitting packages (small, medium and deep) will play a vital role in landscaping Ireland's future housing stock. Previous Sustainable Energy Authority of Ireland (SEAI) retrofitting scheme take-up has been welcomed in Ireland [9].Therefore, implementation of the SEAI's residential roadmap targets to sizeably reduce domestic residential energy usage and carbon consumption by 2050 is imperative [10]. Various scenarios have been developed with retrofitting to varying degrees of up to 1 million Irish homes in order to achieve substantial Irish residential sector decarbonisation. Targets are in accordance with European Commission 2050 goals to cut EU CO_2 emissions by 90% and energy consumption by 50% [11].

However, it is important appropriate investigation into perceived operational saving benefits is carried out assessing the true effect of residential retrofit financial grant packages offered by SEAI [12]. Issues such as occupant and physical 'take-back', energy usage offsetting, tenant thermal comfort level and internal temperature changes require attention. A 2008 SEAI residential sector report mentioned data on comfort levels or internal temperatures for residential dwellings was unavailable for Ireland with UK values assumed [13]. Without substantial quality thermal comfort and internal temperature data on retrofitted residential buildings in Ireland, it is difficult to truly assess the impact of future national retrofitting schemes.

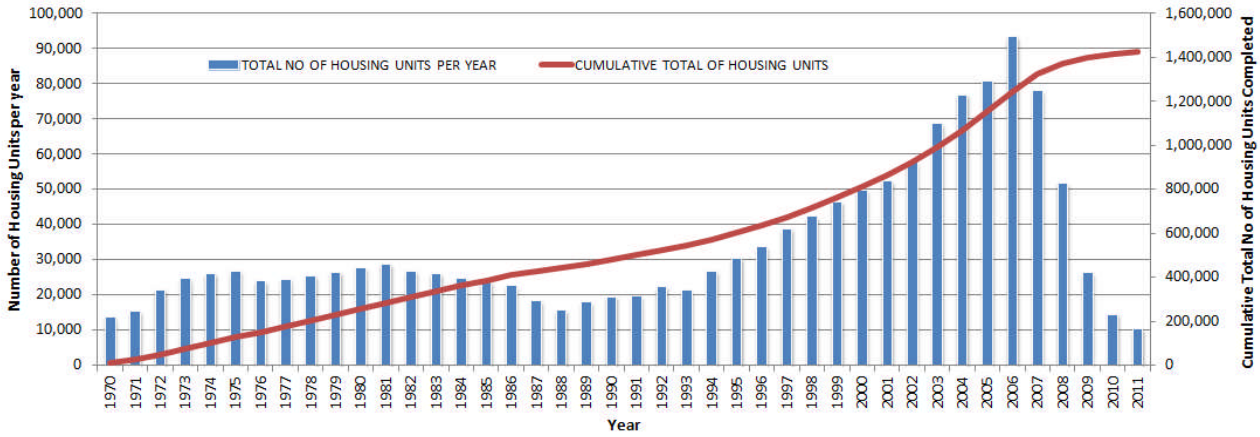

Fig. 1: Housing unit completions from 1970-2011 according to Central Statistics Office data [14].

Improvement of the energy efficiency of the existing housing stock is a core element of Ireland's National Energy Efficiency Action Plan [15]. 199 ktCO_2 (CO_2 emissions) of the currently proposed reductions target relates to state incentivised insulation and heating system upgrades to existing houses, over the life time of the plan. These savings accounts for 8% of the overall reduction forecast for the residential sector. The *Better Energy Homes* and *Better Energy Warmer Homes* are the primary grant schemes in operation in Ireland at present, targeting houses constructed prior to 2006 and 2002, respectively [9, 12]. Anticipated energy savings are the primary motivating factor for individuals part-taking in such state incentivised schemes with comfort gain forming the second most important factor influencing any investment. Previous studies have highlighted possible mean energy savings (21%) of natural gas demand through the SEAI Home Energy Saving (HES) energy retrofitting scheme for a sample of homes when observed over a two year period [16]. Interestingly, a lifecycle analysis retrofit study conducted as part of Rebound initiative on common house types retrofitted to various degrees highlighted client 'take-back' as a concern for residential retrofit project [17, 18]. In that study, the observed before and after works mean temperature data was used to develop specific Dwellings Energy Assessment Procedure (DEAP) [19] models to assess the impact of temperature take back on CO_2 emissions savings resultant from the works, determining the level of direct rebound effect, i.e. the amount of potential CO_2 emission reductions taken back as additional warmth in the properties. Unexpectedly high levels of 'take back' were predicted, if the observed short range temperature increases were to be sustained in the longer term [17, 18]. Furthermore environmental life cycle assessment (LCA) studies on residential case study buildings highlighted the importance of actual operational energy (OE) and carbon (OC) usage in home as a true carbon footprint indicator instead of current BER system limitations [8, 20]. Therefore, before the largest national retrofitting scheme is undertaken in Ireland it is imperative the true potential of retrofitting project initiatives is carefully assessed.

This paper presents findings from a case study set of typical masonry residential buildings in Ireland to determine the efficacy of typical insulation and building fabric upgrade works of residential buildings in reducing energy and greenhouse gas emissions, as well as their affect on the perceived thermal comfort of the occupants. This is achieved by monitoring 19 houses in Ireland and assessing the internal environment, energy consumption, comfort and occupant behaviour, before and after typical residential insulation improvements. These houses are located in a residential housing estate in Ballyshannon, Co. Donegal, Ireland. Operational monitoring started from November 2012 with upgrade retrofit works completed in December 2012. This paper contains provisional case study results as monitoring is ongoing. However, a full economic and environmental lifecycle analysis is presented, which considers both the energy consumption and carbon emissions embodied in the retrofit works together with those associated with the operation of the home.

2. Case study retrofit project overview

2.1 General information

The Highfields residential housing estate in Ballyshannon, Co. Donegal consists of 19 masonry housing units constructed in 2004. The estate is managed by the Cluid Housing Association, which aims to deliver affordable homes to people on housing waiting lists all over Ireland [21]. Housing estate building topology consists of the single-storey and two-storey units, as presented in Table 1. The two-storey 3-bedroom semi-detached homes in this estate have typical average total floor area (110m^2) of semi-detached houses constructed in Ireland, according to CSO data [7]. The two-storey dwellings contain on the ground floor a hallway, living room, combined kitchen and dining room, utility and WC. On the first floor, they contain a landing, bathroom, hot-press (with hot-water storage cylinder) and three bedrooms, The single storey dwellings contain a hallway, one bedroom, bathroom, living room, combined kitchen and dining room, hot-press (with hot-water storage cylinder) and a utility. All of the dwellings have an attic space. The heating systems in the homes are a central heating system using an oil-fired condensing boiling and a solid fuel open fire in the living room.

Table 1: A breakdown of the Highfields Cluid housing estate by house type and total floor area.

House Type	House Number	Total No of Houses	Total Floor Area (m^2)
Two-storey semi-detached	7,8,9,10,16,17,18,19	8	110
Two-storey mid terrace	2,3,12,13,14	5	110
Single-storey end-of-terrace	1,4,11,15	4	67
Single-storey semi-detached	5,6	2	67

Located north east of Ballyshannon, house orientation varies through the estate site layout, as seen in Figure 2. Houses numbered 5 through to 10 are orientated in a north-south direction with the front of the houses southerly facing. House numbers 11 to 15 are opposite in orientation. House numbers 1 to 4 have front openings facing easterly, as seen in Figure 2, with Highfields 16 to 19 are not aligned with the other 15 homes. Their front openings are in a predominantly south-westerly direction. A photo of houses 7 to 10 is also provided in Figure 2.

Fig. 2: Highfields estate orientation layout map and photo of sample masonry estate homes.

2.2 Upgrade retrofit works

Thermal upgrade retrofit works were completed in mid-December 2012 on all 19 estate homes. A basic upgrade in thermal cavity wall and ceiling insulation was conducted in accordance with the Better Energy Homes scheme offered by SEAI [12]. Theoretical U values of building fabric ceilings and walls in all homes were improved as a result.

2.2.1 Pre-works BER

As seen in Figure 3, average pre-works BERs ranged from D2 to C3 for estate houses. BER results are expressed in terms of annual primary energy consumption ($kWh/m^2/yr$) and annual carbon dioxide emissions ($kgCO_2/m^2/yr$) based on input data to the Dwelling Energy Assessment Procedure (DEAP) software calculation tool [19]. Depending on the intensity value achieved an alphabetical grade rating is assigned to the assessed dwelling. For the Highfields estate pre-works, annual primary energy consumption and carbon dioxide emissions varied from 185-294$kWh/m^2/yr$ and 47-75$kgCO_2/m^2/yr$, respectively, according to the collected BER certificates shown in Figure 3.

2.2.2 Post-works BER

As depicted in Figure 3, an expected improvement in BER is recorded in all homes post-works following retrofitting. Average post-works BERs ranged from D1 to C2. For the Highfields estate post-works, annual primary energy consumption and carbon dioxide emissions varied from 169-267$kWh/m^2/yr$ and 43-67$kgCO_2/m^2/yr$ respectively, according to the collected BER certificates as shown in Figure 3. As a result, it would be expected that client perception of internal thermal comfort would improve and average internal temperature increases would be experienced as a result of insulation works.

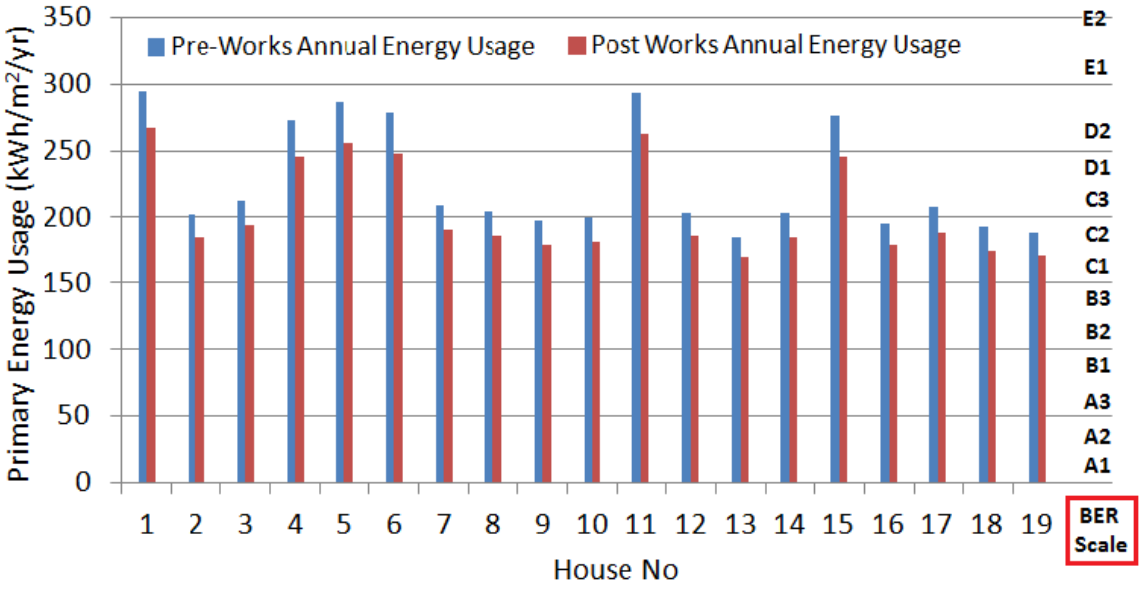

Fig. 3 Building Energy Rating (BER) of Highfields estate pre and post insulation upgrade works.

2.3 Data instrumentation/inventory

Pre-works residential analysis required installation of oil, temperature and relative humidity (RH) recording devices. They were installed in selected estate homes, as indicated in Figure 4. Lascar electronic temperature and RH sensors EL-USB-2 and EL-USB-2-LCD were installed in 15 estate houses on November 22nd 2012. Devices were planned to be left onsite in all 15 homes for the duration of the heating season and beyond. Intermediate downloading of data occurs on subsequent site visits. 10 Apollo smart oil monitors were installed onsite in 10 houses that utilised oil-fired central heating and water systems. Sensors to obtain real-time electricity usage were also installed to obtain electricity usage in selected homes. A thermographic camera was utilised to perform thermography both pre- and post-works on selected estate houses. Digital cameras and camcorders were also used onsite were necessary.

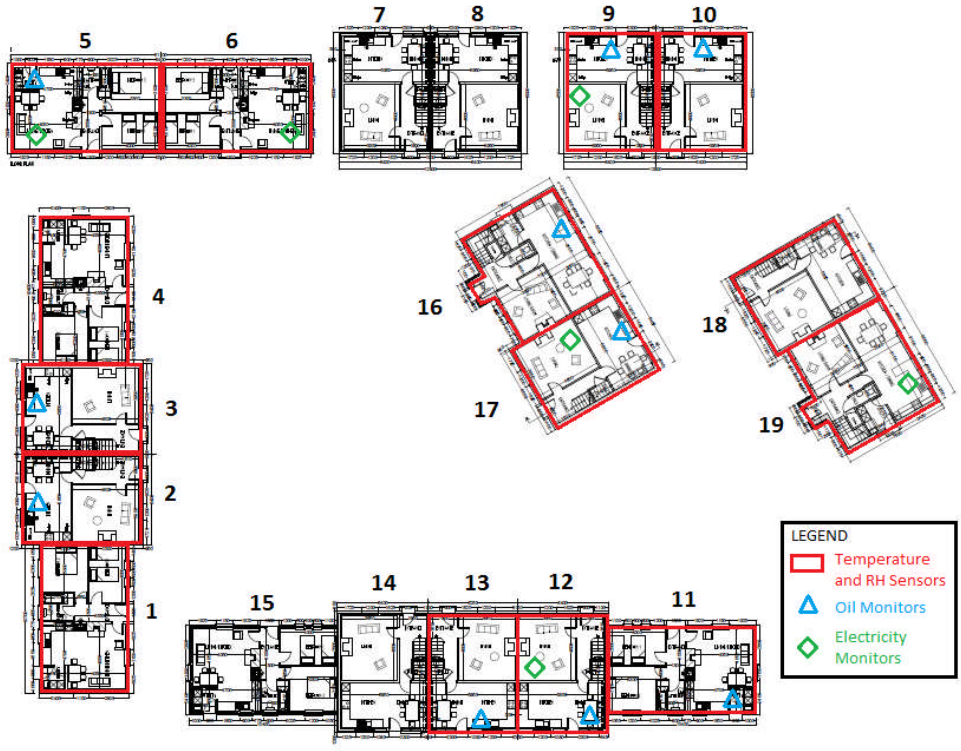

Fig. 4: Location of temperature and relative humidity sensors, oil and electricity monitors.

2.4 Occupants surveys

As part of the study, strategically designed surveys were conducted on tenants both pre- and post-insulation works. Information was gathered with respect to number of residents per house, number of years living at the dwelling, average time spent at home, average energy spending expenses per house and existing appliance usage is collected. Other important issue such as internal thermal comfort perception and relative tenant behaviour is regularly recorded. Continuous thermal comfort surveys are carried out at every site visit to maintain a database of tenant internal comfort levels.

2.5 Weather data

Weather data was gathered from a Met Eireann operated weather recording station at Ballyshannon for daily rainfall, maximum and minimum temperatures for the available period from January 2011 to January 2013, as seen in Figure 5. External temperature and/or rainfall, as well as other external environmental conditions, may influence final result interpretation. Thus, further data, such as relative humidity and global radiation, will be obtained from another weather station operated by Met Eireann in the locality (Finner, Bundoran, which is 5km from the site).

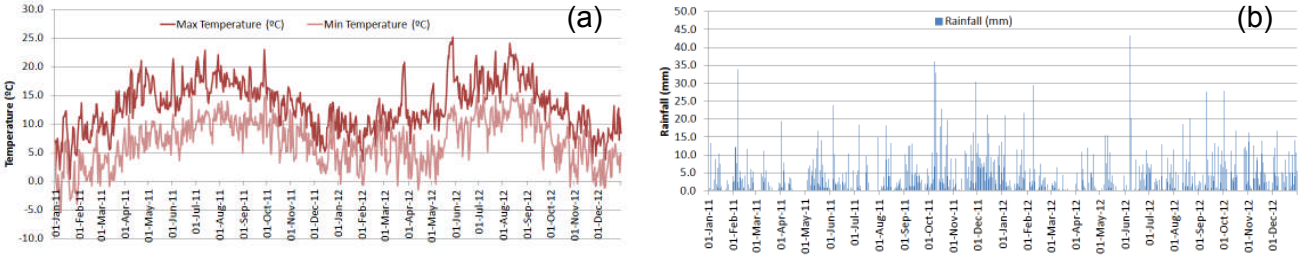

Fig. 5: (a) Maximum and minimum daily temperature data and (b) rainfall (mm) from a Met Eireann Ballyshannon weather station from January 2011 until January 2013

3. Results and discussion

Provisional results from the installed data equipment and tenant surveys are presented in this section.

3.1 Internal thermal comfort and temperatures

Figure 6 presents data from installed temperature and relative humidity sensors pre- and post-retrofitting works from a number of case study homes. Three sets of results (kitchen, living room and bedroom) are presented from a three bedroom two-storey semi detached house (House No 9). Comparative kitchen and living room results are extracted from the adjoining two storey house (House No 10), while a bedroom from House No. 3 (a two-storey semi-detached bungalow is also displayed. The location and orientation of these dwellings can be seen in Figure 4.

Initial observation of provisional results suggests a slight immediate increase in internal temperatures following insulation upgrade works completion. External temperature data corresponding to period of analysis time suggests maximum values rarely exceeding 10 ºC and minimum recordings peaking below 0 ºC. It is assumed home space heating requirements were required during this period with home space heat retention an important building fabric factor. Following retrofitting, relatively stable pre-works house internal temperatures are displayed in many houses, such as all rooms in House No. 6 (see Figure 6 (a), (c), (e)), as well as the living room in House No. 10 (see Figure 6 (d)), with peaked rises in internal temperature following retrofitting. On the other hand, the internal temperature of the kitchen in House No. 10 has larger fluctuations (Figure 6(b)), as well as the bedroom in House No. 3 (Figure 6(f)), as these houses rely more on solid fuel heating in the open fire in the sitting room during the day, whereas the occupants in House No. 9 have the oil-fired central heating on throughout most of the day. Furthermore, these

rooms typically have lower internal temperatures, which is due to low space heating being used by the occupants in these rooms. In some houses, internal temperatures reduce after a period, which may be caused by user behaviour or external influences (for example, in House No. 9 – see Figure 6(a),(c),(e)). Thermal space heat retention building fabric properties improved after retrofitting. Thus, after an initial increase in internal temperature in the house post-works, some occupants reduced the amount of space heating they used (i.e. had the central heating system for shorter periods of time or less often).

Average internal temperature, relative humidity and dew points vary substantial for individual case study homes as Figure 6 demonstrates. Two similarly designed rooms can have significant differences in internal temperature and relative humidity, as Figure 6 demonstrates. Therefore, significant variations in user behaviour cannot be ignored when estimating actual energy and carbon savings following retrofitting. Future analysis will investigate this effect further.

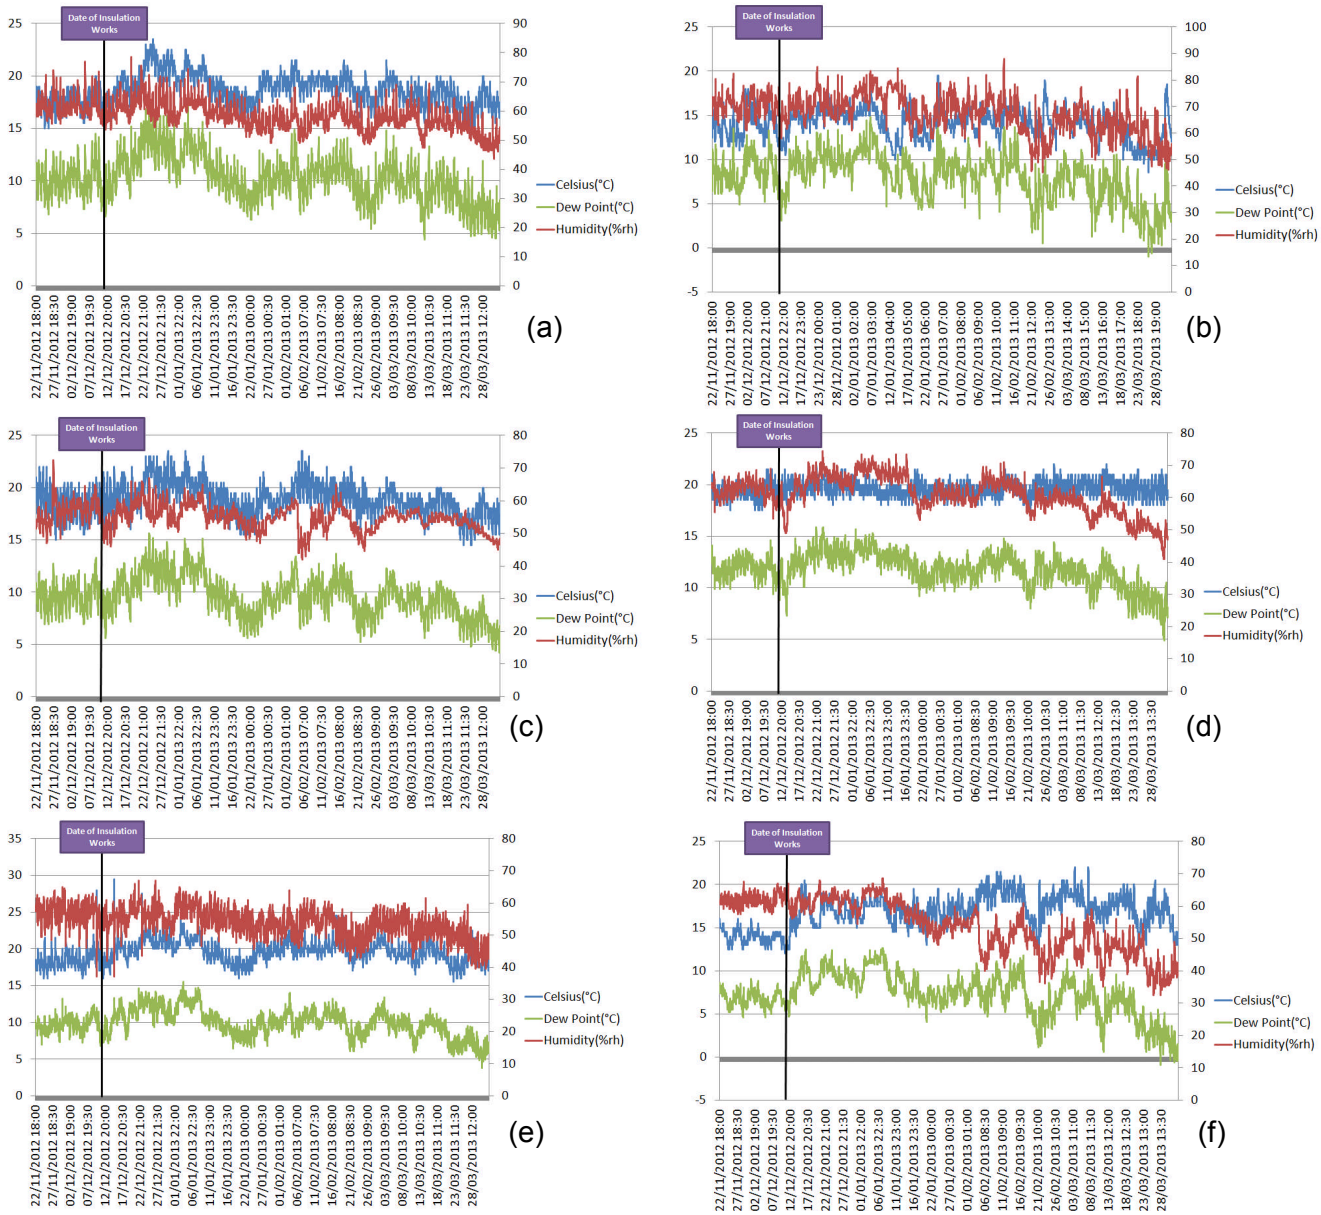

Fig. 6: Provisional temperature and relative humidity results recorded in case study homes. Results are taken from the following locations: (a) House No 9 Kitchen (b) House No 10 Kitchen (c) House No 9 Living Room (d) House No 10 Living Room (e) House No 9 Bedroom (f) House No 3. Bedroom.

Tenant perception on the internal thermal comfort of their homes pre- and post-retrofitting reflects favourably on the perceived benefit of retrofitting to the internal environment of houses. A perceived general increase in internal thermal comfort standards by the occupants following completion of the insulation upgrade works can be clearly seen in Figure 7. When residents were asked post-works if the insulation upgrade works would be of thermal comfort benefit, 90% surveyed felt the works would be of thermal comfort benefit.

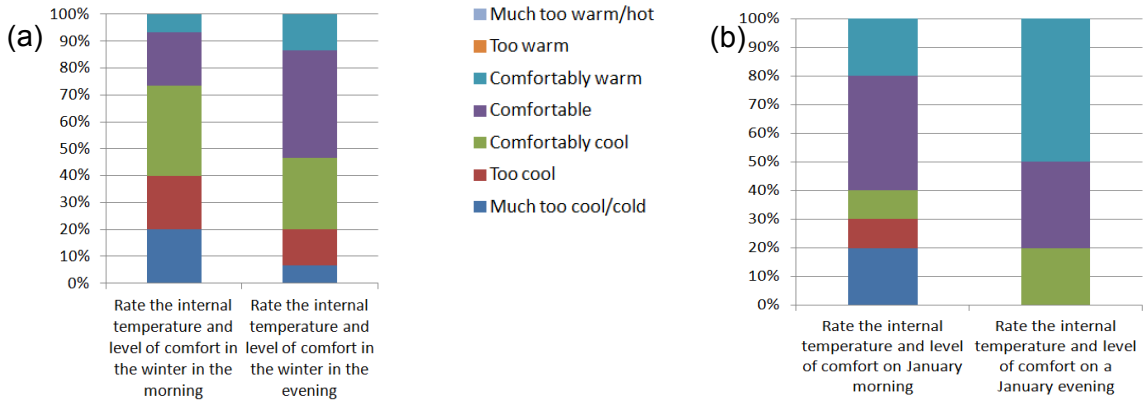

Fig. 7: Results from an occupant survey rating house internal comfort level (a) pre-works and (b) post-works

3.2 Energy and carbon usage

One important energy and carbon usage analysis area is occupancy electricity usage habits and trends. Estimated rationalised electricity usage data pre- and post-retrofitting works was collected from all estate homes and is presented in Figure 8, where the average daily electricity usage is given in kWhr per m^2 of floor area of the dwelling. Three scenarios are outlined in Figure 8 – pre-works, post-works and post-works excluding the three week Christmas period. Average daily electricity usage for a period pre-works and average daily usage post works are calculated from electricity usage data recorded. In some dwellings, electricity usage over the Christmas period would not be typical of other periods during the winter. Thus, a special compensation period of 3 weeks over Christmas is excluded in the third scenario, which was post-retrofitting works.

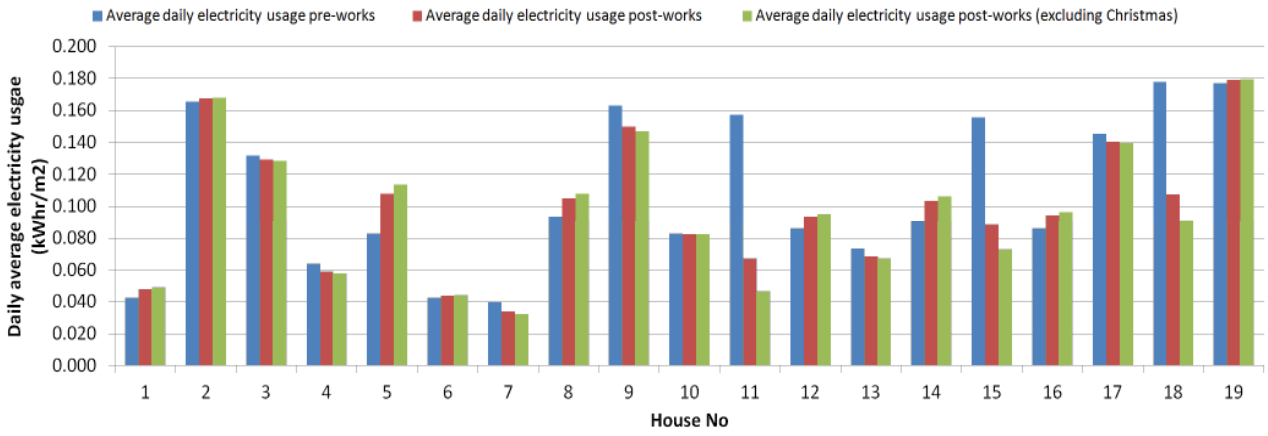

Fig. 8: Average estimated daily electricity usage in each estate house for the period from November 2012 to April 2013 per m^2 of floor area.

As can be seen from Figure 8, the average electricity daily usage varied significantly between dwellings in the estate, even for the same house type and occupancy level. For example, for the one-bedroom single-storey dwellings (i.e. Houses 1,4,5,6,11,15) there was a difference of over

3.75 times the average daily electricity usage between House no. 1 and 11 prior to retrofitting of the houses. The reason for the significant differences is that some houses used personal electric heaters for additional space heating in addition to the oil fired central heating systems and/or solid fuel open fire (e.g. House 11 and 15), whereas others had a back boiler behind the solid fuel open fire in the sitting room, which connected to the central heating system, and did not use additional personal electric heaters (e.g. House no. 1 and 4). It is noteworthy that both House 11 and 15 had significantly lower average electricity usage post-retrofitting works, which was due to lower use of personal electric heaters.

From Figure 8, nine of the case study houses (Houses 3, 4, 7, 9, 11, 13, 15, 17 and 18) experience decreases in average daily electricity usage per m^2 of floor area according to collected data. This represents half the assessed estate homes. It is not possible to assume electricity usage decreases are caused solely by retrofit works although its impact on electricity usage cannot be ignored. A pre-works survey noticed 40% of assessed estate dwellings used electric heaters in the preceding week to the survey. No mention of electricity based heaters was recorded in post-works surveys. Significant average daily electricity usage per m^2 of floor area increases is recorded in certain estate homes (House No 11, 15 and 18). No significant change in household appliance was recorded in any assessed home after the works.

Estimated economic annual energy spending analysis for space heating in Highfields estate homes is based on tenant survey answers and heating season assumptions both pre- and post-works. Average estimated monthly and weekly spending was recorded before and after the works. A heating season assumption of 6 full months and 6 half months of fuel spending is assumed. Improved accuracy of monetary spending on fuel is ongoing with the continuous collection of data through ongoing resident survey studies and increased fuel usage data recordings. Nevertheless, some trends emerged with respect to estimated annual energy spending per m^2 of floor area according to the two housing unit types, as shown in Table 2. For example, an average estimated annual spending reduction of €9 per m^2 of floor area is estimated for the one-bedroom semi-detached bungalows from recorded answers before and after upgrade insulation works. Little or no spending estimation savings are recorded for the larger semi-detached houses assessed based on assumptions and gathered energy spending data. However, there are large variations in monetary spending on each fuel type between similar homes, as indicated in Table 2 by the large coefficient of variation (COV) values.

Substantial savings were recorded in coal usage amongst one-bedroom semi-detached bungalows before and after the works. Slight decreases in average annual heating oil, peat and briquettes and biomass are also recorded in the semi-detached bungalows assessed following retrofitting. A 22% reduction in heating oil average estimated spending per m^2 of floor is recorded for the larger estate homes as seen in Table 2. However, a counterbalance exists with an increase in coal and biomass usage in these homes according to data recorded. Such an offsetting of energy spending can often not be represented in perceived operational energy or carbon savings.

Ongoing analysis aims to improve result validity. 60% of assessed estate tenants had found noticeable savings in energy usage following the upgrade insulation works, while 30% had not according to survey results. The remainder were unsure. Such results favourably represent the client perceived residential retrofitting approach.

Table 2: Average estimated annual spending by fuel type per m^2 of floor area according to the two predominant estate housing unit types.

House Type	Fuel Type	Pre-Works		Post-Works		Difference
		Average	COV	Average	COV	Average
Semi-detached bungalows ($67m^2$)	Heating Oil	€6.6	0.93	€5.1	1.07	-€1.50
	Coal	€11	0.8	€5.4	0.87	-€5.7
	Peat	€0.5	2.24	-	-	-€0.5
	Briquettes	€0.9	1.37	€0.4	1.73	-€0.5
	Biomass	€1.2	1.63	€0.6	1.18	-€0.6
	Total	**€20**	**-**	**€9**	**-**	**-€9**
Semi-detached two storey ($110m^2$)	Heating Oil	€7.9	0.56	€6.40	0.2	-€1.60
	Coal	€5.6	0.69	€6.10	0.72	+€0.5
	Peat	-	-	-	-	-
	Briquettes	€0.2	3.16	€0.1	2.65	-€0.10
	Biomass	€0.7	1.51	€1.80	1.19	+€1.10
	Total	**€14**	**-**	**€14**	**-**	**€0**

Environmental lifecycle assessment (LCA), in terms of energy and carbon, found average initial embodied energy (EE) and embodied carbon (EC) of installed building materials according to acquired bills of quantity to account for 9% and 12% of lifecycle energy and carbon over a 60 year lifespan pre-retrofitting works, respectively. Average operational energy (OE) and operational carbon (OC) accounted for the majority of lifecycle energy and carbon of the estate homes.

Based on post- and pre-retrofitting works BER results, perceived annual OE savings (16-27kWh/m^2) and OC savings (4-8kgCO_2/m^2) in the estate houses should benefit residential occupants financially in the long term. Theoretical annual energy savings should equate to between 1696-2113kWh and 1769-2079kWh for larger and smaller estate homes, respectively. Therefore, assuming a domestic delivered energy cost of 26 cent for electricity [22], annual estimated energy savings range from €438-549 and €467-541 for larger and smaller estate homes, respectively. Similarly, assuming a domestic delivered energy cost of 9 cent for oil [22], annual estimated energy savings range from €151-190 and €162-187 for larger and smaller estate homes, respectively. Over a 60 year lifespan, perceived financial operational savings are substantial.

Average estimated annual spending reductions estimated from surveys of occupants of the semi-detached single-storey dwellings amounted to €9 per m^2 of floor area for fuel requirements as a result of retrofitting. All semi-detached single-storey dwellings have a total floor area ($67m^2$). According to Table 2 results, average estimated annual spending savings as a result of the retrofitting works will equate to approximately €603, which is substantially higher than the estimate obtained using the assumptions in the Dwellings Energy Assessment Procedure (DEAP), which is the Irish official method for calculating and rating the energy performance of dwellings. Thus, BER retrofitting estimations are relatively conservative according to these results for the semi-detached bungalows. An over-estimation in perceived operational savings for the semi-detached two storey estate dwellings is recorded. Care must be taken with regard to perceived OE and OC results as a result of retrofitting domestic buildings. Provisional results highlight the significance of perceived operational energy savings when used as a benchmark. Issues such as physical and occupant 'take-back' and energy usage offsetting may have an impact in retrofitted results. Further analysis over a longer period will highlight such issues.

4. Conclusions

In-depth analysis into the efficacy of residential retrofitting packages for Irish residential building

was conducted on a residential housing estate in Ballyshannon, Co. Donegal. Noticeable improvements in internal temperature and occupant perception of internal thermal comfort was recorded in many homes following completion of basic cavity wall and attic (ceiling) insulation upgrade works in December 2012. Provisional results recorded half the assessed homes held a noticeable average daily electricity usage decrease per m^2 of floor area following completion of works. Provisional findings from occupancy surveys recognised the significance of perceived operational monetary savings as a result of retrofitting compared to actual or relative occupant savings. Care is needed when utilised as a retrofitting energy benchmark. The study presented in this paper involved only short span monitoring of the houses before and after works, so it is difficult to determine if the observed internal temperature and energy usage trends will be sustained in the longer term. Future Irish retrofitting strategies may need to account for the actual operational savings impact compared to the perceived for various retrofitting packages on Irish residential buildings. Methods of engagement and more sustainable consumption behavioural models need to be developed, including the communication of the link between behaviour and actual energy bill reduction, which is the primary driver for individuals participating in home energy efficiency schemes in Ireland [18]. Further research in this area is required and may help reduce the direct rebound effect of occupants taking excessive levels of increased comfort. Such measures may be beneficial in ensuring net CO_2 savings are achieved after insulation works and that Ireland's national commitments in terms of CO_2 emission reductions are met.

Short Summary

Today building renovation in Europe is characterized mainly by on-site processes, which may be inefficient with regard to cost and time. The E2ReBuild project aimed to further develop, investigate, evaluate and promote new cost-effective and energy efficient retrofit strategies. [1]
Within the seven Demo projects, innovative industrialised renovation methods and prefabricated façade and roof elements were developed and implemented. The evaluation of their realization process provided feedback from practice, identified dependencies and causal motives and showed needs for future actions of policy makers and stakeholders.
A key aspect for successful renovation within the E2ReBuild demonstrations was the quality of the applied collaboration model. Appropriate team set up, coordination in early planning stages and joint development guaranteed optimization and a smooth workflow for renovation. Further the choice of the *Design-Bid-Build* or *Design-Build* approach influenced the collaboration on how responsibilities and risks were handled and thus the contractual situation among owners, planners and contractors.
However, neither the *Design-Build* nor the *Design-Bid-Build* approach could sufficiently meet the requirements of an optimized team set up. Within both approaches stakeholders struggled with uncoordinated actions, misunderstandings, lack of knowledge-sharing within the team and the interface between planning and construction. A lot of know-how got lost due to changed actors or the missing know-how of relevant actors (e.g.: the timber element manufacturer) in early planning stages.
However, current procurement legislation hinders early collaboration and appropriate team set up. In future, actions within legislation and changes of traditional renovation routines are necessary. Procurement legislation should enable teams to offer their services for planning and construction together or to integrate relevant know-how in early planning stages. In future, the influence of appropriate team set up and communication as driving forces for joint development and optimization regarding quality, costs and time have to be recognized. Finally, all interviewed stakeholders within E2ReBuild stated a high replication potential of the applied technologies, processes and models – provided that framework conditions would facilitate their implementation.

Keywords: Building Renovation; Energy-efficiency; Industrialization; Prefabrication; Collaboration;

1. Motivation and objectives

Facing the demand of renovating buildings constructed between 1945-1980 more efficient construction methods, processes and models with regard to quality, cost and time are urgently needed. New technologies such as prefabrication have been developed and applied in several demonstration and pilot projects in Europe, but they haven`t been implemented on the market yet. The vision of the FP7 project E2ReBuild (2011-2014) is to facilitate, promote and support the transformation of the retrofitting construction sector from the current craft and resource based construction towards an innovative, energy-efficient industrialised sector [1]. E2ReBuild aims to further develop, demonstrate and promote cost-effective, energy-efficient retrofit strategies for broader application on the market. A better understanding of obstacles that hinder a broad implementation of new renovation methods, processes and models on the market should be created.
First feedback from practice showed that industrialised methods and prefabrication were especially sensitive regarding collaboration among actors. Uncoordinated actions, misunderstandings and unclear responsibilities were reported. Beside that, building owners claimed that procurement legislation restricted their choice of planners and contractors.
What is needed are appropriate collaboration models supporting the development of cost-efficient solutions and their application within building renovation. Thus, the analysis and evaluation of collaboration models within E2ReBuild aimed to:

- Identify framework conditions that influence appropriate collaboration.
- Uncover barriers and risks that hinder successful team set up.
- Identify necessary actions within legislation and traditional construction routines.
- Present key aspects for successful collaboration models.

2. Methodological approach

Based on a dialogue between researchers, developers and owners the seven Demonstration projects served as source for analysis and evaluation of the applied collaboration models.

In a first step, interviews, site-visits and stakeholder discussion panels were held to collect experiences of practioners, stakeholders, authorities and residents. This empirical “Bottom-up” approach provided new insights and a better understanding of causal relations of motives and operative forces in practice. Due to varying national and project specific framework conditions, each project was analysed beyond its own background.

In a second step, this information was processed in collaboration charts and action line diagrams in order to allow comparison and crosscutting analysis of the seven Demo projects. The collaboration chart showed the groups of involved actors along with their specific role in the project. Communication and relationship were displayed with line thicknesses correlating to the intensity. The different colours of the ellipses showed the group an actor was assigned to (e.g.: owner, planners, contractor, residents, authority, etc.).

The action line diagram showed the different actions of actors in relation to the project progress. The groups of actors and colours used in the action line diagram are similar to those in the collaboration chart in order to enable a comparison between organizational diagram and the sequence of actions, process steps and milestones in the action line diagram. The adjustment of groups and colours and additional milestones helped to understand their influence on time and timeslots in the project.

3. Definition

While the term collaboration model could not be found in literature and was wrongly interpreted as a business model, the definition in E2ReBuild goes beyond the description of an architecture for value creation. *“It describes coordinated and cooperative processes that enable an entire project*

team with all involved actors and stakeholders to achieve target-oriented concerted actions for the common goal of successful building renovation with industrialized methods and/ or prefabricated components. The structure of communication channels with defined interfaces and the definition of clear responsibilities, rights and obligations are crucial for smooth process chains and successful collaboration." [2] p. 10.

Figure 1: Demo project Augsburg, Grüntenstrasse (DE). The residential area with 2 building blocks (in total 60 units), was renovated with the TES Energy Façade[1] – a prefabricated timber element system. The renovation solution convinced due to the innovative character and the possibility to enlarge the building envelope by enclosing of balconies with the same system. Source pictures: lattkearchitekten, Gumpp&Maier, CCTP;

4. Experiences: Design-Bid-Build vs. Design-Build approaches

The analysis of the collaboration charts and action line diagrams showed differences and similarities within the applied models. Two basic models for the planning and construction process applied in the E2ReBuild project were identified and analysed:

- The *Design-Bid-Build* model (*Figure 2*, *Figure 3*) applied in Augsburg and Munich (DE), in Roosendaal (NL) and Voiron (FR).
- The *Design-Build* (*Figure 4*, *Figure 5*) model applied in Halmstad (S), London (GB) and in Oulu (FI).

Generally the *Design-Bid-Build* model (*Figure 2*, *Figure 3*) was characterized by the „Bid" as an own clear step between design and construction and the resulting individual contracts between planners (architects, engineers), contractors (builders, manufacturers) and the building owner.

[1] "TES" is the abbreviation for **T**imber **E**lement **S**ystem (www.tesenergyfacade.com)

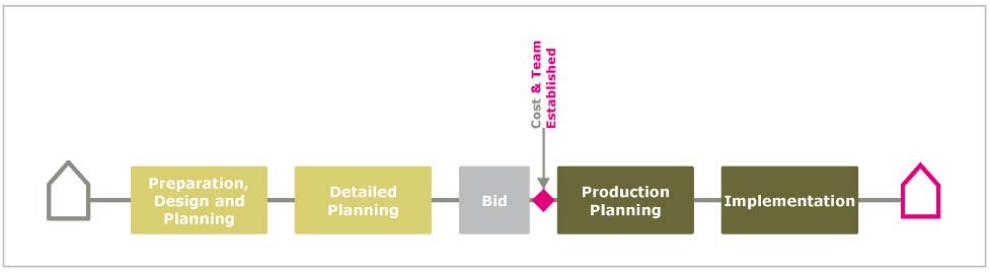

Figure 2: Simplified action line diagram. Within the Design-Bid-Build process all contractors were chosen by the tender process („Bid“).Therefore the timber element manufacturer as contractor was integrated into the team after planning and detailed planning phase and was not able to influence design and planning to optimize the solution according to the manufacturing capabilities. Source figure: [1] p.45;

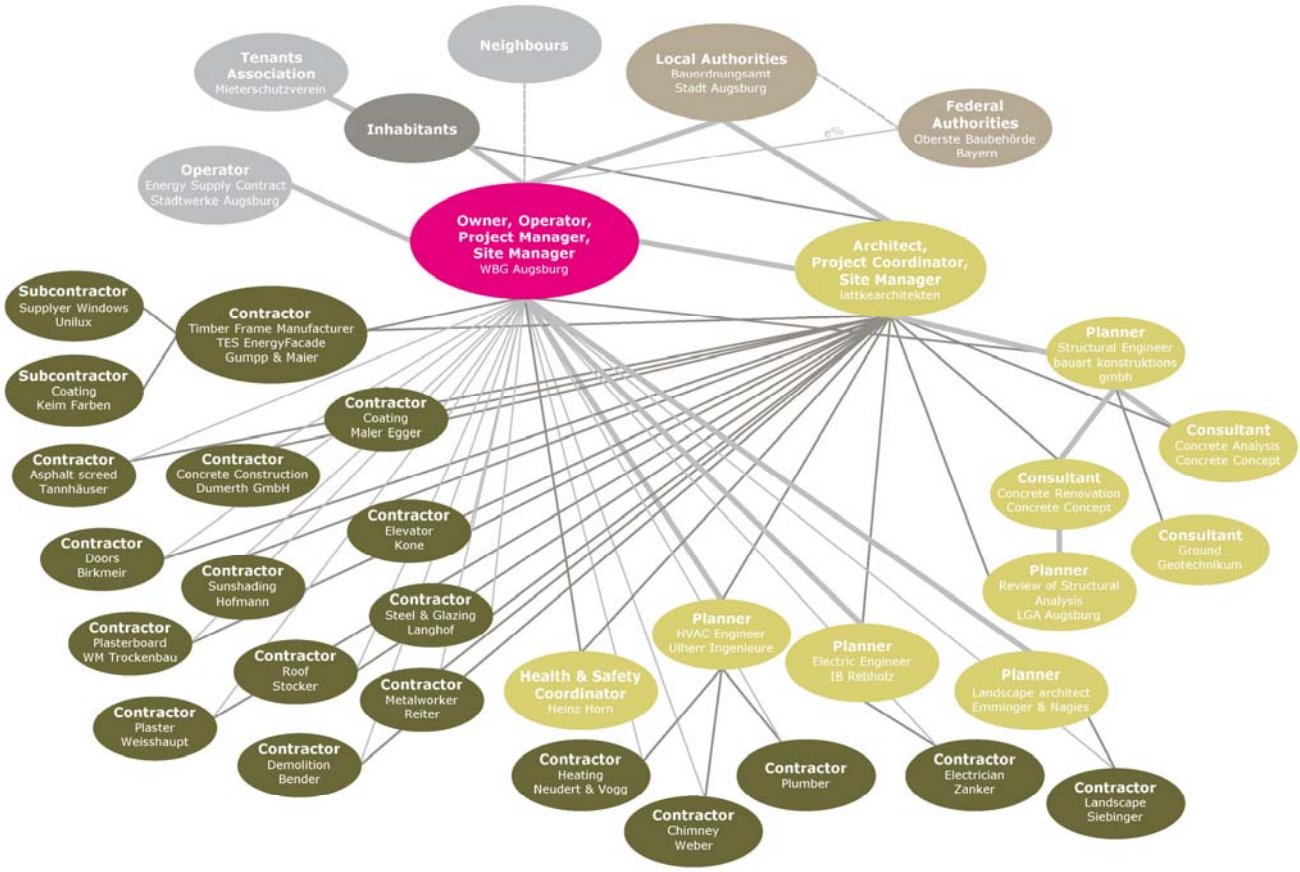

Figure 3: Collaboration chart. The Design-Bid-Build model applied in the Demo project Augsburg, Germany. The architect and the owner shared responsibilities. The contractors were appointed by the tendering („Bid“) and were bound with individual contracts to the owner. Responsibilities (for example for tenants claims) were shared between owner and architect. Source figure: [1] p.21;

The *Design-Build* model (*Figure 4, Figure 5*) is based on one *Total Contractor* who is responsible for design and construction and who has in-house departments for planning or is allowed to recruit subcontractors for design and planning. This model avoids tendering of individual trades, the planners and contractors are chosen by the *Total Contractor* with reference to the costs fixed in the global contract with the client. Basically, the partners in the team are selected by the *Total Contractor*. Within the E2ReBuild Demo project, the clients were able to object individual subcontractors. However, the pressure to keep costs is a determining factor of this model. ([1], p. 44, 48-49)

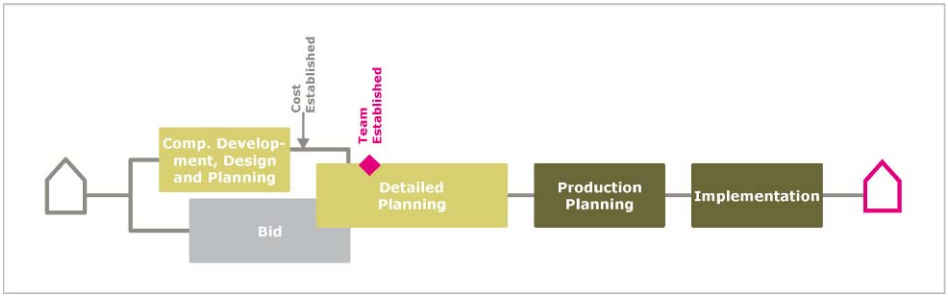

Figure 4: Simplified action line diagram. Within the Design-Build process the Total Contractor delivers a „ready-made“ building renovation to the owner. The contracting can be based on a tender or a negotiation process. The principle of the Design-Build models is based on merging planning and construction under the umbrella of one responsible contractor. The selection of possible subcontractors is determined by the costs fixed in the contract. Source figure: [1] p. 44;

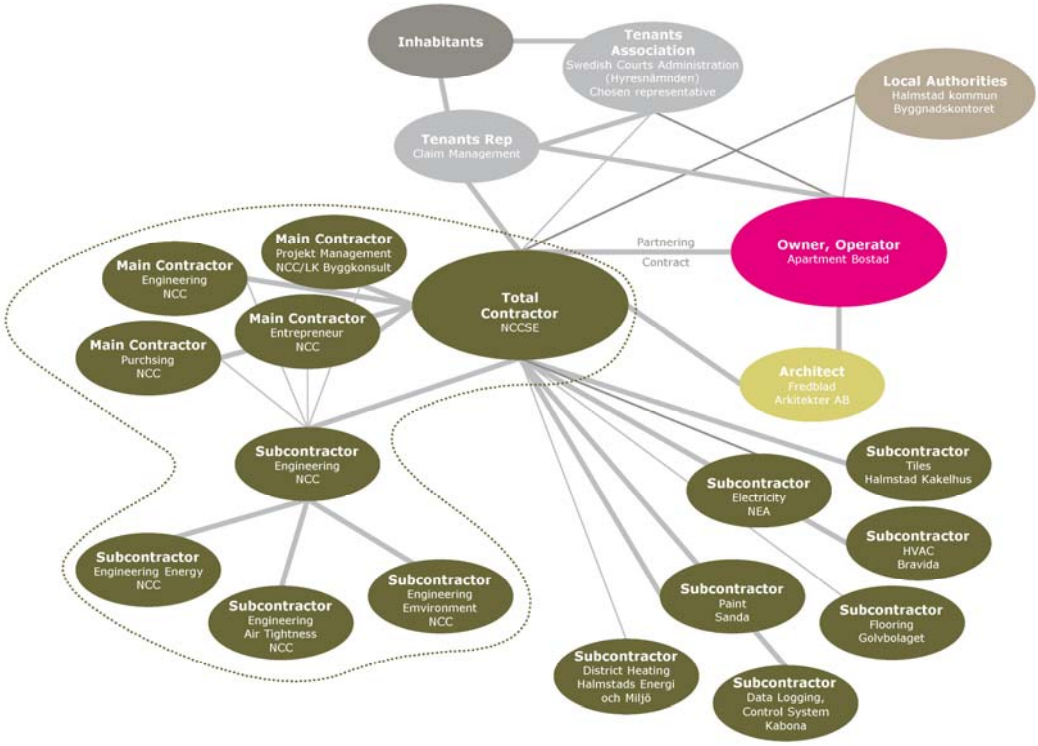

Figure 5: Collaboration chart. Basically the chart of the Demo project Halmstad (Sweden) shows a typical Design-Build model. But the new approach of a so-called Partnering Contracting between the Total contractor and the owner targeted to share the risk and success equally between both partners. Nevertheless the communication and claim management was handled by the Total Contractor. Source Figure: [1] p.25;

In some Demo projects, variations of the basic models such as the *Partnering Contracting (Figure 5)*, a team of *Main Contractors* (*Figure 6*) were tested. For example, the *Partnering Contracting* in the Halmstad Demo (*Figure 5*) where the owner and the *Total Contractor* acted as a partner was a variation of the *Design-Build* model. Here, the range of works was developed in cooperation, but the client made the final decision. Despite the financial risk and success were shared equally, responsibilities for communication and claim management lay in the hands of the *Total Contractor* and he had to guarantee energy savings within the first two years of operation. ([1], p. 23 and 48)

The Demo in Roosendaal (The Netherlands, *Figure 6*) followed the *Design-Bid-Build* model, but the four *Main Contractors* (HVAC, external façade cladding, timber manufacturer and builder) were obliged by the owner to act as a team in order to optimize joint development and share knowledge.

While the builder was informally commissioned to act as a coordinator – the owner wanted to avoid additional charges necessary to employ a *Total Contractor*. ([1] p. 36 and 48)

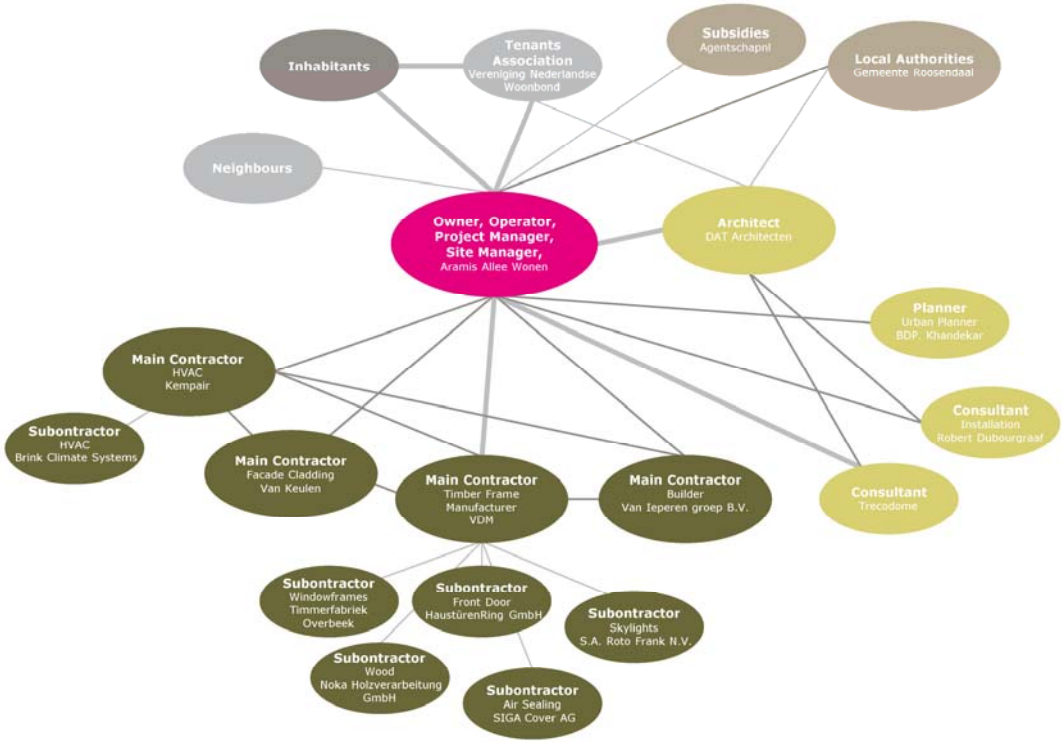

Figure 6: Collaboration chart. In the Design-Bid-Build model applied in the demo project Roosendaal, The Netherlands, the four Main Contractors were obliged to act as a team. Source figure: [1] p. 37;

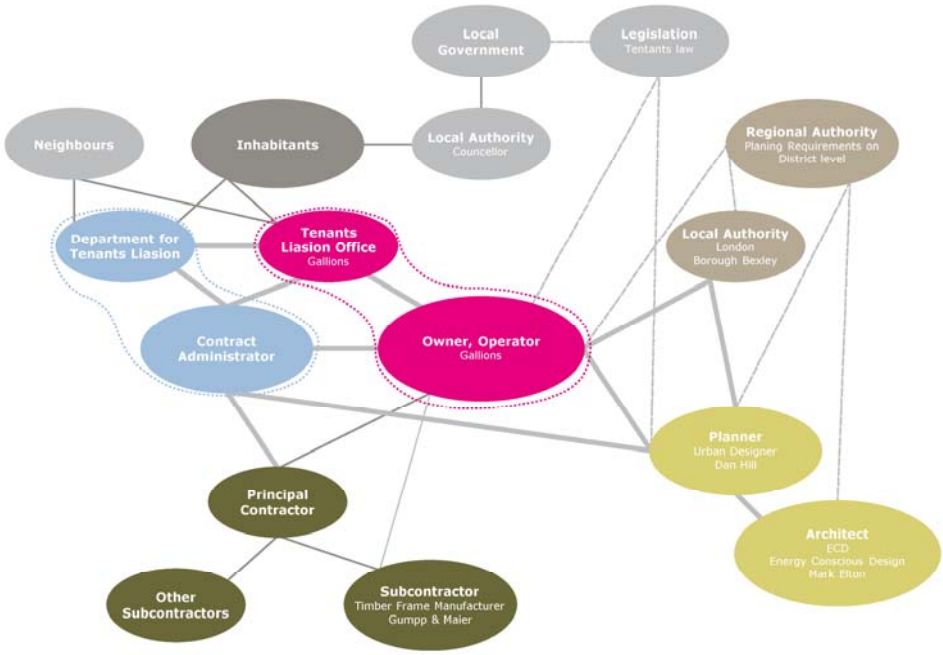

Figure 7: Collaboration chart. In the Design-Build model applied in the Demo project London, Great Britain, the Contract Administrator established and supervised the compliance with contractual and legal conditions. Source figure: [1] p. 42

A specific approach of the Design-Build approach was identified in Great Britain. The *Design-Build* model is common for renovation works performed by owners such as the housing owner of the London Demo project (*Figure 7*). But this *Design-Build* model was influenced by the approach how building permission is granted in Great Britain. The procedure was divided in two parts, the *Planning Permission* and the *Building Regulation Approval*. The *Planning Permission* was used to evaluate the aesthetic and functional aspects of the building renovation without considering technical specifications. However, it enabled the city authorities to influence and determine how the building will fit it in its surroundings. The subsequent *Building Regulation Approval* relied on a positive *Planning Permission.* Hence, the effort of the first step could be kept very low. After the positive *Planning Permission* was granted a separate architect had to be designated[2]. Therefore, actual design and planning (of technical specifications) could only start afterwards. The contractors in Great Britain are not bound directly to the owner. They are bound by subcontracts to the assigned *Principal Contractor.* An additional *Contract Administrator* provided a clear contractual relation (and distance) between the *Principle Contractor* and owner. ([1], p. 40 and 48)

In Munich (*Figure 8*) the housing association had been accustomed to choose out of a pool of planners they knew. For about 10-12 years, they worked with this so-called *Design team* model. Since regulations (*VOF*[3]) have changed they were obliged to tender design and planning services in many cases (depending on the threshold) and report mixed experiences (good ones and bad ones in terms of collaboration and quality of design and planning).

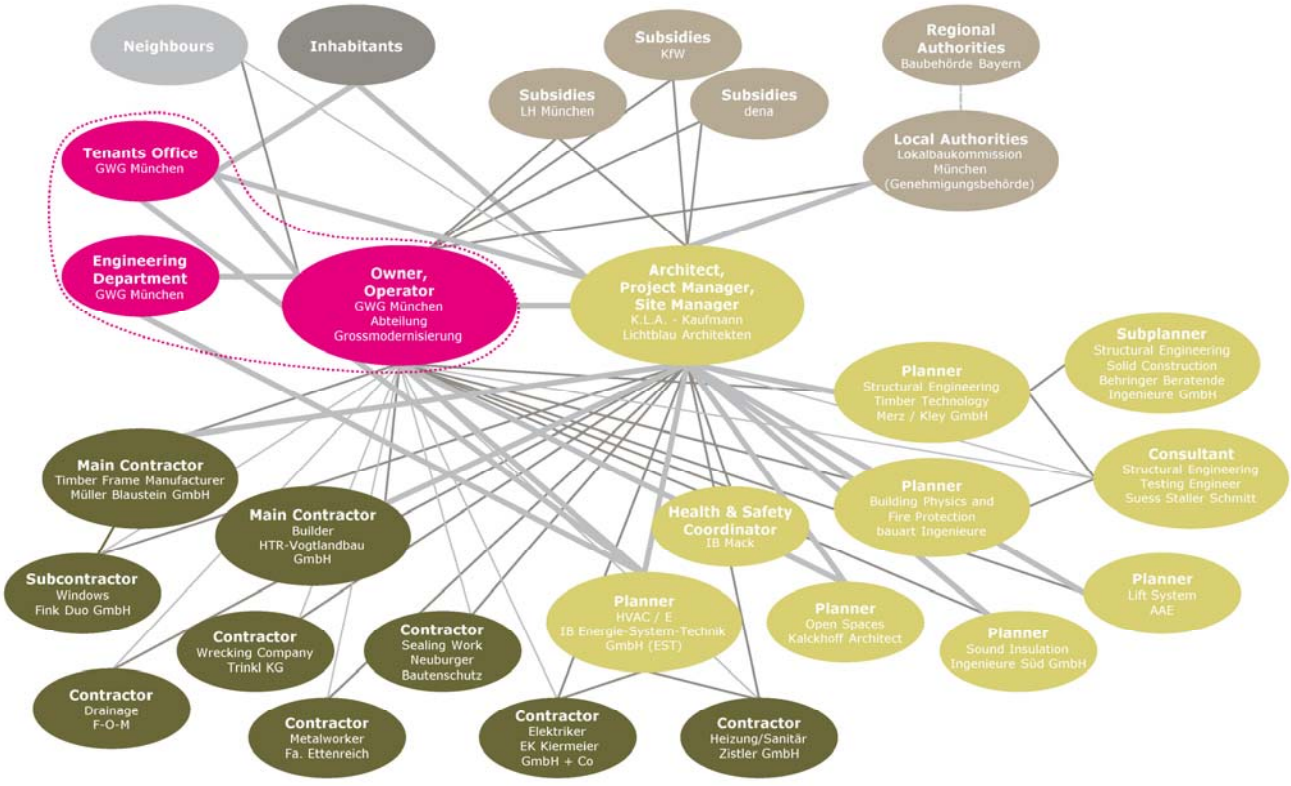

Figure 8: Collaboration chart. The Design-Bid-Build model applied in the demo project Munich, Germany. The housing owner had in-house departments for engineering and tenants affairs. Due the renovation in an unoccupied situation the communication during planning mainly targeted on new tenants. First contact person was the Tenants` office of the housing association; detailed wishes were forwarded to the architect. Source figure: [1] p. 17;

[2] While within the first phase an urban designer was needed, the architect for the *True Design Phase* had to be experienced in structural design and construction planning. Within the Demo in London this architect was a sub-contractor of the urban designer.

[3] The *VOF* „*Vergabeordnung für freiberufliche Leistungen*" rules procurement for supplies and services for freelancers.

The strong commitment of the housing owner of the Demo in Augsburg (Figure 3, Figure 9) to try new renovation methods (the *TES Energy Façade*) and the many years of experience were visible in his active role within the entire process. The specific action line diagram (Figure 9) shows the interconnections of the owner to all other groups of actors, as well as plenty of milestones that marked starting points for actions (contract, agreement, fixed planning, etc.). The process steps are very clearly divided according to the specific skills and know-how of the partners in the project team.

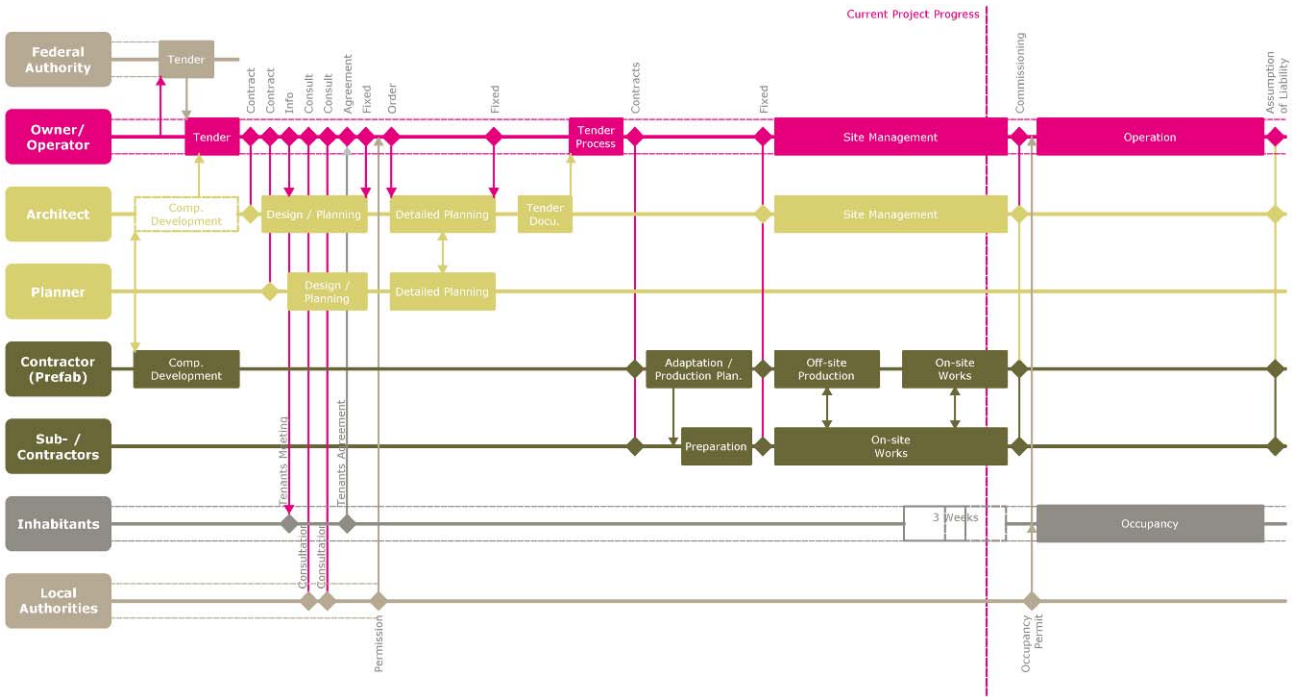

Figure 9: Action diagram Demo project Augsburg. The active role of the owner is visible by the connections to the action lines of other actor groups (magenta lines). Beside steering and controlling the renovation, he took responsibility for the communication and claim management for tenants, the communication towards city authorities and the site management for the entire renovation inside the building. Source figure: [1] p. 22;

4.1 Communication

All Demo project stakeholders showed high awareness of communication with residents and regarded it as a key factor for successful renovation. However, each stakeholder had a different approach on how to handle it. Some addressed tenants personally, were in charge of the communication and claim management and built upon long years` relationship and trust[4]. Others transferred the responsibility to the contractors and the site-manager[5].
However, whether owner or contractor, a high personal effort was necessary in any way in order to keep residents informed and to take care about quick and efficient reactions on their claims. Especially renovation measures in occupied apartments were very sensitive regarding sufficient and careful communication towards tenants.
In contrary, communication among professionals as a tool for joint development within building renovation was a rather neglected aspect despite the fact that the interface between planning and construction was very sensitive. Within the Demos it was seen that know-how from planning phases got lost due to teams planning without manufacturer or insufficient communication and information structures. Frictions in the knowledge chains caused delays and failures in construction and implementation. Misunderstandings and lacking coordination reduced the implementation quality.

[4] This situation was valid for all Design-Bid-Build approaches in the E2ReBuild project.
[5] As claims are seen as a risk, the claim management is shifted to the contractor. This was characteristic for all *Design-Build* approaches in the E2ReBuild project.

Finally, the full potential of industrialised renovation methods could not be exploited as planners were not informed about the ranges of possible cladding materials or 3D nodes were forgotten to be developed carefully, etc.

4.2 Responsibilities and risks

The question of risks and responsibilities dominated the collaboration in the Demos and this was handled differently in the *Design-Bid-Build* and the *Design-Build* approaches. Within the *Design-Build* approaches, the risks and responsibilities were generally shifted to the contractors. Claims concerning renovation, voiced by residents, were seen as "risk" and therefore nearly the entire responsibility for communication[6] and claim management was transferred to the contractor. In this point, the Demo in London was an exception. As within the first phase until *Planning Permission* no *Principal Contractor* was appointed at this time, the housing association took the sole responsibility for the initial information to residents.

4.3 Role of the owner

The choice of model based on the traditional models of the building owners and was influenced by their policy and the role they wanted to take (or could take) in the renovation project.

Hence, housing associations with no or little in-house knowledge (or departments) in the field of construction and renovation choose the *Design–Build* model. Due to the outsourcing of responsibilities and risk to the *Total Contractor*, internal personal effort was reduced.[7] Demos, such as Halmstad and Oulu recognized the advantage of planning and implementation beyond the umbrella of one responsible *Total Contractor* who provided a "ready-made" building renovation in the requested quality with fixed costs. Thus, within the *Design-Build* models clients and owners had less effort, but also less influence on processes, methods and the choice of partners. And the extended responsibilities led to higher costs. For example the owner of the Demo project in London refers to 15-18% of costs for planning and construction ([1] p. 48).

In contrary, owners with many years of experience in construction and renovation choose the *Design-Bid-Build* model. In most cases they had own in-house departments (Augsburg, Munich) and many years of experience in supervising building renovation. Not only precisely defined targets but also a clear picture of methods, processes and materials influenced their role in the process. They stated clear renovation objectives, expected results and executed measures. They stated the importance to steer and control the entire process to guarantee the quality of the construction works and a very quick and efficient reaction to upcoming trouble. They recognized the advantage to influence processes, methods, results and the ability to supervise actors and with it the final success. The more active role of the owner saved costs and provided a bigger range of influence within the process and the team set up (as far as possible regarding procurement regulations).

4.4 Procurement framework

The common way of tendering restricted the owners to work with planners or contractors they knew and trusted. They would have preferred to work with regionally anchored companies which ensured in their opinion higher implementation quality, quicker reaction on the removal of defects and easier liability handling. Further-on changes of manufacturers doubled the work: For instance, a re-design of the prefabricated modules was necessary after the change of the manufacturer due to the result of the tendering process ([1] p. 35). All stakeholders stated the importance of an early selection of planners and contractors and recognized advantages in a harmonized team set up suitable for the specific renovation task and the skills and capabilities of the professionals and

[6] Except initial tenants meetings to inform about renovation.

[7] For example, only one employee of the building owner was required to handle renovation affairs for the Demo Halmstad.

manufacturers. But selecting planners, contractors and putting a team together was often hindered by public procurement legislation – either if the owner was a "*body governed by public law*" ([5] Art. 1 (9) c) or if public money was used for financing the renovation (e.g.: public subsidies). While this European Directive [5] was the common basis for subsequent national legislation, it was interpreted slightly differently in the Member States. However, the new application thresholds regulation EC 1251/2011 published on Jan. 2012 state that contracts above 200.000 EUR for all service contracts, design contests, etc.[8] require public procurement and thus restrict target-oriented selection of planners and contractors.

5. Conclusions and Outlook

The experiences and the feedback from the E2ReBuild stakeholders showed future efforts in policy and decision making to close existing gaps within legislation concerning public procurement. The establishment of teams after the detailed planning phase (by public tender) did not support joint development and collaboration urgently needed in early planning stages. Design and construction teams should be motivated and enabled (on legal basis) to offer services for collaborative design, planning and realization within public tendering. Only teams set up according to their know-how, skills and manufacturing capabilities will facilitate high quality renovation and keep up with time and costs.

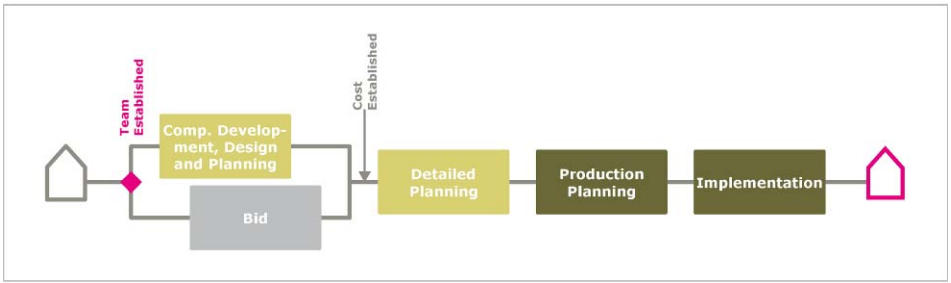

Figure 10: Simplified action line diagram. Within a Team model an entire consortium is founded on a partnership basis. All relevant planners, professionals and manufacturers are included in the team. They offer services within tender or negotiation procedures together. Source figure: [1] p. 68;

In future, teams based on equal partnership of independent companies should be allowed to offer services for planning and implementation of renovation solutions together. Clients would be able to choose between different options and could opt for the most convenient solution for their specific needs. The process to optimize the renovation strategy solution, the quality and finally the costs would start right after the team establishment. As such, knowledge and skills could be kept in the team, and manufacturing capabilities would be available.

That kind of tender process cannot be done with detailed technical specifications. However, this could be solved with functional descriptions for tender. The subsequent procurement would be based on negotiated procedures. However, current legislation does not provide the appropriate framework.
A few models following similar approaches have been realized already[9], but their implementation required special arrangements with authorities and chambers. For example, the *Construction Team* model applied in the German Federal State of Baden-Württemberg based on an establishing a cooperation of the design and construction team before the public tender process. The *Chamber of Architects* developed these models and a lot of projects already used this approach successfully. In the project realized in *Mainz-Grossberg* ([6] p.75-125) the owner (a non-profit housing association) launched a public tender targeted for so called C*ompetition Consortia*. Every consortium needed prescribed participants from planning and building. A series of other contractors could be part of the team or the services were covered with a subcontracting party. The owner arranged the

[8] www.ec.europa.eu/internal_market/publicprocurement/rules/current/index_en.htm
[9] For example the "Bauteammodell" in Baden-Württemberg. See [6] p.75f.

framework with the *Chamber* and arranged information campaigns. They committed themselves to award only the entire consortium - a split between design and implementation was not possible. In the end this *Construction Team* model[10]) brought cost-advantages by exploiting synergies between technical and economical optimization, ensured a highest reliability in terms of quality and time.

The experiences of the E2ReBuild project showed efficient industrialised retrofitting required collaboration models based on teams or partners working together and coordinated centrally by an experienced actor. In future, efficient team set up will depend on how partners` skills, know-how and manufacturing capabilities can be considered. Sufficient communication and information structures collaboration models will have to ensure know-how and information sharing – a precondition for joint development and optimization of solutions regarding costs and time.

As seen in this project, neither the current traditional *Design-Bid-Build* nor the *Design-Build model* could sufficiently meet the requirements for industrialised renovation methods. The feedback from stakeholders showed that all Demo project teams struggled to sustain continuous and smooth workflow and to keep up with time and costs. Depending on the specific project framework and national conditions, each Demo project team had to tackle various obstacles and barriers. Nevertheless, similar requirements on organizational level and obstacles within legislation were identified:

- Communication and know-how exchange among professionals was crucial for industrialised renovation methods and the application of prefabricated façade and roof elements.
- The linkage between the planning team and the contractors. Early and good integration of relevant contractors (e.g.: the timber element manufacturer) ensured optimization of workflow, costs, renovation time and implementation quality.
- Procurement framework restricted owners to compose teams according to project specific requirements and hindered collaboration of planners and contractors in early planning stages.

Finally, traditional renovation routines have to change. Awareness for early integration of relevant know-how carriers (such as manufacturers) and sufficient communication among professionals as driving force for the optimization of renovation solutions is necessary.
Nevertheless, all stakeholders within the E2ReBuild reported a high replication potential within the applied solutions that should be exhausted in future.

Cost optimal building standards – evidence based! The case of Austria

Walter Hüttler

Short Summary

The new EPBD requires that the cost optimum over the life cycle of buildings is taken into account when requirements for the energy performance of buildings are established. National minimum standards should be set by the Member States based on the cost optimum for construction costs and operational costs. Therefore, the European Commission has submitted the regulation No. 244/2012.

A crucial question regarding the cost-efficiency of nZE buildings is whether calculated energy demand and costs assumptions are corresponding with measured energy consumption and real cost data from buildings in use. Up to now there is little empirical evidence to answer this question on a broad basis, even in those countries where a considerable number of nZE is already realized.

This paper is based on recent research results based on a broad empirical survey by e7 together with the Austrian Federation of Limited-Profit Housing Associations (gbv). The survey was launched in order to collect energy consumption AND cost data from innovative multi-family-residential buildings which can be regarded as nZE buildings in order to analyze the cost-effectiveness of those buildings. The paper presents results derived from a broad sample of about 90 buildings.

Based on this survey, there is empirical evidence that the measured energy consumption for heating in nearly zero energy buildings is lower than for low-energy buildings. However, the difference in practice is significantly lower than expected from design values.

Whether passive house or low energy standard: there is a broad range of factor three, in the actual energy consumption, depending on accurate construction, proper operation of the building and user behavior. It would be misleading to draw conclusions from studying only small numbers of buildings. On the other hand, this provides a high potential for the optimization of the buildings operation and thus to reduce running costs for the users.

Maintenance costs vary widely and those buildings with ventilation systems tend to have higher maintenance costs. The lower energy costs of passive–house and lowest-energy building types therefore tend to be partly compensated for by higher maintenance costs.

In general, the lower costs for heating energy do not compensate for the higher investment costs for the passive-house standard of building. At least for the specific situation in Austria it seems, that lowest-energy standard (energy heating demand about 20-30 kWh/m².a) turns out to be the range for cost-optimal building standards. This is well in line with theoretical calculations on cost-optimal building standards for multi-family-residential buildings in Austria, carried out independently in 2012.

Keywords: Cost-optimality, residential buildings, energy use, cost-optimal building standards,

nearly zero energy buildings

Abstract

A crucial question regarding cost-optimal buildings standards and the cost-efficiency of nZE buildings is whether calculated energy demand and costs assumptions are corresponding with measured energy consumption and real cost data from buildings in use. Up to now there is little empirical evidence to answer this question on a broad basis, even in those countries where a considerable number of nZE is already realized.

This paper is based on recent research results based on a broad empirical survey by e7 together with the Austrian Federation of Limited-Profit Housing Associations (gbv). The survey was launched in order to collect energy consumption AND cost data from innovative multi-family-residential buildings which can be regarded as nZE buildings in order to analyze the cost-effectiveness of those buildings. The paper presents results derived from a broad sample of about 90 buildings.

Based on this survey, there is empirical evidence that the measured energy consumption for heating in nearly zero energy buildings is lower than for low-energy buildings. However, the difference in practice is significantly lower than expected from design values.

Whether passive house or low energy standard: there is a broad range of factor three, in the actual energy consumption, depending on accurate construction, proper operation of the building and user behavior. It would be misleading to draw conclusions from studying only small numbers of buildings. On the other hand, this provides a high potential for the optimization of the buildings operation and thus to reduce running costs for the users.

Maintenance costs vary widely and those buildings with ventilation systems tend to have higher maintenance costs. The lower energy costs of passive–house and lowest-energy building types therefore tend to be partly compensated for by higher maintenance costs.

In general, the lower costs for heating energy do not compensate for the higher investment costs for the passive-house standard of building. At least for the specific situation in Austria it seems, that lowest-energy standard (energy heating demand about 20-30 kWh/m².a) turns out to be the range for a cost-optimal building standard.

This is well in line with theoretical calculations on cost-optimal building standards for multi-family-residential buildings in Austria, carried out independently in 2012.

Keywords: Cost-optimality, residential buildings, energy use, cost-optimal building standards, nearly zero energy buildings

1. Cost optimality: Legal and methodical background

The recast of the Energy Performance of Buildings Directive (EPBD) introduced, in Article 9, “nearly Zero -Energy Buildings” (nZEB) as a future requirement to be implemented from 2019 onwards for public buildings and from 2021 onwards for all new buildings. The EPBD defines a nearly zero energy building as follows: A nearly zero energy building is a “building that has a very high energy performance […]. The nearly zero or very low amount of energy required should to a very significant extent be covered by energy from renewable sources, including renewable energy produced on-site or nearby.”[1]

Acknowledging the variety in building culture and climate throughout the EU, the EPBD does not prescribe a uniform approach for implementing nZE Buildings and neither does it describe a calculation methodology for the energy balance. To add flexibility, it requires Member States to draw up specifically designed national plans for increasing the number of nZE Buildings reflecting national, regional or local conditions. The national plans will have to translate the concept of nZE Buildings into practical and applicable measures and definitions to steadily increase the number of nZE Buildings.[2]

Furthermore, the new EU Directive requires that the cost optimum over the life cycle of buildings is taken into account when requirements for the energy performance of buildings are established. National minimum standards should be set by the Member States based on the cost optimum for construction costs and operational costs. Therefore, the European Commission has submitted the regulation No. 244/2012 in accordance with the objective clause of the EPBD in March 2012. Within the scope of this EU regulation, the methodological approach for the analysis of cost optimality of requirement levels is determined bindingly.[3]

The cost optimality principle acts as a bridge between the standard energy performance – as it is usual on today's markets – and the intended goal of reaching nearly zero energy buildings by 2020 (at least for new construction). In this sense the period between now and 2020 can be interpreted as a "transition period" during which the markets are forced to adapt and to apply a life-cycle cost perspective instead of the usual construction cost perspective.[4]

It has to be stressed, however, that the cost optimality principle as defined in the EPBD offers high degrees of freedom when it comes to applying it in the building regulations. Although the EU regulation on cost optimality provides uniform regulations in some respects – e.g. concerning included cost elements, calculation algorithms and analysis period – it allows room for national stipulations in many key areas, such as:

- Definition of the reference building related to important assumption such as size, form, compactness, share of window areas etc.,
- Selection of variants (packages of measures) which are assessed,
- construction costs (and most important construction cost differences for different qualities),
- maintenance costs of relevant building elements and related inflation rates,
- the assumed (technical resp. economical) life-time of building elements,
- discount rates,
- starting level of energy prices,
- energy price trends (although the regulation includes a recommendation to use the "official" EU forecast member states are allowed to use other forecasts for their assessments).

According to a survey done in the frame of the EPBD concerted action in 2011 (before the EU regulation was submitted in March 2012) most of the member states intended to follow a microeconomic approach instead of or together with a macroeconomic approach (which would mainly include GHG emissions as externalities).[5] Up to now, the number of available cost-optimal calculations for different reference buildings according to the EU regulation is quite limited, although considerable work has been done during the last years in developing the application of life-cost-analysis in building practice.

At present, cost-optimal calculations are available only for a limited number of countries, e.g. for residential buildings in Estonia[6] and Austria[78]. The first comparative study with practical examples of cost-optimal calculations for Austria, Germany and Poland was only recently carried out by BPIE in cooperation with The Danish Building Research Institute (SBi), the German Institut Wohnen und Umwelt (IWU) and e7 Energie Markt Analyse (Austria).[9] Although these countries had not announced officially their nZEB definitions, within the cost-optimal calculation performed in this study, packages of measures leading to very low energy buildings have taken into consideration (primary energy demand between 30 and 70 kWh/m².a). The results of this study show, that the difference between actual and cost-optimal energy performance is between 10 and 20% in Austria and Germany, according to different assumptions on input factors and heating systems, whereas there is still a "very big gap" between current requirements and cost-optimal levels in Poland.

2. nZE Buildings in a total cost perspective – the case of Austria

A crucial question regarding the cost-efficiency of nZE buildings is whether calculated energy demand and cost assumptions are corresponding with measured energy consumption and real cost data from buildings in use. Up to now there is little empirical evidence to answer this question on a broad basis, even in those countries where a considerable number of nZE is already realized. If any, it is mostly data for single objects, primarily focusing on measured energy consumption.

Even worse is a reliable data basis when it comes to real costs: so called “additional investment costs” for nZE buildings depend on the actual building standard in the respective country and the availability of cost competitive building components like triple glazing windows. Costs for energy consumption, maintenance and replacement costs are further the crucial elements when it comes to the question of life-cycle-costs.

Regarding the question of actual energy consumption compared to theoretical consumption, it is documented for a sample of 200.000 cases in the Netherlands that there is a considerable difference in both directions, due to the fact that “in very bad performing dwellings the energy use is not as high as expected due to a lower comfort level (behavior) and in very high classified dwellings not as low as expected due to lacking performances of the buildings and services (building control) and the rebound effect (behavior)”.[10] Earlier and fundamental research regarding the rebound effect was already published by Haas and Biermayr (2000)[11] based on a sample of 12 thermally retrofitted buildings in Austria and Berkhout et al (2000).[12]

A considerable number of nZE demonstration projects is well documented in the R&D program “Building of Tomorrow” in Austria. However, the evaluations of these buildings focus on energy consumption and give little or no indication on running costs or life-cycle-costs.[1314] Therefore, in 2011 the Austrian Federation of Limited-Profit Housing Associations (gbv) together with e7 launched a broad survey in order to collect energy consumption AND cost data from innovative multi-family-residential buildings. The aim of this study was to analyze the cost-effectiveness of nZE buildings compared to “normal” low energy buildings.[15]

The following figure 1 shows the distribution of energy heating demand categories within the sample of 128 buildings from the survey carried out. The major part of the buildings within the sample were built between 2006 and 2010, thus securing that consumption data and actual data on running costs are available at least for 2-3 years.

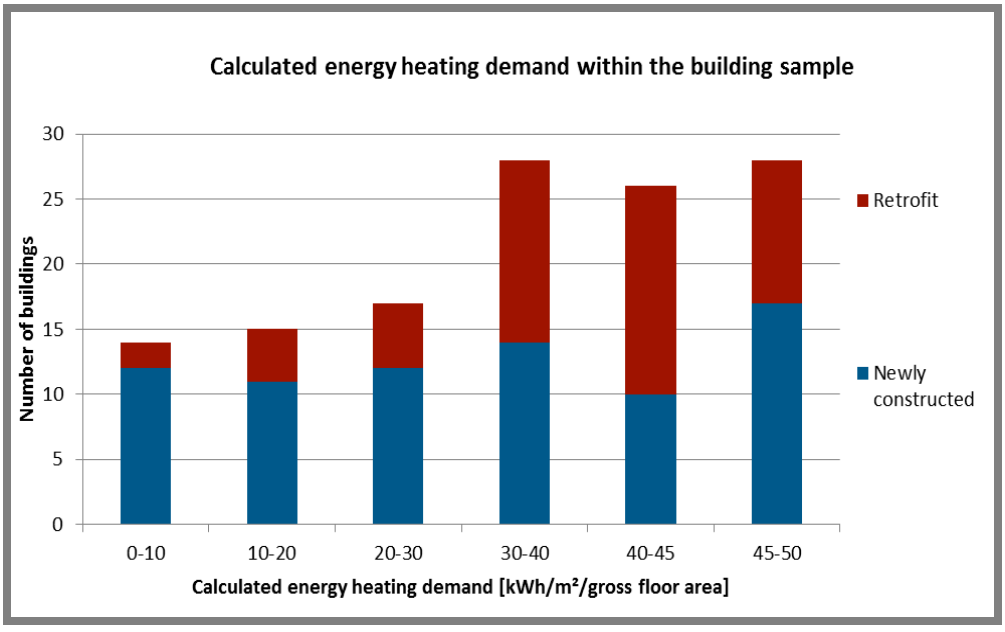

Fig. 1: Calculated energy heating demand in the Austrian multi-family residential building sample (Source Hüttler, Rammerstorfer, Tudiwer, 2013)

The focus of this project was on multi-family-residential buildings with (calculated) heating energy demand lower than 50 kWh/m².a, covering the range from low-energy buildings to lowest-energy buildings to passive-house standard.[16] Energy consumption data were provided by the housing associations for at least two or three years for each building. Results derived from a broad sample of about 60 buildings indicate that the measured energy consumption for heating in NZE-buildings is in reality significantly lower than in low-energy-buildings. However, data show also a broad

variance of real consumption data of about factor three within each group (appr. 15-50 kWh/m².a passive-house / 20-70 lowest-energy / 30-90 low-energy-buildings). Therefore, it could be quite misleading to draw far-ranging conclusions from single objects or a small sample of (selected) buildings.

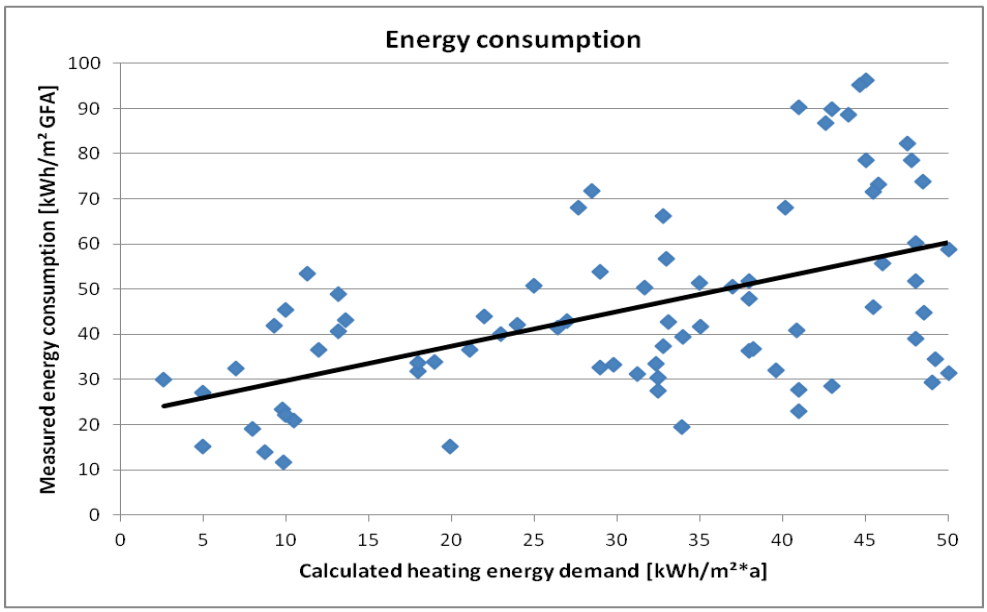

Fig. 2: Energy consumption for heating vs. calculated heating energy demand in nZE multi-family-residential buildings (Source Hüttler, Rammerstorfer, Tudiwer, 2013)

Costs for energy consumption for heating are easily available only for those buildings with central heating systems. Furthermore it has to be differentiated between heating and hot water. Maintenance costs were becoming an increasingly important issue mainly due to mechanical ventilation systems, which are a crucial element of the passive-house-concept but also more and more frequently installed in lowest-energy buildings due to air-tight construction.

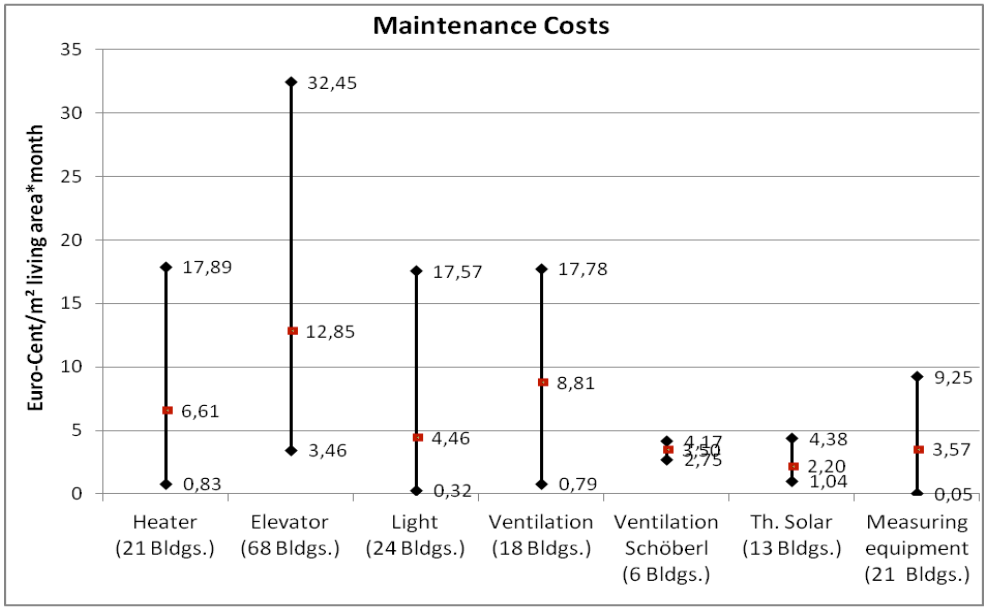

Fig. 3: Maintenance costs in nZE multi-family-residential buildings (Source Hüttler, Rammerstorfer, Tudiwer, 2013)

Not surprisingly there can also be observed a broad variety of maintenance costs in practice. Maintenance costs for ventilation systems range from 0,8 till 18 ct/m².month with an average of about 9 ct/m²m.month, depending mainly on the system (central or decentralized ventilation, frequency of filter exchange, quality of filters and adequate contracts with external maintenance contractors. Best practice studies for a limited number of 6 buildings show that the maintenance costs for central mechanical ventilation systems can be limited to a range from 3 to 4 ct/m².month, whereas decentralized ventilation systems result in maintenance costs of 10 ct/m².month on average.[17]

Buildings with ventilation systems trend to have higher maintenance costs compared to buildings without ventilation systems. Consequently, lower energy costs for heating which can observed in lowest-energy and passive-house-buildings are tending to be partly compensated by higher costs for maintenance.

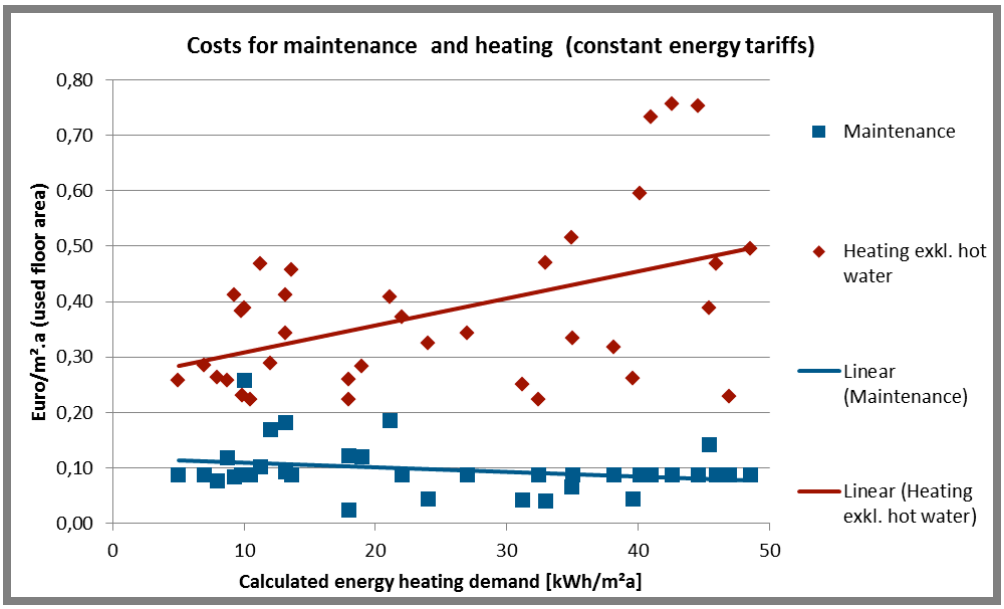

Fig. 4: Energy costs for heating and maintenance costs in nZE multi-family-residential buildings (Source Hüttler, Rammerstorfer, Tudiwer, 2013)

Specific investment costs (€/m² used floor area) are depending on different factors: most important of them the size of a building, since small and less compact buildings have significantly higher specific costs than large and very compact buildings. Further cost components which influence the comparability of building costs are the number of elevators and if there is an underground garage for each dwelling or not. Furthermore regional differences in building cost levels can be generally observed. So one has to be very careful when it comes to comparison of investment costs with regard to different energy standards.

The following graph shows a sample of 40 nZE buildings with (calculated) energy heating demand lower than 50 kWh/m².a. Whereas the specific investment costs for individual buildings vary considerably due to factors mentioned above (regional cost differences etc.) the trend line results in additional specific costs for passive-house buildings of about 100 €/m² compared to low-energy standard (which is mandatory in Austria since 2012). A more detailed analysis show, that the additional costs for passive-house standard seems to be significantly lower for large and compact buildings (appr. 40-80 €/m²) compared to additional costs for small and less com pact buildings (appr. 120-200 €/m²).[18]

One has to mention that the economic ratio of the passive-house according to the (initially) strictly reduced concept based on the idea that additional investment costs for the improved building shell and mechanical ventilation are partly compensated since there is no need for a conventional heating system. This has been successfully proven in practice for a number of buildings but it

turned out that in practice (at least in Austria) most of the multi-family-passive houses are built with mechanical ventilation AND a more or less conventional heating system. Decoupling heating and ventilation allows lower air-change rates and reduces the risk of unhealthy dry air indoor conditions during the winter and is therefore state of the art in passive-house technology. Consequently, to have both mechanical ventilation AND a conventional heating system is questioning the initial idea of cost-effective passive-houses.

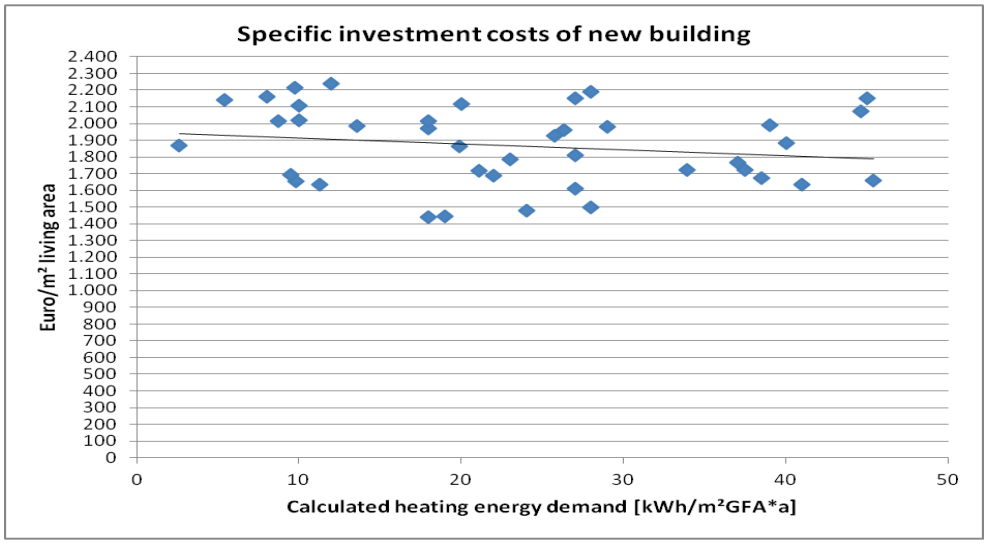

Fig. 5: Specific investment costs for nZE multi-family-residential buildings depending on the energy standard (Source Hüttler, Rammerstorfer, Tudiwer, 2013)

Finally, putting together the data on running costs and investment costs in a simplified total cost calculation over 20 years (net present value, without reinvestments for technical installation and without declining-balance, 3% energy cost increase per year) the results show that lower costs for energy heating do not compensate the higher investment costs for passive-house standard in general. At least for the specific situation in Austria it seems, that lowest-energy standard (energy heating demand about 20-30 kWh/m².a) turns out to be the range for cost-optimal building standards.

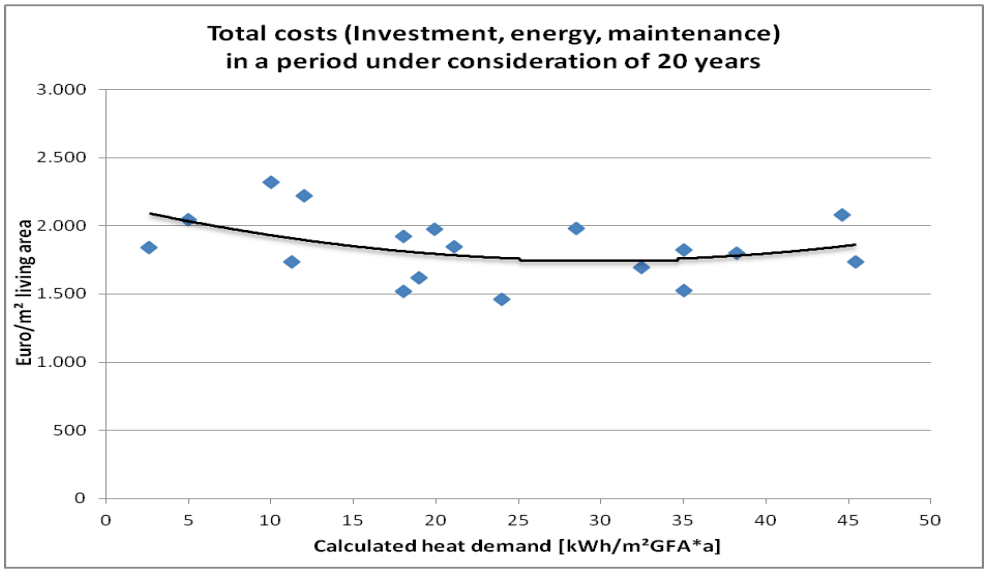

Fig. 6: Total costs (investment, energy, maintenance) in nZE multi-family-residential buildings depending on the energy standard (simplified calculation without reinvestments for technical installation, 3% energy cost increase per year) (Source Hüttler, Rammerstorfer, Tudiwer, 2013)

Approximately, this is quite in line with theoretical calculations on cost-optimal building standards for multi-family-residential buildings in 2012[19]. Results from different organizations based on three different data sets lead to comparable results.

The results of Bednar et al. from the Technical University Vienna was made for two different reference buildings and show an “cost-optimal” heating energy demand of about 20 kWh/m².a for large residential buildings (80 dwelling) whereas the “cost-optimal” heating energy demand for a small residential buildings (6 dwellings) is about 40 kWh/m².a.

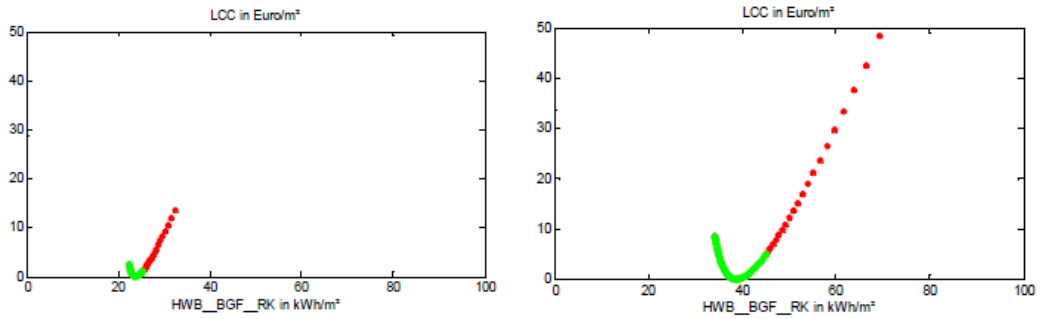

Fig. 7: Cost-optimal building standards for multi-family-residential buildings: large (80 dwellings) left and small building (6 dwelings) right graph. The y-axis describes the global cost difference between the different standards in €/m² (Source Bednar et al., 2012)

Cost-optimality calculations for a residential building with 30 dwellings done by e7 show a cost-optimum range between 20 and 30 kWh/m².a (heating energy demand) (Fig. 8). This is in line as well with the cost-curve derived from our empirical data (Fig. 6) and with the calculations of the Technical University Vienna (Fig. 7).

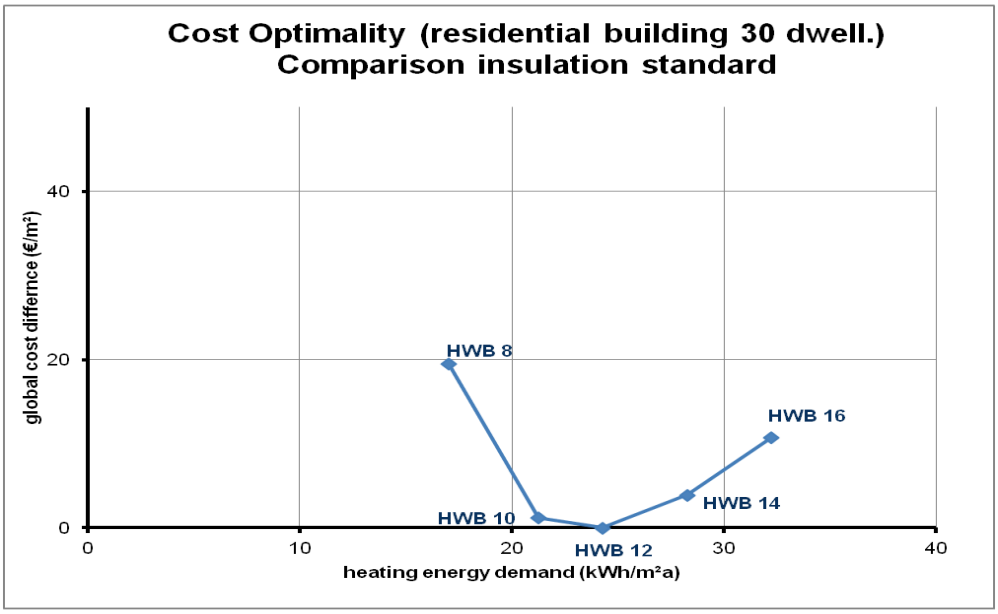

Fig. 8: Cost-optimal levels for multi-family-residential buildings (30 dwellings). The y-axis describes the global cost difference between the different standards in €/m² (Source Leutgöb and Rammerstorfer, 2013)

Based on these calculations it is obvious that the passive-house standard seems actually not to be the cost-optimum for residential buildings. One of the main reasons, why a considerable number of passive-house buildings in Austria were realized during the last years is financial incentives

integrated in the housing subsidy schemes of the federal regions. For example, the additional subsidy for building a residential passive-house is 120 €/m² in Tyrol. Consequently, the housing association "Neue Heimat Tirol" is able to offer dwellings in passive-house standard at the same rent conditions as usual low-energy buildings for their tenants.[20]

3. Conclusions

Based on both theoretical calculation and the analysis of evidence based cost and consumption data from buildings already in use for 3 to 5 years a plausible range for cost-optimal building standards could be identified for Austria. The combination of different approaches carried out independently seems to be a promising way to define nZE buildings based on cost-optimal levels. Furthermore, this reflects only the sheer economic perspective, not including other important parameters like living comfort or practical usability. The results of this analysis may be applied in general to other countries, results in details are very country specific. Therefore, theoretical calculations and analysis based on real data from practice have to be done for each country.

Abstract

There are about 54 billion square metres existing buildings in China. In the wake of structural degradation and the enhancement of China's building energy saving standards, large numbers of China's existing buildings need to be rehabilitated.

A comprehensive assessment system for the existing building's refurbishment in China is developed to evaluate the necessity and the specific direction of strengthening and renovation of the evaluated buildings, considering the structural safety, energy saving, indoor and outdoor environment, local content and cost with three-level indicators. In addition, an assessment to forecast the remaining life of the existing buildings after retrofitting which reflects the effectiveness of the refurbishment and the technical economic analysis of the retrofitting is also presented in the system. Finally, a public building in Liaoning province of China is analysed as a case study to demonstrate the feasibility and validity of the system.

Keywords: Existing Building; Refurbishment; Comprehensive Evaluation; Energy Efficiency; China

1. Introduction

Currently, the total area of existing buildings has increased to more than 54 billion square meters in China. More than 11 billion square meters in the old buildings have problems with respect to safety and inner environment. Instead of rebuilding, taking strengthening and retrofitting measures for the old existing buildings are more reasonable. China's construction industry has begun to enter the period of renovation and strengthening from the period of construction [1]. Hence, integrally, comprehensive, and reasonable evaluation of the refurbishment of the existing buildings in China is of great importance.

Most developed countries had formulated their own evaluation systems according to their own state of development [2] in the aspect of assessment of residential building. For example, the Housing Quality Indicators System (HQIS) of England evaluates the residential buildings from 10 partial evaluation indexes of the location, design and performance key factors; Department of Housing and Urban Development (HUD) of America presents the objects of Housing Quality Standard (HQS) including all the independent housing types and collective housings, and the main certification contents of this system have 13 main aspects of health, safety of the residential performance; In the Residential Quality to Ensure the Promotion Law (RQEPL) of Japan, the application area of the industrial building performance's system is extended to all residential buildings. The benchmark of the residential performance of Japan set part performance index instead of comprehensive indexex,

which mainly includes 9 aspects for the evaluation of the new residential content and includes evaluation, repair and recycling for the evaluation of residential points.

The previous works concerns economic indicators (revenue, profit, and depreciation), technical indicators (safety, applicability, durability) and environmental indicators (pollution) of existing buildings [3] separately. The assessment result of existing building may be segmentary and leading to a deficient refurbishment decision. In this study, a comprehensive evaluation of strengthening and retrofitting for existing buildings consider the technical and economic indicators integrated with environment index [4] , making the existing buildings in accord with the sustainable development and people-oriented objectives. Accordingly, a multi-objective and multi-level comprehensive evaluation system for the existing building strengthening and retrofitting in China, which is conducted as elements of building renovation for existing buildings, is developed. A public building in Liaoning province of China is analysed as a case study to demonstrate the feasibility and validity of the system.

2. The comprehensive assessment index system

In order to guarantee the objectivity of assessment result, a series of quantitative indexes are established along with some traditional qualitative indexes, while, the social and humanistic ecology are taken into account.

In the process of the establishment of the index system, we also refer to some developed countries' existing assessment index systems of building performance and green building assessment systems, such as the British BREEAM, American LEED [5], Australian NABERS and Japanese CASBEE [6]. Considering the current situation of China, we also made reference to the Technical Standard for Residential Performance Evaluation (GB/T50362-2005), which was implemented on March 1, 2006, and Green Building Evaluation Standard of China (GB/T50378-2006), enforced on June 1, 2006 (referred to as the "standard"), which is used for evaluating residential and office buildings, shopping malls, hotels and other public buildings.

The evaluation index system includes six indexes as follows: 1) land saving and outdoor environment; 2) energy saving and energy utilization; 3) water saving and water resources utilization; 4) materials saving and material resources utilization; 5) quality of indoor environment; 6) operation management (residential construction), the whole life cycle comprehensive performance of the buildings (public buildings) [7-9].

A Comprehensive Assessment System for the Strengthening and Retrofitting of Existing Residence (CASSRER) is designed with 3 level indicators as shown in Figure 1. Level one includes 6 indicators, such as architecture and structure, indoor environment, energy saving, outside environment, regionalism and economy. Level two includes 23 indicators, such as architectural design, noise and sound insulation, material energy-saving, distribution of buildings, Level three contains 100 marking criteria.

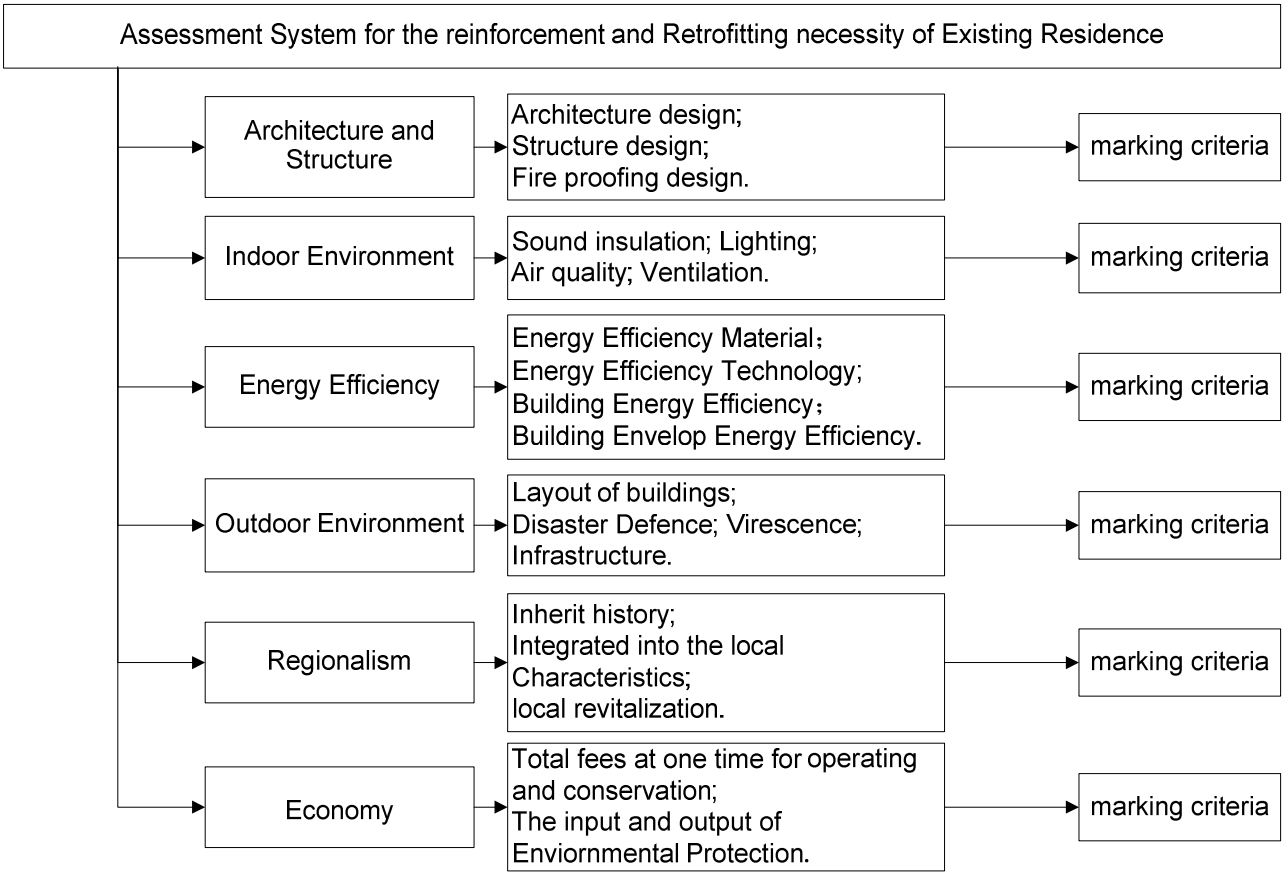

Fig. 1 Assessment System for Strengthening and Retrofitting necessity of Existing Building

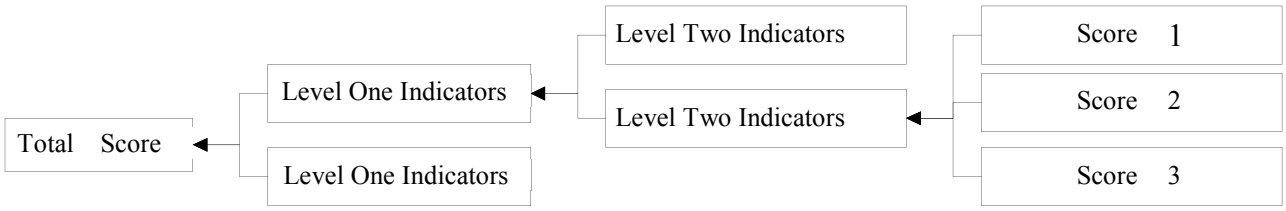
3. Weights system

3.1 Method for determining weights

This paper adopted the analytic networks process (ANP), which use comparison matrix function in the super decision software (1.4.2), to determine the weight system based on a questionnaire survey of experts.

Through the questionnaire survey, the relative importance of the 6 level one indicators and 23 level two indicators was determined, which was consistent with the AHP. According to the principle of stakeholders, this survey mainly referred to the people worked in building research institutes, design institutes, real estates, residential construction, construction consulting companies and residents. A total of 200 questionnaires were issued. 188 effective questionnaires were taken back and 12 questionnaires were invalid. Finally, the weights system of the comprehensive evaluation system for the strengthening and reconstruction of existing buildings in China was established, as shown in Table 1.

Table 1 Weights System



First level index	First level weights	Second level index	Second level weights
Architecture and Structure	0.416	Architecture design	0.220
		Structure design	0.434
		Fire-proofing design	0.345
Indoor Environment	0.113	Noise and sound insulation	0.228
		Sunshine and lighting	0.240
		Air quality	0.277
		Ventilation	0.255
Energy Efficiency	0.313	Building energy efficiency	0.197
		Energy efficiency technology	0.120
		Energy efficiency material	0.193
		Building envelope energy efficiency	0.339
		Water-saving	0.248
Outdoor environment	0.066	Distribution of buildings	0.162
		Disaster protection	0.283
		Vegetation and green	0.253
		Infrastructure	0.301
Regionalism	0.050	Inherit history	0.325
		Integrated into the local Characteristic	0.217
		Local revitalization	0.458
Economy	0.042	Total fees at one time	0.143
		Operating and maintenance fees	0.344
		Environment protection investment	0.245
		The production of environment protection	0.268

3.2 Scoring Method

The comprehensive evaluation system for the strengthening and retrofitting of existing buildings obtains a score through the evaluation of each indicator. As weight grade method has advantages

for the multi-level evaluation index system, the evaluation system for strengthening and retrofitting of existing buildings adopted the weight grade method to calculate each indicator score and the total scores. Firstly, we calculate the actual score of each level-two indicator. Then, all level-two indicator score is multiplied by the corresponding weight and accumulated the results. Finally, we obtain level one indicators' scores, as shown in Fig. 2. According to the indicator score of the evaluated level one indicator for the existing building, the classification modification necessity can be further obtained. Also according to the score of the appraisal object, we can make a comprehensive evaluation on the necessity of building's refurbishment.

Fig. 2 Scoring Method

In this paper, the architecture and structure, indoor environment, energy saving and outdoor environment of four level-one indicators are divided into as objective indicators, meanwhile, the regional and economic indicators of two level-one are divided into as subjective indicators, and we used different scoring methods for different characteristics of the subjective and objective indicators. The objective indicators uses 0/1 scoring method, namely the score is 1 for meeting the criteria, or scores 0. Five grades that scoring points for the subjective indicators are excellent, good, fine, qualified and bad, and respectively correspond to 1, 0.8, 0.6, 0.4 and 0.2 of the five scores. Evaluation grade is decided according to the evaluation scores, and the preliminary rating standard is set for: 1. Being in urgent need of refurbishment (0 ≤score ≤ 30); 2. Being in need of refurbishment (30 < score< 60); 3. Being in no need of refurbishment (60 < score < 100).

4. Case Study

4.1 Project Profile

A laboratory building located in Liaoning Province of China (Fig. 3), which was constructed in 1992, was evaluated by the proposed system. The main characteristics are as follows: five-story brick structure of the body, 3882 square meters in building area , the shape coefficient is 0.28, window to wall ratio are 0.218 (East), 0.051 (South), 0.219 (West), 0.226 (North). Under the barriers of economic condition and policy, there were virtually no energy efficiency and thermal insulation measures were token when constructed, energy-saving construction was conducted on April, 2007.

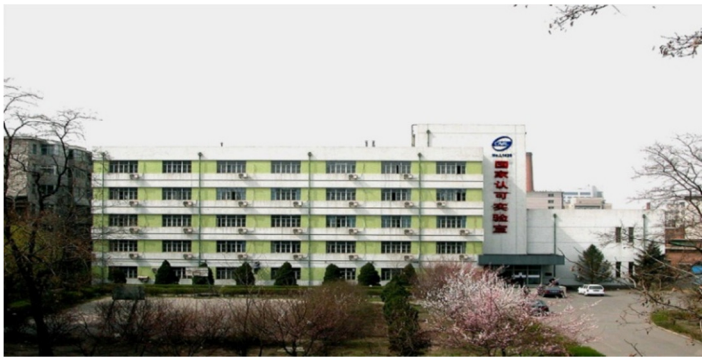


Figure 3 The Laboratory Building Before Strengthening

4.2 Evaluation of the Building Before Refurbishment

Evaluation of the building before refurbishment was implemented through the Comprehensive Assessment System for the Strengthening and Renovation of Existing Residence(CASRRR) developed based on the proposed method of the paper, the result is shown in figure 4. It can be seen from the figure that: the comprehensive score of the building is 43, the total rating is "modification", the comprehensive performance is low. The outdoor environment and regional score is 66 and 76 respectively, which indicate that the two aspects are well behaved. Other three scores in building and structure, indoor environment and economy are between 30 to 60 points, which need appropriate strengthening and appropriate renovation; but the score of energy efficiency is 24, which exposed some problems like high energy consumption, low efficiency. It is shown obviously in radar map that the whole score of the area is lesser due to the various uneven scoring, and affects the comprehensive performance of the building.

The Indicator Scores

Total Score	43.00	Renovation
Building and Structure	46.00	Renovation
Indoor Environment	54.00	Renovation
Energy efficiency	24.00	Urgent Renovation
Outdoor Environment	66.00	No Renovation
Regional	76.00	No Renovation
Economy	45.00	Renovation

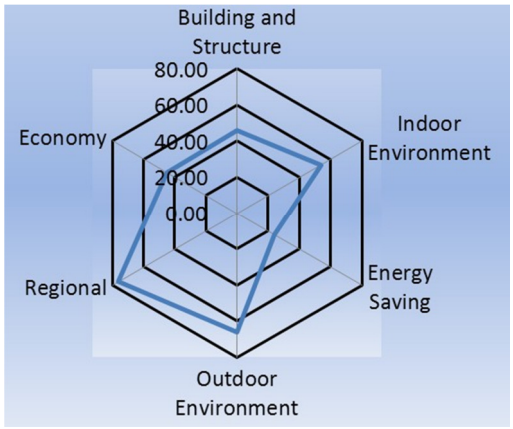

Figure 4 Evaluation Results of the Building Before Refurbishment

4.3 Building Refurbishment Scheme

In the process of refurbishment of the laboratory building, some new technologies of energy efficiency, new materials and integrated application of solar energy technology, water reuse, wind power generation technology were adpoted. Table 2 is a list of the adpoted renovation technologies. Figure 5 is the building after reburbishment.

4.4 Evaluation after the Refurbishment of the Building

Evaluation of the building after refurbishment was conducted through the CASRRR. The result is shown in Fig. 6，in which the comprehensive score of the building is 65, indicating that no renovation is needed.

By comparing the Fig 4 and Fig 6, we can see that the three terms of the building and structure, indoor environment and economy increase slightly, while the building and structure and the rating of economy still need to be improved, but it has been close to the requirements; at the same time the energy efficiency increased significantly, the effect of refurbishment is remarkable.

Table 2 Energy Efficiency Refurbishment Scheme of the Laboratory Building

The serial number	Renovation project		Technical elements
One	Outer renovation	Outer wall	Increase the thermal insulation layer on the basis of the outer original wall which is 370mm thick.
		Outer window	Change the side-hung steel windows with double glazing by the side-hung plastics-steel single frame windows with double glazing, in some floors with low-E glass.
		Roof	Use polystyrene board 120mm thick keeping insulation
		Floor and ground	Increases the phase change heating storage floor in apart of room.
Two	The renovation of inner system	Heating system	Replace one-pipe uplink system with a dual-pipe system, increase the heat flow and temperature control valve, replace the radiator.
		Air condition system	Removal of the split type air conditioner, and using modular air cooled chiller.
		Water supply system	Use water-saving appliances and purified water
		Power supply system	Itemized metering
		Intelligent system	Integrated wiring technology
Three	Apply new technologies	The application of solar technology	Using solar water heating system; Using the solar air heating technology; Using the natural ventilation technology.
		Reclaimed water reuse technology	Collect domestic sewage for water recycling, then through the high efficient bacteria strengthen BAO technology, make the treated water used for flushing and landscape irrigation water.
		Wind generation technology	According to energy conversion principle, through the wind turbine converts wind energy into electricity. It will supply power to street lamp, lawn lamp ahead the building.

Figure 5 The Laboratory Building after Refurbishment

After the comprehensive refurbishment, the score of different aspects of the building tend to be equal, the area of radar chart expands considerably, in that way we can get a great benefits with less economic cost through scientific and reasonable planning for the refurbishment work.

The Indicator Scores

Total Score	65.00	Renovation
Building and Structure	50.00	Renovation
Indoor Environment	62.00	Renovation
Energy efficiency	85.00	Urgent Renovation
Outdoor Environment	66.00	No Renovation
Regional	76.00	No Renovation
Economy	51.00	Renovation

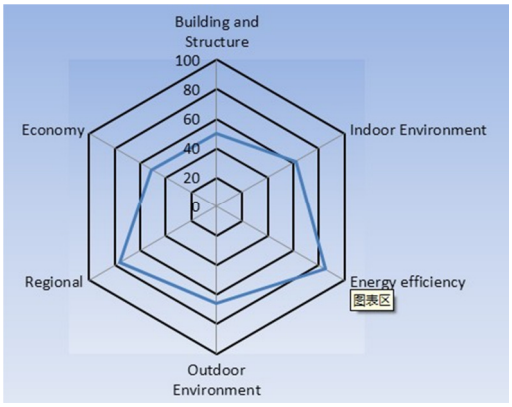

Figure 6 Evaluation Results of a Building after Refurbishment

5. Conclusion

An existing building strengthening comprehensive evaluation system, including 6 level one indicators, 23 level two indicators, is developed in this paper. The evaluation system provides a useful tool for assessing the performance of existing buildings, the grade of strengthening and reconstruction necessity as well as the specific direction of strengthening and reconstruction can be determined. The method can figure out the refurbishment potentiality of existing buildings in 6 aspects regarding the architecture and structure, the indoor environment, energy saving, environment, regional and economic. A case building evaluation verified the feasibility of the proposed system.

Short Summary

This paper focuses on the specification of critical points in the assessment of a chosen building to be elaborated according to EN 15978 [2] and EN 15804 [3]. It is based on the scenario for a specific building refurbishment – underground part of the building was maintained, upper part was deconstructed and built as new re-using the most of the deconstructed building materials possible. The calculations of environmental performance are not part of this paper, but are planned as a next step of the future work of the authors.

Keywords: Life cycle assessment; refurbishment; building assessment; environmental performance of buildings

1. Introduction

Life cycle assessment of buildings is nowadays used first of all for new buildings. The situation is quite different in assessment of existing buildings and their refurbishments. There are only quite few LCA analysis for existing buildings in the world, and most of them are only simplified versions. It is clear that we should focus on LCA of existing buildings because it is generally known that new buildings represent just a minor portion of the total number of buildings (for example the annual growth rate of new buildings added to the housing stock is 1.5%) [1]. From this point of view, we are able to influence the overall environmental performance of buildings more efficiently if we also focus on improvements of the existing ones.

It emerged from the background research that there is not a sufficient number of relevant examples of life cycle analysis of refurbishments of existing buildings. Furthermore, the assessment method according to the European Standard EN15978 Sustainability of construction works – Assessment of environmental performance of buildings – Calculation method [2] is quite new and no LCA studies have been done so far. It has been decided to create a detailed LCA of a typical Czech existing building intended for refurbishment. Detailed scenarios are modelled for individual modules of life cycle of the building and particular and problematic issues are defined within the process.

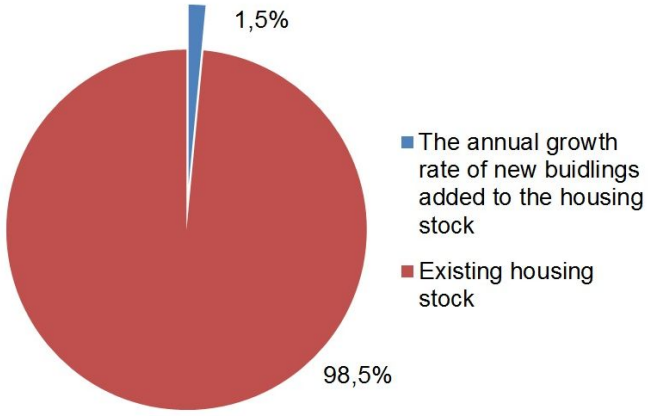

Fig. 1: The annual growth rate of new buildings added to the housing stock [1].

2. Methods

As a model case serves a residential building which went through a refurbishment process. The building is in the first part described according to the requirements of the norm [2]. The second part of this paper addresses the problematic issues and uncertainties that emerge during creating a model and scenario of the building life cycle assessment.

2.1 Building model

"The purpose of the building model is to enable the quantification of the mass and energy flows. This quantification should be organised in a structured way according to the norm" [2].

Our building is a one family house in Pilsen (Czech Republic) which went through a refurbishment process which was finished in 2010 (Fig. 2). The original floor space was 81,7 m2 and 142,8 m2 is the floor area after refurbishment. New living space with rooms for children was created in the attic.

Fig. 2: LCA subject - family house in Pilsen (Czech Republic) which went through a refurbishment process (left – original state, right – after refurbishment).

The basic constructional principals of the refurbishment were:

- Keeping the original built-up area;
- Using parts of the original foundations;
- Deconstruction of the walls;
- Using the original bricks for the new construction of the walls (hand cleaned);

- Rising up the roof to create new rooms;
- HVAC DUPLEX unit used for ventilation and heating (runs on gas boiler) ;
- Fire place with heat accumulation reservoir;
- Solar collectors;

2.2 Purpose of the assessment

The purpose of the assessment is defined by the goal, the scope and the intended use of the assessment. In our case, the intended use of the assessment is according to the norm [2] following:

- Assistance in decision making process (for example comparison of the environmental performance of different design options);
- Documenting the environmental performance of the building;

2.3 Specification of the object of assessment

2.3.1 Functional equivalent and reference unit

As the results of this case study are to be used for comparisons with another scenarios of the building construction, the functional equivalent is the family house for 4 persons, meeting the requirement of the heat transfer coefficient for low energy house (the same coefficient as will be defined for other scenarios), and all fire protection and static requirements of Czech building laws. The required service life of the building will be the same for all scenarios as well (e.g. 50 years, see chapter 2.3.2).

In case of comparison of different building design assessments (e.g. new building will have larger floor surface than the refurbished one), the reference unit per $1m^2$ or per 1 person will be used.

2.3.2 Reference study period

"The default value for the reference study period shall be the required service life of the building. Any deviations from this (see below) shall be clearly stated and reasons explained" [2].

There are several problematic issues regarding the service life of the building or a particular building component. Service life can be divided into **moral service life** or **technical service life**. Moral service life is not usualy identical with the technical service life. It is common that buildings reach their moral service life limit before reaching the real technical service life limit. Such buildings do not fulfil the needs of building operation and they are being demolished although the technical condition of their construction is good.

It is more or less possible to determine the technical service life of a building or its component but the moral service life is quite unpredictable. It is impossible to define future social or urban changes that would influence the building use and its moral service life.

2.3.3 System boundary

"The system boundary determines the processes that are taken into account for the object of assessment. In this context, the object of assessment is the building and its site. This includes all the upstream and downstream processes needed to establish and maintain the function(s) of the building, from the acquisition of raw materials to their disposal or to the point where materials exit the system boundary either during or at the end of the building life cycle" [2].

The building assessment process was studied according to the system boundaries and modules given in [2] and [3]. The results are given in chapter 3.

2.3.4 Scenarios of the building life cycle

In this case, the scenario of a specific building refurbishment was determined. It included the deconstruction of the existing above-ground part and maintenance of the underground part of the

building. Large part of the deconstructed building materials (e.g. bricks), were re-used in the new construction. In a different point of view, this scenario could be taken as a new construction with re-use of existing materials, but as the foundations were maintained, the refurbishment is more likely (at least according to the Czech building law system).
Other scenarios as possible renovation of existing building (without the deconstruction of the upper part) or completely new construction including demolition of the old building were not part of this study, but will be studied in the future work of the authors.

3. Results

The building refurbishment assessment process according to the modules A-D given in [2] and [3] was studied. The critical points expected during the assessment were stated and summarized in tables (Tables 1, 2, 3 and 4)

3.1.1 Product and construction process stages – A modules

Table 1: Product and construction process stages of building assessment and definition of critical issues in assessment of particular processes.

Module	Process	Relevant for the case study	Critical Issue / uncertainty
A1 Raw material supply		Yes	These data for building products should be gathered from **EPD**s [3]. However, in Czech Republic there are almost no EPDs for building products. Generic data should be used in that case, but as stated in [4], this could lead to incomparable and unreliable results. Another problem is the inclusion of **re-used materials**, e.g. bricks. Since they are not transported anywhere and used as they are, only some cleaning should be included. No further environmental impacts are caused by the re-used products. For that, no EPD should be needed. Another question is the **cut-off rules**. According to EN 15804 [3], 1% of energy or materials flow is allowed for a process, and 5% in total for modul A1-A3. Regarding the new materials, the 1% impact could be equal to the impact of the cleaning of the re-used product. But as the impact of the re-used product will only be the cleaning, it needs to be included. Therefore, the question is, if it must be included or excluded.
A2 Transport		Yes	
A3 Manufacturing		Yes	

Module	Process	Relevant for the case study	Critical Issue / uncertainty
A4 Transport (of final product)	Transport from manufacturer	Yes	The calculation of product transport from manufacturer or from the last storage is possible. But the knowledge of any other transport or intermediate storage and distribution impacts is very unlikely. The detailed tracking of each product would be needed. These impacts could be used on average data from producer statistics, but even this is very complicated.
	Transport of the construction equipement	Yes	The transport of the construction equipment will in this case include only scaffolding.
	Losses due to transportation	Yes	Impacts related to losses due to transportation need to be based on some statistics, which probably will bring more uncertainties into the assessment.
A5 Construction – installation process	Ground works and landscaping	Yes	-
	Storage of products	No	-
	On site transport	No	-
	Temporary works	No	-
	On site production and transformation	?	The on-site production and transformation of the product is a question in this case. For instance as the bricks need to be cleaned, should the cleaning be included in this module?
	Heating, cooling, ventilation etc,	Yes	Based on practical experiences and assumptions or simplified calculations if made in the design stage. Can bring uncertainties.
	Installation of products and ancillary materials	No	-
	On site water use	Yes	Based on practical experiences and assumptions or simplified calculations if made in the design stage. Can bring uncertainties.
	Waste management		Waste management impacts are considered minor in this scale, but their inclusion will be very complicated considering the data quality and availability. The cut-off rules should maybe be defined.

3.1.2 Use stages – B modules

Refurbishment is a term that describes a building intervention into a construction object. In the Czech Republic, it is not clearly defined where lies the line between building alternations, refurbishment or a new building which is reusing old constructions.

There is also possibility of building addition or on the other hand demolition of its part. It is impossible to predict these actions in the LCA model of a building. This brings a huge uncertainty into LCA model and scenarios that are used in it.

Another problematic issue is a possibility of future change of building use. This can have a large impact on its overall performance and the LCA assessment.

Table 2: Use stages of building assessment and definition of critical issues in assessment of particular processes.

Module	Process	Relevant for the case study	Critical Issue / uncertainty of / unpredictable change of
B1: Boundary of the installed products in use	Impacts and aspects arising from the normal (i.e. anticipated) conditions of use of components of the building	Yes	- Defined by standard CEN/TC 351 which has not been published yet (current status: drafting process).
B2: Boundary of maintenance	The production and transportation of the components and ancillary products used for maintenance	Yes	- Transportation distance, methods, effectivity and technology
	Cleaning processes in interior and exterior, processes for maintaining the functional and technical performance of the building fabric and technical systems	Yes	- Cleaning technology - Interior and exterior - Building adaptations - Building use - Technical systems
B3: Boundary for repair	Production of the repaired components	Yes	- Production of repaired parts
	Transportation of the repaired part	Yes	- Transportation distance, methods, effectivity and technology
	Waste management of the removed part	Yes	- Recyclation process - Legislative changes
	The end of life stage of the removed part	Yes	- Determination of operation life (durability) of particular components or the whole building

Module	Process	Relevant for the case study	Critical Issue / uncertainty of / unpredictable change of
B4: Boundary for replacement	Production of the replaced component	Yes	- Production technology of replaced components
	Transportation of the replaced components	Yes	- Transportation distance, methods, effectivity and technology
	Waste management of the removed components	Yes	- Recyclation process - Legislative changes
	The end of life stage of the removed component	Yes	- Determination of operation life (durability) of particular components or the whole building
B5: Boundary for refurbishment	Production of the new building components	Yes	- Production technology of changed components
	Transportation of the new building components	Yes	- Transportation distance, methods, effectivity and technology
	Construction as part of the refurbishment process	Yes	- Construction technology - Legislative changes
	Waste management of the refurbishment process	Yes	- Recyclation process - Legislative changes
	The end of life stage of replaced building components	Yes	- Determination of operation life (durability) of particular components or the whole building
B6: Boundary of the operational energy use	Energy used by building-integrated technical systems during the operation of the building	Yes	- Technical systems - Building use - Legislative and norms - Difference between calculated and real energy demand - Operational life of building - Technological and scientific progress
B3: Boundary of the operational water use	Operational water use	Yes	- Technical systems - Building use - Difference between calculated and water demand

3.1.3 End of life stages - C modules

“The end-of-life stage of a building starts when the building is decommissioned and is not intended to have any further use. At this point, the building’s demolition/deconstruction may be considered as a multi-output process that provides a source of materials, products and building elements that are to be discarded, recovered, recycled or reused” [2].

The building is decommissioned when it reaches its moral or technical service life. It can be very difficult to reach reasonable results in C modules as well as in D modules. Processes that are being described in this module happen in distant future (50 - 60 years) so it is very complicated to determine technologies and energy demands for their execution. Therefore it is necessary to come

out from presumptions and estimations and this fact has to be stated in the scenario of LCA.

C module describes also the way how processes connected to recycling or further reuse of materials should be involved in the assessment. Although the description is quite detailed it is not entirely clear. Correct interpretation of this process will be more and more important in the future because the tendencies aim rather to reuse and recycling than disposing materials to dumps.

Table 3: End of the life stages of building assessment and definition of critical in assessment of particular processes.

Module	Process	Relevant for the case study	Critical Issue / uncertainty of / unpredictable change of
C1: Boundary for the deconstruction	Processes on deconstruction site	Yes	- Deconstruction/demolition technology - Temporary buildings on site - All deconstruction processes after decommissioning - Primary on- site sorting
C2: Boundary for transport	Transportation connected to deconstruction process until the end-of-waste state is reached	Yes	- Transportation distance, methods, effectivity and technology - Amount of transported material
C3: Boundary for waste processing for reuse, recovery or recycling	Processes before the end of life cycle of a material or a product	Yes	- Problematic determination of point when a waste becomes a product intended to be reused
C4: Boundary for the disposal	Possible post-transportation treatment that is necessary before disposal	Yes	- Environmental loads resulting from final disposal of materials - Technology progress - Disposal methods

Table 4: Assessment of benefits and loads beyond the system boundary and definition of critical issues in assessment of particular processes.

Module	Process	Mandatory Assessment	Critical Issue / uncertainty of / unpredictable change of
D: Boundary for the benefits and loads beyond the system boundary	Environmental benefits or loads resulting from reuse, recycling and energy recovery	Yes	- Reuse / recycling methods may change in future

4. Conclusions

This study of problematic issues during creation of LCA model of a building is a beginning of a complex project of LCA assessment of existing building.

The results of this preliminary study show us several critical issues that influence the overall LCA result. The common feature of the critical issues is their **unpredictability in the future**. This unpredictability should be always taken into account when creating LCA scenarios and interpreting their results.

The major uncertainties that influence most of the modules and are hard to be predicted are following:
- Service life (moral and technical) of building and particular parts;
- Change of building use;
- Social and urban changes;
- Technological progress in transport methods, construction processes, ways of disposal, recycling etc.;
- Legal changes;
- Insufficient data on environmental performance of materials and building components.

The resulting LCA will always be accurate only within a certain **probability measure** which is hard to be determined as well because the number of possible development scenarios may be infinite.

Short Summary

This paper summarises the results of the recent research Methods and Concepts for Sustainable Renovation (MECOREN) carried out at VTT. The project aimed at creating new understanding about

- sustainable refurbishment concepts for residential buildings.
- environmental and economical impacts of alternative refurbishment concepts
- suitable methods for the environmental assessment of refurbishment concepts.

Alternative refurbishment concepts were studied on the level of the Finnish residential building stock. Different refurbishment concepts were compared by assessing the impact in terms of energy and greenhouse gases.

When assessing the greenhouse gases (GHGs) of buildings and the effect of refurbishment on GHGs, it is important to choose a right method with the help of which the emissions of energy are calculated. This is especially important when district heat and electricity are used as sources of energy.

The paper also assesses the significance of embodied environmental impacts in sustainable refurbishment projects. The environmental impact of renovation materials was compared to the saved environmental impact due to the energy saving achieved with the help of refurbishment. The demolition and building a new building was also considered as an alternative.

The assessment of the economical potentials of refurbishment concepts was carried for cases where an extensive refurbishment is needed for an out-dated building. However, also separately done refurbishment measures such as changes of windows, refurbishment of facades etc. should lead to a reasonable improvement of energy performance. The economical life cycle impacts of refurbishment depend on the investment cost and the reduction of energy consumption. However, a successful refurbishment also affects the resale value of the building. A significant increase in the value (market value) by means of extensive refurbishment can be achieved when the building is located in a relatively valuable neighbourhood and when the whole neighbourhood is renovated at the same time. Compensation can also be achieved by increasing the density of the area (with the help of extensions such as an additional storey or building).

Keywords: Sustainable renovation

1. Introduction

This paper presents the main results of the research project Methods and Concepts for sustainable Renovation (MECOREN) carried out at VTT in 2009–2012 (Häkkinen 2012). The overall research project was a Nordic collaboration. The project had the following research partners: VTT in Finland, SINTEF in Norway, SBI in Denmark and KTH in Sweden.

The paper analyses the impacts of alternative renovation scenarios on the Finnish building stock in terms of greenhouse gases (GHGs). The study focused on residential buildings. The calculations were carried out for years 2010, 2020 and 2030. In addition to the assessment of the renovation concepts of building stock, the objective of the paper is also to

- discuss and give recommendations about the use of environmental data for energy sources
- discuss and make conclusions about the significance of building materials in renovation projects from the view point of greenhouse gases and total energy use
- assess and make conclusions about the economic impacts of building renovation.

Information on total floor area of the Finnish housing stock was used as the basis for the analyses. The total floor area of the Finnish housing stock was first divided into age groups based on the available statistical information on residential housing stock.

In the next phase, the size and performance of buildings in different age groups were defined. The defined performance includes the types of structures, floor height and volume of a building, number of inhabitants, and heating energy, electricity and water consumption. These defined figures were then used as an input for creating exemplary buildings which were dealt with by the energy calculation program WinEtana.

By using the information of the exemplary buildings and the composition of the current housing stock, a theoretical maximum energy saving potential for the Finnish residential stock can be calculated. This was done by applying different energy saving measures to the exemplary buildings. The measures under study were: additional thermal insulation, replacement of windows, replacement of ventilation system and implementation of solar heating.

Based on the assessed energy savings, also savings in GHGs can be calculated. These calculations were based on energy production profiles in Finland.

The housing stock develops and changes over time. Thus the estimation of the current housing stock is not sufficient for estimating the situation in 2020 and 2030. New construction adds the floor area of the housing stock and obsolescence, deterioration and finally demolishment decreases it.

The degree of building degradation was taken into account, since energy renovations are often feasible only in the connection of other renovation. The study used an assumption that energy renovations are made only when the buildings would need renovation in any case.

2. Environmental profiles for electricity and district heat

In order to assess the environmental potential of different renovation concepts the environmental profiles for heat and electricity was calculated as an average value for 2004–2008.

The models built for the calculation of the average electricity supply and heat production include fuel extraction (heavy fuel oil, hard coal, natural gas extraction, greenhouse gas emissions from peat manufacturing), electricity and heat production both in electricity and combined heat and power (CHP) plants, net imports and transmission losses. The used allocation methods for CHP are energy allocation and benefit distribution. Due to lack of data, separate heat production is taken into account only for heavy fuel oil (78% of heat produced with oil is from separate production in 2008). Other fuels are mainly used in CHP plants (75–95% of heat produced in CHP) and the shares of separate production are smaller.

Table 1: LCA based environmental profiles for average Finnish electricity (considering net imports).

	Benefit		Energy	
	Electricity	**District heat**	**Electricity**	**District heat**
CO2 fossil, kg/MWh	309	236	222	273
CO2 biogenic, kg/MWh	121	134	67.5	160
CH4, kg/MWh	0.821	0,364	0.709	0,424
N2O, kg/MWh	0.000654	0.000397	0.000523	0.000448
GHG, kg/MWh	330	245	240	283

The GHGs of electricity produced in condensing power plant has been earlier assessed to be 966 g/kWh (Holopainen et al. 2010).

The newest prediction made by the Finnish Ministry of Employment and Economy was done in the connection of the new climate and energy strategy. On the basis of preliminary information and in accordance with the newest base scenario the predicted emissions for district heat and electricity are as follows:

Table 2: Predicted emissions for district heat and electricity

Characteristic emission, g CO2/kWh	**2010**	**2020**	**2030**
Electricity delivery	230	179	36
District heat	243	216	191

The base scenario takes into consideration the measures already decided such as feed tariff for electricity delivery, subsidies for renewable energy and nuclear power plants already received positive decisions in principle. The allocation of fuels in CHP district heat and electricity was done on the basis with energy method. The scenario also assumes that all electricity is produced in Finland in 2020 and 2030. The scenario considers the assumed decrease of energy demand for heating of buildings. This scenario takes into consideration the impact of energy performance regulations and the impact of changes in building stock (demolition of building and building of new buildings). In addition, the scenario assumes that the use of heat pumps is increased so that those contribute to 7 TWh of the use of primary energy. It also assumes that oil heated houses change the heating system and make use of ground heat pumps and the houses heated by electric air heat pumps.

3. Environmental impact of materials in building refurbishment

The objective of this part of the study was to assess the significance of building materials in building renovation in terms of GHGs. The environmental impact of renovation materials was compared to the saved environmental impact due to the energy saving achieved with the help of renovation. This study considers:

- Two refurbishment methods
- External insulation – with new additional insulation, new façade and roof
- Replacement renovation – with replaced and additional insulation and with a new façade of the same type
- Demolition level
- Partial demolition and renovation (cases M1 and M3) (see Table 4)
- Total demolition and new construction (cases M2 and M4) (see Table 4)
- Two refurbishment targets
- Low energy building structures,
- Passive energy building structures.

Environmental impact for renovation materials was based on VTT's database. The assessed operational energy (Table 3), the renovation cases (Table 4) and the assessed GHGs for the different cases (Table 5) are presented in the following tables.

Table 3: Operational energy for the studied case (existing multi-storey building, 29 apartments), for renovation and for new construction.

	Existing building	Renovation, Low energy envelope	Renovation, Passive structure envelope	New, Passive energy building
	MWh/a (kWh/m^2)	MWh/a (kWh/m^2)	MWh/a (kWh/m^2)	MWh (kWh/m^2)
Heating energy (district heating)	241 (130)	93 (50)	70 (38)	18 (10)
Service water heating	94 (51)	94 (51)	94 (51)	94 (51)
Electricity	82 (44)	55 (30)	55 (30)	55 (30)
Total	417	242	219	166

Table 4: Refurbishment cases for concrete multi-story building

Structure	Low energy structures		Passive energy structures		
	Case M1	Case M2	Case M3	Case M4	Case new
Demolition	–	Outer concrete layer	–	Outer concrete layer	Existing building
Exterior wall	W1 (3 layer rendering façade)	W2 (100 mm concrete with tile façade)	W1 (3 layer rendering façade)	W2 (100 mm concrete with tile façade)	concrete element with tile facade
Base floor	B1 (EPS + parquet)	B1 (EPS + parquet)	B1 (EPS + parquet)	B1 (EPS + parquet)	(EPS + parquet)
Roof	R1 (asphalt mastics cover)	R1 (asphalt mastics cover)	R1 (asphalt mastics cover	R1 (asphalt mastics cover)	asphalt mastics cover
Window	Quadruple pane window	Quadruple pane window	Quadruple pane window	Quadruple pane window	Quadruple pane window

These cases indicate that the increased material consumption because of refurbishment to the level of low-energy and passive-level structures causes an increase in GHGs but this is significantly lower compared to the saved GHGs because of saved operational energy.

4. Energy consumption of the current housing stock and energy saving potential

The heating energy use and electricity use were calculated for all residential buildings by using model buildings. An exemplary building was created to present each of the different age-type groups in the building stock as explained earlier (Section 1), and these model buildings were then used for calculating the energy consumption of the housing stock.

When buildings exit the housing stock, savings in heating energy and electricity consumption take place. This also results in a decrease in GHG emissions, assuming that the emissions for the different energy types remain unchanged over time. Buildings also undergo energy renovations, which decrease their energy consumption, and result in reduced GHG emissions. Finally, the heating method of buildings may be changed causing changes both in energy consumption and GHG emissions.

The results show the total energy consumption of the building stock, after all buildings in renovation need have been renovated with a certain renovation method. Results are for all residential buildings; the year of consideration is 2030.Table 6 shows that the assessed GHG saving potential of different renovation alternatives ranges from 3% (solar heat installation) to 27% (a combination of renovations). In addition to energy renovations, buildings may also undergo renovations related to their heating systems. The study focused on detached houses, since

changes in their heating systems are relatively easy to implement, and, for example conversions from electrical heating to geothermal heating has already become quite popular. Table 7 shows the assessment results for GHG emissions, if all the detached houses with electric heating and oil-heating changed their heating method by 2030.

Table 5: GHGs for a multi-storey building (operation period 50 years)

	Existing building, no renovations	Refurbishment to low energy building Case M1	Low energy building new construction Case M2	Refurbishment to passive structure Case M3	Refurbishment to passive structure Case M4	Passive structure building, New construction Case M New
Demolition			342		342	21 702

Roof		16 650	16 650	21 314	21 314	45 024
Partition floor						107 566
Window		9 776	9 776	9 776	9 776	9 776
TRP to site		237	857	268	889	7 066
Heating	2 533 770	979 879	979 879	736 359	736 359	185 472
Electricity	915 327	606 095	606 095	612 279	612 279	612 279
Hot water	991 475	991 475	991 475	**2,673,676**	991 475	991 116
Total	**4,440,572**	**2,625,874**		**2,398,452**	**2,446,578**	**2,260,151**
Total/m^2	**2,400**	**1,419**	**1,445**	**1,296**	**1,322**	**1,222**

Table 6: GHG-emissions of buildings, no-renovation scenario compared to scenarios where different energy renovation methods are applied.

	CO2-equ emissions from heating			CO2-equ emissions, electricity use			Total CO2-equ emissions		
	Total Mt	Saving Mt	Saving %	Total Mt	Saving Mt	Saving %	Total Mt	Saving Mt	Saving %
2030, no energy renovations	9.30	0	0%	2.00	0	0%	11.30	0	0%
Passive-level envelope	7.43	1.88	20%	2.00	0	0%	9.43	1.88	17%
Ventilation renovation	8.52	0.79	8%	2.07	-0.07	-3%	10.59	0.72	6%
Solar heat installation	8.96	0.35	4%	2.00	-0.01	0%	10.96	0.34	3%
Window renovation	8.78	0.52	6%	2.01	-0.01	0%	10.79	0.51	5%
Renovation combination	6.13	3.17	34%	2.07	-0.07	-4%	8.21	3.10	27%

Table 7: Effect of the assumed change in heating method on GHGs

	CO2-equ heating			CO2-equ electricity use			Total CO2-equ emissions		
	Total Mt	Saving Mt	Saving %	Total Mt	Saving Mt	Saving %	Total Mt	Saving Mt	Saving %
2030, no energy renovations	5.169	-	-	1.204	-	-	6.373	-	-
2030, electric heating changed to ground heating	3.721	1.448	28%	0.852	0.352	29%	4.573	1.800	28%
2030, oil heating changed to wood heating	2.718	2.451	47%	1.198	6	1%	3.916	2.457	39%
2030, electric heating changed to ground heating, and oil to wood heating	1.270	3.899	75%	0.845	0.359	30%	2.116	4.257	67%

The change in heating methods may not necessarily cause energy savings, but it may lead to significant GHG emission savings. If all the detached houses with electrical heating changed their heating method to ground heating, and all houses with oil-heating to wood heating, estimated GHG savings would equal to about 4.3 Mt, or 67%, compared to the baseline case.

5. Effect of calculation rules

As there is a rapid change in the assessed CO_2 values of electricity and district heat between the years 2010, 2020 and 2030, the possible consideration of this change in LCAs of buildings has a significant effect on final results. It is here recommended that especially when making building level and stock level life cycle assessments over 50 years' period, the assessed change in emission values should be considered. An example of the significance of the issue is given in the following.

When the GHGs because of total operational energy use during 50 were calculated (section 3) by using the emission values of 2010, the result is significantly bigger (1.99Mt CO_2e) than when the total GHGs are calculated considering the predicted change in the emission values of electricity and district heat (the assessed result falls to1.44 Mt CO_2e). Thus also the share of building materials from the total GHGs increases (in this example it increases from below 20% to roughly 25%). The share of materials in the latter case roughly equals to the combined share of heating and electricity while the heating of water is responsible for roughly 50% of the assessed GHGs.

However, when making building stock based analyses about the significance of renovation scenarios, it is also important to take into account, whether a particular decrease in the demand for delivered electricity is actually needed as a partial measure in order to make the change (decrease of GHGs) to happen. The ability of building sector to react to the challenge is an important prerequisite for Finland in order to be able to respond to the requirements of decreasing GHGs. The role of building sector is double in such a way that it is first important to decrease the GHGs of the building stock with help of improved energy performance and indirectly to enable the better power generation (in terms of GHGs) with the help of reduced demand for delivered electricity.

Section 4 shows assessment results for the final energy use and related GHG emissions of the Finnish residential building stock in 2020 and 2030. According to the results the total final energy demand in 2030 would be 29 TWh including 29 TWh for heating spaces and 9.2 TWh because of the use of electricity. This assessment takes into account the assessed outgoing share of the current stock and the share of buildings needing either light or thorough renovation during the coming years. It is also based on assumption that an effective combination of energy renovation measures would be done for those buildings that need thorough renovation. The share of electricity

from the assessed 29 TWh is 27% (7.8 TWh). However, the total use of electricity could be further decreased by roughly 4 TWh with help of ground heat pumps of detached houses. Assuming that the energy is produced with help of district heat and electricity and by using either 2010 values or predicted values for GHGs, we receive different results for the assessed impact of building stock in 2030:
The assessed GHGs of the existing building stock is 9.1 Mt by using the present values
The assessed GHG of the existing building stock s 4.7 by using the predicted values (2030)
If we further consider the assessed savings in demand for delivered electricity because of the change of attached houses from electrical heating to ground heat pumps, we receive the following results:
The assessed GHGs of the existing building stock is 8.1 Mt by using the present values
The assessed GHG of the existing building stock in 2030 is 4.5 by using the predicted values.

6. Economical assessment of renovation concepts

The potentials to remarkably and economically improve the energy performance of buildings are linked to the cases where an extensive renovation is needed for an out-dated building. However, also separately done changes of windows, refurbishment of facades etc. should lead to a reasonable improvement of energy performance. On the basis of the study, the life cycle impacts of successful renovation concepts can be summarized as follows:

- significant reduction of energy consumption and related GHGs
- reasonable increase of investment cost
- reasonable savings in life cycle costs
- increase of resale value.

The most significant increase in economic value (market value) with the help of extensive renovation can be achieved when the building or the block of buildings is located in a relatively valuable neighbourhood and when the whole neighbourhood is renovated at the same time. In these cases the costs of renovation can be compensated with the help of the increase of market value. This can also be realised by increasing the density of the area. Effects on economic values of houses and buildings and departments may sometimes be significant because of improved performance and because of aesthetical improvement.

The economic and environmental impact of the renovation of certain building types and groups was also assessed. The assessment was done for detached buildings from 1940–1959, detached buildings from 1980–1989 and for residential blocks of flats from 1960–1069 and 1970–1979. These groups of building were selected because of their big share from the whole building stock. Alternative renovation concepts were as follows: Renovated with 100mm thermal insulation, Renovated with 100mm thermal insulation and ventilation renovation, Renovated with passive level envelope, Renovated with a combination of renovations. On the basis of economical assessment results the following recommendations are given:
All studied alternative energy saving methods are favourable in the case of detached houses from 1940-1959 as the effect of the improved insulation of envelope is very high. Also almost net zero energy level may be achieved in an economical way when connected to an extensive renovation and when there is a need to improve the quality of indoor climate.
In the case of relatively new detached houses (1980-1989), almost net zero energy target is the most economical when there is a need for extensive renovation and need to improve the quality of indoor climate.
In the case of detached houses the target of almost net zero energy building is recommended while in the case of residential blocks of flats passive level envelope and possible renewal of ventilations are the most economical when there is a need for extensive renovation and need to improve the quality of indoor climate.
The economic impact studies were also made regarding the whole existing building stock. In the case of required renovations it was assumed that 75% of all buildings which need thorough renovations shall be renovated with 100mm additional thermal insulation and 25% of them with 100mm thermal insulation and ventilation renovation. The total volumes, cost savings, investment costs, needed annual support and labour effects of renovation concepts in the whole residential building stock in Finland were assessed to be as follows:

Table 8: The assessed total volumes, cost savings, investment costs, needed annual support and labour effects of renovation concepts in the whole residential building stock in Finland

Whole residential building stock Total area 266 000 mill. m^2 (2010), renovated area 140 000 m^2 by 2030.	**Renovated area in year mill. m^2/y**	**Corresponding annual heating cost savings in average mill. €/y**	**Corresponding extra investment costs mill. €/y**	**Annual need for public support (10-15% of investment) mill. €/y**	**Labour effects Person years/y**
Renovated totally with required energy savings	7.0	-45	+650	65 100	9 000
Renovated totally by new ventilation and passive level envelope	7.0	-70	+1 350	150 200	17 000
Renovated totally to almost net zero energy buildings	7.0	-140	+2 750	270 400	31 000
Renovated 50% by new ventilation and passive level envelope and 50% to almost net zero energy buildings	7.0	-105	+2 050	150 200	26 000

Short Summary

The aim of the paper is to evaluate the efficiency in retrofitting the built asset in order to choose the most sustainable strategies. Generally, this topic has not been afforded in a building life cycle prospective [1,2] and only few authors faced the problem in a systematic way [3,4]. Nowadays, although new European Standards are under publication, a method to assess the environmental impacts (LCA) and economical costs (LCC) from renovations and refurbishments activities along the service life of a building still needs to be developed [5,6]. From these considerations, this work aims to give a contribution in defining a practical LCA and LCC-based method applied to a specific case study.
A multi-storey residential building located in Northern Italy was analysed in order to evaluate different renovation alternatives. This reference building has a very high refurbishment potential: indeed, it has quite low energy efficiency (despite connected to a high efficiency district heating system), an insufficient robustness against actual seismic standards and a very poor acoustic insulation.
The approach here adopted is based on the evaluation of a wide range of possible refurbishment alternatives. Then, an optimization matrix was developed combining the optimal elementary activities and defining a mix of beneficial renovation actions: substitution of external windows, increase in envelope insulation, etc. Improvements of the heating system efficiency were not taken into account among the alternatives. Finally, the most sustainable renovation alternative (Option B) was identified and compared to a second scenario (Option A): full demolition and reconstruction of a new building with the same volume, but a primary energy consumption for heating of 13.92 kWh/m^2-year.
The results clearly point out that Option B is the most sustainable choice, both in terms of energy and GHG saving as well as economical costs reduction. The demolition activity, both in terms of environmental impacts and economic costs, does not significantly affect the results.

Keywords: Renovation; Housing; Sustainability; LCA; LCC; Retrofitting; Carbon Footprint.

1. Introduction

During the Italian economic boom of 50s-70s sustainability and end of life scenario were not taken into account in the building sector. In the following years a social and environmental conscience on sustainability and refurbishment has spread among the stakeholders.
A research carried out by Cresme (Center for Economic, Social Market and Construction Research) in the 90s stated that, in the last years, 55% of the building stock has been

affected by maintenance and refurbishment activities, unlike what was happening in 60s-70s when new buildings amounted to 70-80% of all construction works. Nowadays, the trend towards the quest of technical solutions aiming at a sustainable development with a look at future generations is a growing phenomenon.
In the building sector, resources exploitation, energy consumption and harmful gas emissions have to be taken into account and cannot be neglected in order to obtain an improvement in energy and environmental efficiency.
ENEA (Italian National Agency for New Technologies, Energy and Economic Sustainable Development) stated that energy exploited for domestic hot water and heating in Italian residential buildings is about 30% of national energy consumptions and is the cause of 25% of national carbon dioxide emissions. To restrain this growth, refurbishment strategies have to be studied alongside the research of recyclable and sustainable materials.
As European environmental policies aim to reduce energy consumptions and environmental impacts (Blengini et al [8]), Italian standards look at energy strategies, from national to local scale, with a perspective mainly addressing, through direct and indirect statements, the decrease of operational primary energy (and focusing more specifically on heating).
Thomsen et al. [9] consider the good potential of building refurbishment strategies thanks to the environmental sustainability and energy efficiency that could be reached, as stated in Kyoto protocol, compared to the resource exploitation involved in a demolition. These refurbishment activities concern adaptation to standards, environmental sustainability, envelope energy efficiency and improvement of usability and building quality.
On the basis of these issues, an economical and environmental analysis has been carried out (LCC and LCA) on a case study to compare a building energy refurbishment and a complete demolition followed by a new building reconstruction. The case study is a social housing linear building in Brescia, Italy.
From the merely environmental point of view a refurbishment prevents the soil consumption, the energy exploitation to produce new materials and the economical and energy costs if compared to demolition and new building construction (Schultmann et al. [10]).
The analysis has underlined the economic and environmental advantages both of refurbishment and demolition plus new construction in a scenario in which building energy efficiency and operational performances and consumption have been improved.

2. Methodology

2.1 System boundaries and functional unit

The aim of the research is to compare two building refurbishment strategies, through an LCC and LCA, and to identify the one that gives the greatest economical and environmental advantages.
Building service life is an important parameter to evaluate life cycle impacts (ISO 15686 [24]). A 50-year service life has been taken into account, agreeing with Itard et al. [11], to make a comparison between demolition plus new construction (Option A) and refurbishment (Option B) activities.
Option A consists of, in the present case study, building demolition and subsequent construction of a more efficient building, comprising its operational phase in the service life. The evaluated steps, following UNI 15978 [12], are:

- "END OF LIFE" (C 1-4): end of life of materials, components and technological plans of the building;
- "BENEFITS AND LOADS BEYOND THE SYSTEM BOUNDARY" (D): materials' recycling, such as steel and mixed waste from demolition. Allocation methods are not considered because the avoided impacts have been already taken into account and the construction of the existing building is not included within the boundaries of the system [13];

- "PRODUCT" and "COSTRUCTION PROCESS" (A 1-5): construction of the new building, including the site's management in terms of electric energy and machinery's fuel consumptions;
- "USE" (B1-B6): consumption for heating, domestic hot water, gas for eating and electric energy during the building's service life. Maintenance (B2) and requalification-recoveries (B3-5) phases have been neglected because they are the same either for Option A and Option B, so, for the sake of comparison, they don't affect the results. Moreover, maintenance can be considered independent from technology solution, excluding the surface finishes, which are the same in both Options analyzed.

Option B comprises only some energy refurbishments:

- "USE" (B1-B6-B5): implementation of energy performances and evaluation of the consumptions for heating, domestic hot water, gas for eating and electric energy during the building's service life. Maintenance (B2) and repair (B3-B4) phases have been neglected as in Option A.

In Option B "END OF LIFE" phase (C 1-4) has been neglected because information about the sequence of activities for dismantling and recycling or for disposal of construction and demolition waste [8] are difficult to foreseen and are subjected to great variability due to the hand work and to the complexity of disposal system.
Moreover, the study of Option B is focused only on energy refurbishment, neglecting the benefits that could be generated from acoustic insulation, anti-seismic features or architectural upgrading.
The functional unit considered for LCA and LCC is 1 m^2 of living area, to compare the obtained values with similar analysis [13-16] either in performances and in service life.

2.2 Impacts and database

The environmental impact indicators considered for the analysis are the Cumulative Energy Demand (CED) and the CO_{2eq} emissions into the air.
Only non-renewable CED is considered, because the renewable CED is negligible.
The emissions of CO_{2eq} have been divided in different contributions, according to ISO 14067 [17] and PAS 2050: 2011 [12].
Amounts of materials are primary data relative to the case study, while materials production and other processes are secondary data taken from Ecoinvent 2.0 database and calculations performed with Simapro 7.3.3 Software.
Besides, in the economical analysis only the technical costs of the building operations have been taken into account and the overheads, the charges related to safety, business profits, VAT and the increasing of price of money during the life cycle have been neglected.
The unitary costs evaluation has been conducted according to Italian building price list [19], considering material costs and not finished works.
Some Italian building companies have provided primary data both for environmental impacts and for costs of some activities, such as demolition works or insulation addictions.

3. Case Study

The building case study is located in the Casazza neighbourhood of Brescia (Italy) and was built in the 60-70s. The six-storey building, with also an underground floor, has a rectangular plan and the main orientation follows the axis NE-SW.

IDENTIFICATIONE OF TIME	Contemporary (1964-1975)
CONSTRUCTION MATERIALS	Brick-Cement
TYPE OF CONSTRUCTION	Beams and columns
BASEMENT DIMENTIONS	11m x 42m
TOTAL ELEVATION	22,5 m
GROSS VOLUME	12781 m^3
TOTAL NET AREA (usable)	2046 m^2
PERIMETER WALLS	2296 m^2
ROOF	400 m^2
FRAMES EXTERNAL	351 m^2

Figure 1: Characteristics of the building case study.

The building has a concrete frame, brick walls and a sloped bitumen waterproof covering, with fiber-cement slabs. The windows frame is in PVC and has PVC shutters not isolated.
From the decay analysis, the envelope doesn't seem to have particular problems. In this way, both a complete demolition of the building (Option A) and an energy envelope refurbishment (Option B) could be supposed. The demolition with the hypothesis of a new construction would have the goal of improving thermal, acoustic, seismic performances as well as obtaining a better architectural shape also in terms of flexibility with a wide variety of flat layouts.
The building is served by district heating, used exclusively for heating, while domestic hot water is produced by electric water heaters located in every apartment.
An energy analysis was done to evaluate the existing building's consumption, following the Lombardy Region calculation procedure (DDG 5796 of 11th of June 2009 and UNI-TS 11300): the primary energy need is 169 kWh/m²-year.
Gas consumptions for eating have been chosen on the basis of a "mean family" composition (4 people in each flat).
Finally, yearly electric energy consumption for the "mean family" was evaluated, using a tool suggested by ENEA and the city of Bologna [20] (*Table 1*).

Table 1: COSTS, CO_{2eq} and CED of the existing building (50-year service life).

STEP	COSTS	IMPACTS	
	COSTS [€/m^2]	GWP [kg CO_{2eq}/m^2]	CED [MJ/m^2]
USE Heating	515	1.457	25.450
USE Domestic Hot Water	309	798	12.026
USE Gas Kitchen	68	22	2.450
USE Eletricity	421	1.065	16.400
TOTAL	**1.883**	**3.158**	**44.961**

4. Inventory analysis

Option A, i.e demolition and new construction with better performances, provides an evaluation of end-of-life scenario. The most suitable demolition technique used for the operation is the use of excavators equipped with tongs and shears (De Angelis et al [24]).
Demolition plays the highest contribution in terms of economic costs, whereas waste disposal is crucial for environmental impacts because of the length of treatment processes. To cut down on environmental and economic impacts connected to waste treatment, an in-situ treatment of mixed construction wastes (CER 17.09.04, waste type classification according to the inventory introduced by European Directive n. 2000/532/CE) has been evaluated instead of landfill disposal. This kind of in-situ C&D waste processing produces secondary raw materials using a mobile press. With this machine gravel is obtained and the impacts, which would be generated from the extraction of raw material from the pit, are avoided (De Angelis et al [24]).
The new building has a wooden structure because the aim of the analysis is to focus on innovative systems. This new building has the same living area of the existing building and better energy performances, with a primary energy need of 13,92 kWh/m^2-year. Heating pumps are used both for heating and for domestic hot water, but their construction costs and the corresponding environmental impacts have been neglected. Thanks to 26 m^2 of solar

panels, 60% of domestic hot water request has been ensured, reducing heating pumps electricity consumption.
Gas and electric energy consumptions are evaluated following the same procedure adopted in the existing building, obviously considering a better efficiency.
In *Table 2* the three steps of Option A scenery are summarized.

Table 2: COSTS, CO_{2eq} and CED of Option A (demolition plus new construction) over a 50-year service life.

STEP	COSTS	IMPACTS	
	COSTS [€/m²]	GWP [kg CO_{2eq}/m²]	CED [MJ/m²]
DEMOLITION	116	21	817
CONSTRUCTION	1.090	962	13.087
USE Heating	62	161	2.429
USE Domestic Hot Water	128	331	4.990
USE Gas Kitchen	68	22	2.450
USE Eletricity	347	878	13.526
TOTAL	**1.811**	**2.375**	**37.299**

From the economic point of view, construction costs are higher than the ones of operational phase. The operational phase of the new construction has a lower cost because the primary energy needs are reduced thanks to the higher envelope performances. Operational electric energy consumptions play an important role in GWP and CED impacts. Demolition phase is only responsible of 6% of the total economic costs and of 1% of the environmental impacts; the operational phase is the crucial phase of the building life cycle, as proved by Adalberth et al. [15].
Option B consists in an envelope energy refurbishment aiming at obtaining a reduction of building life cycle consumptions. Some basic activities on envelope have been studied from the economic and the environmental point of view, varying the insulation thickness and the kind of insulation material.

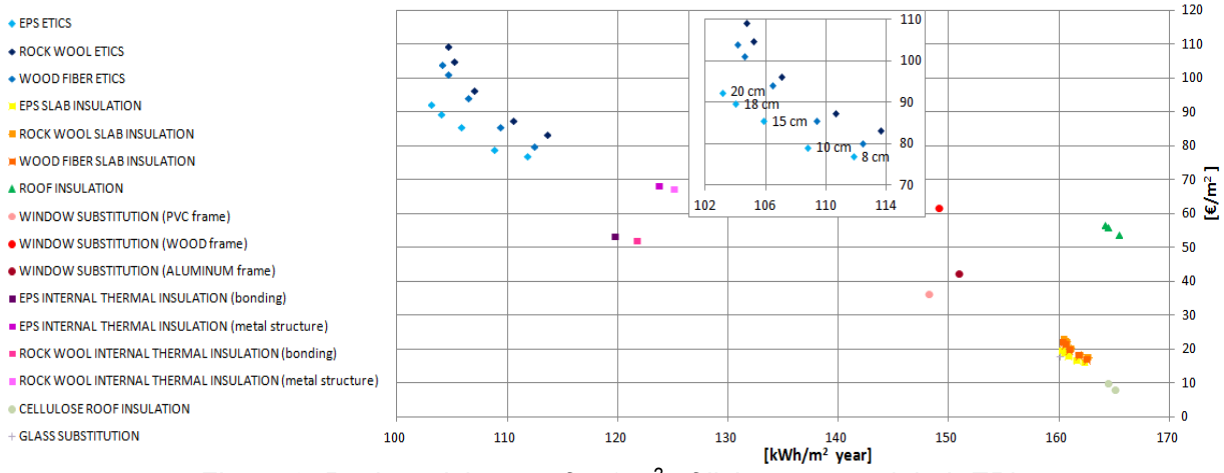

Figure 2: Basic activity cost for 1 m^2 of living area and their EPh.

The basic activities analyzed are:

- External Thermal Insulation Composite System (ETICS), in EPS, or rock wool, or wood fiber, with a thickness of 8 cm, 10 cm, 15 cm, 18 cm and 20 cm;
- Slab insulation, in EPS, or rock wool, or wood fiber, with a thickness of 8 cm, 10 cm, 15 cm, 18 cm and 20 cm;
- Roof insulation, providing the demolition of existing sloped covering and insulating with loose fill cellulose, with a thickness of 15 cm or 20 cm, or with XPS, with a thickness of 10 cm, 16 cm e 18 cm;

- Window substitution, providing a frame in PVC, wood or aluminum and a low-e glass 4-16-4 filled with argon. Glass substitution is also analyzed separately because the existing frame maintain good thermal performances;
- Internal thermal insulation, in EPS or rock wool and plasterboard, varying construction technology (metal structure or bonding).

These basic activities can be applied to other buildings with similar technology. In *Figure 2* primary energy consumptions considering each basic activity are associated to the cost over the life cycle for 1 m^2 of living area in order to identify the optimal energy and economical solution.

The basic activities were combined to find the best set of interventions able to guarantee environmental, economic and energy savings. Moreover, the choice among the basic activities has been done considering those that would have created to inhabitants the less discomfort as possible, so focusing on external interventions. Therefore, internal walls thermal insulation has been avoided.

Furthermore, slab or roof insulation interventions are not able to guarantee an important EPh improvement either varying thickness or material (*Figure 2*). However, in roof insulation a great environmental and economic contribution is given by roof demolition processes that could be otherwise avoided if loose fill cellulosic insulation was used.

From the economic point of view the optimal solution resides in a combination of those basic activities which use the least amount of materials as possible. In addition, aiming at an energy refurbishment, the savings achievable decreasing EPh needs have to be taken into account.

Summing up the construction processes relative to the basic activities and the operational consumption over 50 years is easy to find out the best group of choices that could lead to the optimal economic and environmental refurbishment.

EPh values have been calculated multiplying the energy needs by a coefficient 0.85 to consider the technological plants. Building real energy consumptions have been obtained considering 70% of EPh calculated.

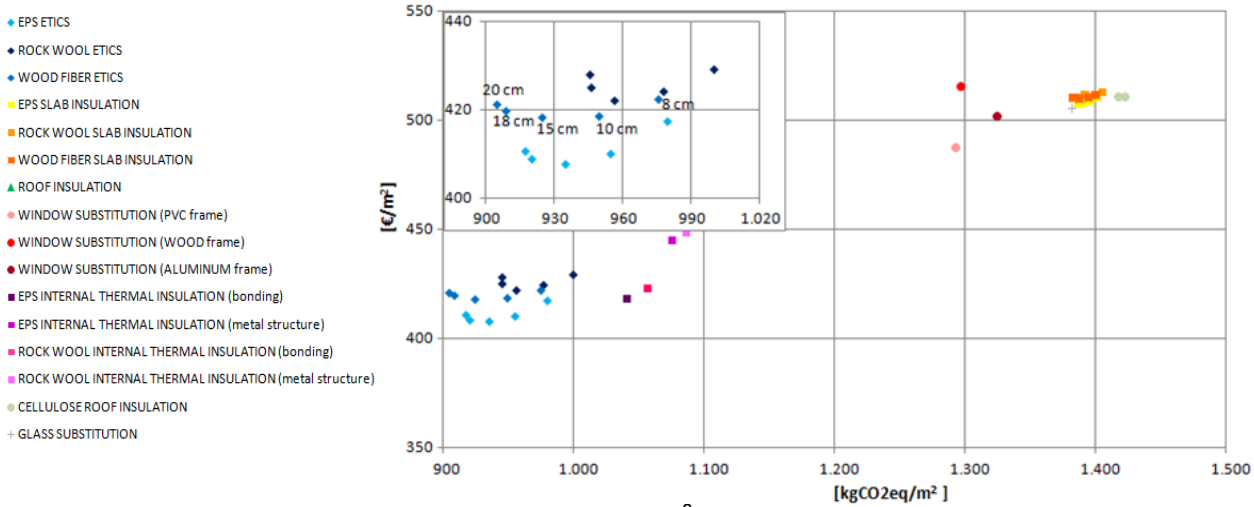

Figure 3: Basic activity cost and their CO_{2eq} for 1 m^2 of living area over a 50-year service life.

In *Figure 3* basic activity cost and their CO_{2eq} for 1 m^2 of living area over a 50-year service life is shown; the same trend is obtained with CED (MJ/m^2), with values ranging from 16'000 to 25'000 MJ/m^2. Heating economic savings with an insulation thickness higher than 15 cm and considering both construction and operational phase are very low. A higher insulation thickness will be an economic loss if compared with the energy savings that could be obtained.

Roof insulation with 20 cm-thick loose fill cellulose the cheapest and the most suitable activity that could be applied. Window substitution involves high costs, but relatively scarce EPh and environmental impacts optimization, even using different materials for the frame.

Anyway, a PVC frame with low-e glasses filled with argon seems to be the most suitable option.
Some combinations of basic activities have been studied in order to find out the mix that is able to guarantee the best economic, energy and environmental performances.
Five combinations have been analyzed and for each of them EPh value of the whole refurbishment has been evaluated *(Table 3)*. These combinations include the activity with the highest, the medium and the lowest performance among the basic activities.
On the basis of the EPh consumptions calculated, the total energy consumptions and environmental impacts over 50-year service life have been assessed. These operational values were added to those of the construction phase.
The basic activities mixes to reach best ratio between performances and costs are summarized in *Table 3.*

Table 3: COSTS, CO_{2eq} *and* CED *of the basic activity combinations over a 50-year service life.*

COMBINATION 1 - EPH 60 kWh/m²-year (EPS ETICS 8cm + CELLULOSE ROOF INSULATION 15 cm + GLASS SUBSTITUTION)	**COSTS [€/m²]**	**GWP [kgCO_{2eq}/m²]**	**CED [MJ/m²]**

TOTAL	**895**	**1.617**	**34.537**
COMBINATION 2 - EPH 49,6 kWh/m²-year (EPS ETICS 10 cm + XPS ROOF INSULATION 16 cm + WINDOW SUBSTITUTION PVC)	**COSTS [€/m²]**	**GWP [kgCO_{2eq}/m²]**	**CED [MJ/m²]**
CONSTRUCTION	212	49	1.015
USE	712	1.517	32.697
TOTAL	**924**	**1.566**	**33.702**
COMBINATION 3 - EPH 48,5 kWh/m²-year (EPS ETICS 15 cm + XPS ROOF INSULATION 18 cm + WINDOW SUBSTITUTION PVC)	**COSTS [€/m²]**	**GWP [kgCO_{2eq}/m²]**	**CED [MJ/m²]**
CONSTRUCTION	219	60	1.228
USE	709	1.509	32.546
TOTAL	**928**	**1.569**	**33.774**
COMBINATION 4 - EPH 34,2 kWh/m²-year (EPS ETICS 15 cm + CELLULOSE ROOF INSULATION 20 cm + WINDOW SUBSTITUTION PVC)	**COSTS [€/m²]**	**GWP [kgCO_{2eq}/m²]**	**CED [MJ/m²]**
CONSTRUCTION	188	46	958
USE	672	1.404	30.717
TOTAL	**860**	**1.450**	**31.675**
COMBINATION 5 - EPH 31,6 kWh/m²-year (EPS ETICS 20 cm + ROOF XPS 18 cm + WINDOW SUBSTITUTION PVC)	**COSTS [€/m²]**	**GWP [kgCO_{2eq}/m²]**	**CED [MJ/m²]**
CONSTRUCTION	228	68	1.416
USE	665	1.385	30.385
TOTAL	**893**	**1.453**	**31.801**

The best basic activities mix used in Option B is:

- ETICS in EPS with a thickness of 15 cm;
- Slab insulation in EPS with a thickness of 15 cm;
- Roof insulation with loose fill cellulose with a thickness of 20 cm;
- Window substitution with a frame in PVC and low-e glasses 4-16-4 filled with argon.

Table 4: COSTS, CO_{2eq} and CED of Option B (refurbishment of existing building) over a 50-year service life.

STEP	**COSTS**	**IMPACTS**	
	COSTS [€/m²]	**GWP [kg CO_{2eq}/m²]**	**CED [MJ/m²]**
REFURBISHMENT	188	46	958
USE Heating	89	250	4.374
USE Domestic Hot Water	93	67	7.493
USE Gas Kitchen	68	22	2.450
USE Eletricity	421	1.065	16.400
TOTAL	**860**	**1.450**	**31.675**

Table 4 shows the life cycle costs and impacts of Option B over 50 years after envelope refurbishment. Domestic hot water boilers have been replaced because the existing ones were obsolete. In each apartment a condensing boiler has been installed, neglecting the environmental impacts generated by their construction. In Option B operational phase is predominant on construction both from the economic and environmental point of view.

5. Results

The comparison between Option A (demolition plus new construction) and Option B (refurbishment) has been developed focusing on economic costs, which affect primarily customers requirements, and environmental impacts, evaluating CO_{2eq} emissions and CED. In *Table 5* costs and environmental impacts are shown.

Table 5: Option A and Option B comparison: COSTS, CO_{2eq} *and* CED over a 50-year service life.

OPTION A			
STEP	COSTS	IMPACTS	
	COSTS [€/m²]	GWP [kg CO_{2eq}/m²]	CED [MJ/m²]
DEMOLITION	116	21	817
CONSTRUCTION	1.090	962	13.087
USE	605	1.392	23.395
TOTAL	**1.811**	**2.375**	**37.299**

OPTION B			
STEP	COSTS	IMPACTS	
	COSTS [€/m²]	GWP [kg CO_{2eq}/m²]	CED [MJ/m²]
REFURBISHMENT	188	46	958
USE	672	1.404	30.717
TOTAL	**860**	**1.450**	**31.675**

Demolition plus new construction (Option A) leads to higher life cycle costs than building refurbishment activities (Option B); if only environmental aspects are considered, this gap is significantly reduced: CED values are really similar. Building envelope refurbishment seems to be the cheapest and the most environmentally friendly activity that could be faced on existing building that need recovery. This refurbishment aims at improving energy performances, decreasing operational consumptions, which are the cause of the highest impacts over the entire building life cycle.
The energy refurbishment studied involves exclusively envelope, neglecting comfort and other performances that could be reached with a new construction. Acoustic performances, seismic behavior and internal flat flexibility guaranteed in a new construction give a further comfort value to inhabitants and cannot be compared with the intervention activities applied in Option B. If, besides energy, these other aspects were analyzed in Option B, maybe the results would be sensibly different. However, among others, operational phase with its heating, domestic hot water, gas and electric energy consumptions are always the main responsible of environmental emissions.

6. Conclusions

Existing building recovery could lead to the choice between energy refurbishment and complete demolition followed by new construction with better performances. These aspects, however, do not consider architectural value or restraints of the existing building.
A new construction assures better performances from the point of view of acoustic and seismic behavior, or internal flexibility and variability of flat layout.
In the Brescia case study analyzed, as confirmed by other studies, i.e. Sartori et al. [21], operational phase is the most impacting phase over a building life cycle, either economically and environmentally. The envelope insulation is one of the easier refurbishment activities on existing building that could assure the decrease of energy consumptions. In this case, the performances that could be attained will never be the same as the ones achievable in a new construction, but significant savings can be obtained upon decreasing heating needs in operational phase.

Life cycle phases other than the operational one can contribute as well to reduce economic and environmental impacts. For instance, the materials choice can strongly influence the final outcomes either positively, especially if recyclable or reusable [8], or negatively, is assembled not carefully (for instance, thermal bridges can lead to an enormous increase in energy needs). In Option A it is the new construction that most contributes to the environmental impacts, while demolition is almost negligible (about 1%). Envelope refurbishment only (Option B) is certainly more advantageous than new construction, at least in terms of energy and money saving as well as of CO2eq emissions reduction.
In conclusion, on existing buildings that still save good architectural and structural characteristics, energy refurbishment seems to be the most suitable and cheapest solution, both from an economic and environmental point of view. Anyway, a careful economic and environmental assessment on the existing building stock has always to be done before acting on it, in order to select the most appropriate intervention solution.

Short Summary

This paper describes the results and conclusions from an LCC and LCA analysis performed on a case study. An actual deep energetic renovation example in Torhout, Belgium was studied on its cost efficiency and environmental impact, comparing it to different other renovation scenarios: standard renovation – in which measures were applied to obtain an energy consumption level similar to the minimal energy requirement (EPB) for new houses and NZE or Nearly Zero Energy renovation, where the as built (or as renovated) situation was used as starting point and additional renewable energy systems were installed to strive to zero energy consumption. This allows on the one hand to verify which scenario is the most interesting in terms of costs and environmental impact, and on the other hand to gain insight in the feasibility of obtaining a NZE level in renovation of houses.

Keywords: Deep Renovation; NZE; Life cycle assessment (LCA); Life cycle costing (LCC)

1. Introduction

In the renovation of single houses the ambitions on energy savings grow, as in the whole building market. The ERACOBUILD One Stop Shop project [1] was aimed to create a larger market for deep renovation of houses and investigated ways to motivate clients to do an integral holistic retrofit. In general, the motivation and reasons for renovating a house are related to comfort improvement, quality of living and the necessity of certain replacements and improvements, and is less about energy savings and cost benefits [2]. Nevertheless, the budget and long term perspectives (return on investment) are important parameters in the decision process in many projects. In a broader frame, also environmental issues gain importance.

Within One Stop Shop several existing ambitious renovation projects ('low energy' or 'passive house') were analyzed on their cost efficiency and environmental impact. The main question was 'how far to go in the energetic renovation in order to be beneficial?'. Next to the costs and environmental loads of the 'as built' project over 30 and 60 years, the costs and impacts of other renovation scenarios with different ambition levels were compared: On the low end, a 'Standard Renovation' is considered, defined as an integral retrofit, but with limited efforts (measures to save energy, comparable to current new building standards in Flanders, Belgium). On the high end, the feasibility to obtain a Nearly Zero Energy (NZE) building by applying additional measures to the *as built* situation is investigated.
In this research, the NZE-level was defined based on the considerations from a BPIE report [3], with (1) a very low primary energy consumption in kWh/m²a on a yearly basis including heating, cooling, ventilation, lighting and aid energy, using nationally defined conversion factors, and (2) renewable energy production on-site, nearby and off-site, where 50-90% of the energy demand is

covered by renewable energy. This definition was translated in practice by 'getting as near to zero energy consumption as possible within the project's site boundary' for the projects under study.

2. Case study

2.1 As built (post renovation) situation

Fig. 1: Retrofit of 2 row houses from the 1970s. Before (left) and after (right) © Benergie.be – Architect L. Dedeyne

Architect Luc Dedeyne renovated and transformed two neighbouring houses, dating from the early 1970s, into a single family house with private practice. As *Fig. 1* shows, one of the goals of the architect was to achieve an 'architectural' façade with all elements (doors, windows, façade finishing) within the same vertical plane. The most important measures in the actual renovation are:

- Replacement of the floor slab on the ground floor and installation 15 cm EPS insulation;
- Replacement of the roof and installation of 32 cm additional mineral wool;
- Renovation of the street façade by demolishing the external part of the cavity wall and installing 24cm of cellular glass with a ceramic materials as finishing layer;
- Replacement of old windows by triple glazed aluminium windows;
- Addition of Vacuum Insulation Panels (VIP) to the aluminium doors and garage door;
- Installation of a large (25m²) solar boiler, floor heating, heat pump and PV-installation (3.4 kWp).

2.2 Considered alternative scenarios

The as built 'Low Energy' renovation with a Heat Pump (coded **LE-HP**) as energy source for heating & hot water is compared to several alternative scenarios:

- A case where the same measures for the envelope were taken, but a condensing boiler on natural gas is used for heating & hot water (**LE-CB**)
- Based on the LE-HP scenario, additional PV panels and a larger solar boiler are added, in order to obtain the **NZE-HP** alternative – this is the most ambitious scenario, striving for Nearly Zero Energy consumption.
- A Standard Renovation scenario is defined, based on minimalistic insulation measures and a condensing boiler (on natural gas) system, coded **SR-CB**. Attention was paid that the same degree and type of façade finishing are kept, in order to be able to compare the costs for the different scenarios.

A summary of the measures in each scenario are given in *Table 1*.

	SR-CB	LE-CB	LE-HP	NZE-HP
Roof	20 cm mineral wool between existing battens	2x16 cm mineral wool on top of existing roof structure (16 cm MW)		
Walls	External insulation: 12 cm cellular glass & glued ceramic tiles	Demolition of external cavity wall, 2x12 cm cellular glass & glued ceramic tiles		
Floor	6 cm sprayed PU foam	15 cm EPS		
Doors & gates	Alu with PU-core	Alu with VIP-core		
Windows	Alu with 1.1 glass	Alu with triple glazing		
Thermal bridges	Not remediated	All solved		
Heating & hot water production	Condensing boiler on natural gas + radiators & floor heating		Heat pump (water/air) + radiators (LT) & underfloor heating	
Solar boiler	/	5 m²	5 m²	25 m²
PV panels	0.9 kWp	0.9 kWp	0.9 kWp	3.4 kWp
Ventilation	Natural ventilation	Mechanical ventilation + heat recovery (system D)		
Air tightn. (v50)	7	2		

3. Cost efficiency

3.1 Methodological approach

The cost efficiency evaluation of the different renovation scenarios considers the relevant life cycle costs over a period of 30 years. The investment costs are based on the real costs documented by the architect and include 6% VAT. Cost data for alternative solutions was obtained from similar projects and reference books, and include all relevant works to the envelope and the technical systems.
The Flemish EPB-software was used to determine a typical energy consumption. This software gives a characteristic value of the primary energy consumption for heating, cooling, hot water production and aid energy. The effects of air tightness and thermal bridges are taken into account. No cooling energy was considered, given that no real overheating risk was present. The same energy consumption data is used for the cost as for the environmental analysis.
For the economic analysis, a cost of 0.2 €/kWh for electricity and 0.08 €/kWh for natural are assumed. A yearly increase of prices of 2.25% is considered.
Maintenance & replacement costs are included, mainly for the technical systems, since these require the most annual maintenance and have a service life shorter than 30 years, and thus will need to be replaced.
The influence of financial incentives is taken into account, but in a way that allows the analysis to be done with or without the influence of subsidies. The subsidy mechanisms available in Flanders on April 1st 2012 are taken into consideration.

3.2 Investment cost

Fig. 2 shows the investment cost for the considered alternatives. The cost for the walls is very significant, because of the special solution chosen (cellular glass & glued ceramic tiles) and the bad condition of the bearing wall when the outer façade wall was demolished, which needed considerable reparation and preparation works.

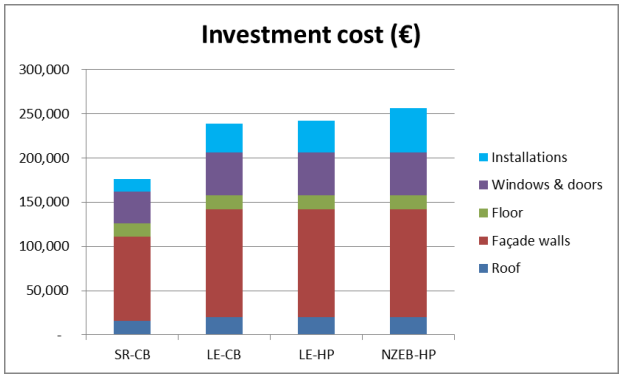

Fig. 2: Investment cost of different renovation scenarios investigated (SR=Standard Renovation, LE= Low Energy Renovation, NZEB = Nearly Zero Energy Building Renovation, CB = Condensing Boiler on Gas, HP = Heat Pump)

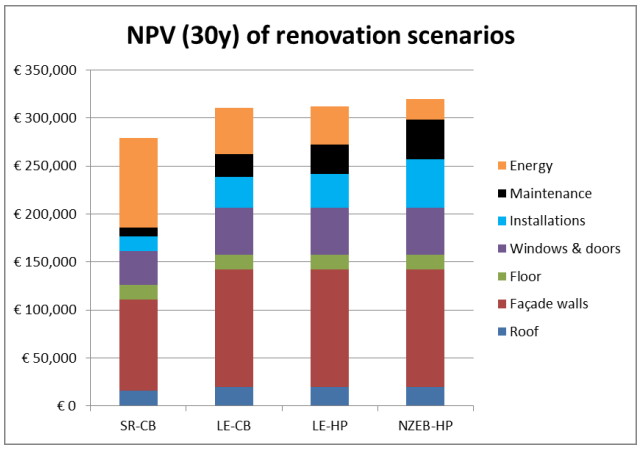

Fig. 3: Life cycle costs over 30 years of different renovation scenarios – without incorporation of subsidies

3.3 Life cycle costs

The energy and maintenance costs are discounted to Net Present Value using a real discount rate of 1.96%. If financial incentives and subsidies are not taken into account, the SR-scenario, which consists of insulating the considered case study house to the required minimal insulation level of new houses shows to be the most interesting in terms of Net Present Value over 30 years.
Fig. 3 clearly shows that the investment costs of the walls are very high, higher than the NPV of the energy consumption accumulated over 30 years. The combined cost of insulating the walls, triple glazing and adding more installation technology is not compensated by the lower energy use.

When taking subsidies anno 2012 into account, the SR-scenario remains the most interesting. The other three scenarios, that have the same envelope, are in the same range of NPV over 30 years. The additional energy savings & the (large) subsidies for PV panels to achieve a “NZE” level do weigh up against the higher maintenance and replacement costs of the larger system, and the NZE-alternative becomes competitive with the LE-scenarios.

4. Environmental impact

4.1 Methodological approach

The environmental impact of the different renovation approaches is analyzed using life cycle analysis (LCA). This technique considers the input (resources, energy) and output (emissions, waste) of the renovation process over its life cycle to quantify its contribution to several environmental issues, such as global warming, the depletion of the ozone layer, or particulate matter. This study makes use of the Ecoinvent life cycle inventory database (version 2.0) [4] and defines the environmental impact using the ReCiPe Mid/Endpoint method (version 1.06) [5]. This method allows to quantify various environmental indicators (each with their proper unit) as well as to determine a global environmental score (expressed in points - Pts) after a process of normalization, grouping and weighting (for this analysis ReCiPe Endpoint (H) / Europe ReCiPe H/A)[6].

The life cycle of the building renovation is set to 60 years for the analysis. Building elements with a shorter life span (like windows and installations) are considered to be replaced during this period. Whereas several interior materials (eg. wall finishes, bathroom or kitchen) are renovated in the *as built* renovation project, these are not considered in the environmental analysis. *Table 1* provides an overview of the different materials and installations included in the study. In addition, the energy

consumption required for heating, ventilation and aid energy during the building's life cycle is considered in the environmental analysis and estimated as described for the cost analysis.

4.2 Impact of materials & installations

The aggregated scores show that the environmental impact of the materials (initially used) for the envelope is 28% higher for the LE (& NZE, since the same materials are used for the envelope) scenario compared to the SR scenario. The largest environmental impact originates, for all scenarios, from the materials used for the floor (*Fig. 4*). The environmental impact of the floor is slightly higher for the SR where sprayed PU foam is considered, than for the LE scenario which applies EPS panels. The large impact of the floor results from both the concrete floor slab and the ceramic tiling used as finishing material.
The global environmental impact of the installations also increases for scenarios with increasing energy performance. This is largely because of the larger number of photovoltaic panels in the NZE scenario. Windows are replaced once in 60 years, the installations are replaced every 15 or 20 years. The NZE-scenario has the highest environmental impact in terms of replacements, because of the large amount of installations (*Fig. 4*).

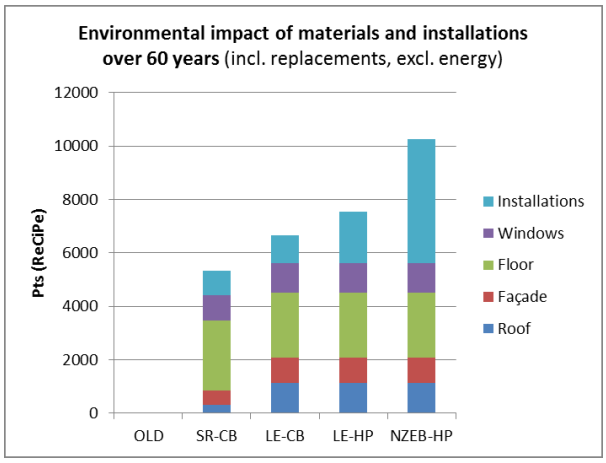

Fig. 4: Environmental impact of the materials and installations over the total life cycle of the building (60 years) for different renovation scenarios. Method: ReCiPe Endpoint (H) V1.06 / Europe ReCiPe H/A / Single score

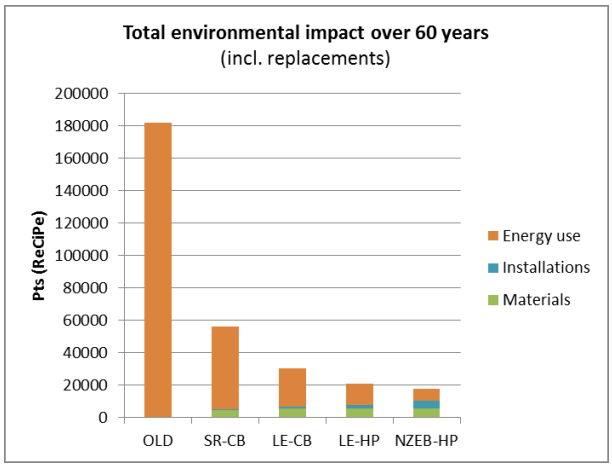

Fig. 5: Total environmental impact of different renovation scenarios over their life cycle. Remark: Different scale than Fig. 4! Method: ReCiPe Endpoint (H) V1.06 / Europe ReCiPe H/A / Single score

4.3 Impact of energy & total impact

The scenarios defined with better energy performances will use less energy for heating, ventilation and hot water. Next to the differences in amounts of energy used per year, also the energy carriers vary between the scenarios. The environmental impact related to the energy use diminishes for scenarios with increasing energy performance: from SR to NZE: -86%. A comparison between LE-CB and LE-HP (where the heating demand is the same) shows the environmental impact is smaller when using a heat pump for heating compared to a condensing gas boiler.

Adding the environmental impacts of materials, replacements and energy use over 60 years together, provides further insights in the total environmental impact of the different renovation measures. The impact related to the energy use clearly determines the total impact (*Fig. 5*). As a result, the environmental impact of the renovation measures decreases for renovations with increasing levels of energy performance (from SR to NZE: -68%).

For illustration, the impact 'over time' of the different scenarios is given in the figure below. It shows that the added materials to achieve lower energy consumption have a small 'environmental pay-back time'.

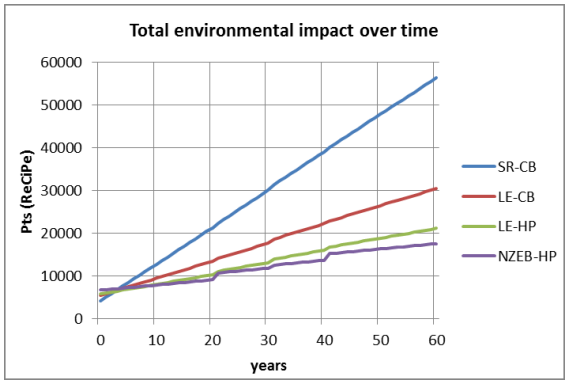

Fig. 6: The environmental 'impact over time' for the different scenarios

5. Discussion of results

5.1 Other case studies

Within the One Stop Shop project, another Flemish renovation case was studied using a similar approach: a renovation of row houses from the 1970s to passive house standard in Wachtebeke, see [7] & [8] for detailed information. The results of this case study lead to similar findings for both the cost and environmental analysis, which enforces the general trend from other research [9][10]. In the Wachtebeke case, the 'Standard Renovation' scenario (SR & K40 - with an insulation level similar to new construction anno 2012) is the most cost efficient over a period of 30 years. In both cases, some insulation was present in the 'old situation', which makes investing in extra insulation measures less efficient. Financial incentives, such as grants for investment and green power certificates for renewable energy, tend to flatten the differences between the more ambitious scenarios and the standard renovation.

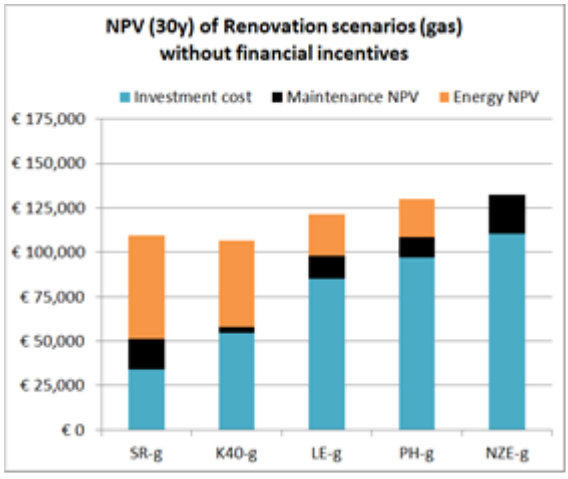

Fig. 7: Life cycle cost of renovation scenarios for Wachtebeke case(all on natural gas) without financial incentives – SR=Standard Renovation – only necessary measures, K40 = renovation to new build minimal standards, LE = low energy, PH = as built Passive House, NZE = Nearly Zero Energy [8]

In terms of total environmental impact, the Wachtebeke case also illustrates that the scenarios with the highest levels of energy performance have the smallest environmental impact over the renovation's life cycle. The global environmental impact of materials and installations increases when going from SR to LE to NZE, but the impact related to the energy use diminishes spectacularly and determines the overall results.
The individual results and more detailed information of both cases can be found in the report that is available on the project website [7].

5.2 Feasibility of NZE level

The results presented in the previous paragraphs show that in the 'NZE' scenario for the Torhout case, where the whole roof surface is used for PV (3.4 kWp) and solar boiler panels (25 m²), it is not feasible to reduce the average annual energy consumption to zero. This is due to the relatively large surfaces of windows and garage doors, with a much higher thermal conductivity than the opaque façade parts. This makes it very hard to reduce energy demand for heating very significantly.
In the Wachtebeke case however, the NZE-level is achievable: covering the roof with PV panels leads to a yearly energy consumption cost of 44 €.

6. Conclusions

In terms of cost efficiency, striving for a very low energy consumption is not cost efficient, due to the high initial investment. Also the elevated maintenance and replacement cost for more sophisticated installations gives the advantage to less complex and less ambitious solutions.
Starting from the as built situation, achieving NZE level is possible using renewable energy techniques, on the condition that the energy demand can be reduced substantially and thus that wall openings are limited – which becomes clear from the comparison between Wachtebeke & Torhout.

In terms of environmental performance, higher levels of energy performance lead to lower environmental impacts. Whereas bringing more materials and installations to a renovation project inevitably leads to higher environmental impacts, this is easily compensated by the reduction of the energy use. The energy use dominates the environmental impact for standard and low energy renovations. The impact of the materials and installations gains importance when striving for the passive house or NZE level. This is related to the strong decrease in energy use, but also to the increase in amount of materials and installations needed to achieve these levels. From this point of view it would be interesting to investigate the environmental impact of different material applications for reaching NZE-level.

It can be concluded that there is still a trade-off to make between cost efficiency and the best option for the environment, within the chosen boundary conditions.

7. Acknowledgements

The authors would like to thank IWT (national funding for the ERACOBUILD One Stop Shop Research project), the project partners (Passiefhuisplatform, Vlaamse Confederatie Bouw, VTT, DTU and Segel) and InnovIris (support in the Technological Advise Service on Sustainable construction for the Brussels Region). A special word of thank goes out to Luc Dedeyne, owner & architect of the described case study (www.Benergie.be).

Katie Symons, Eleni Soulti, Ghada Mubarak: Centre for Sustainable Development, Department of Engineering, University of Cambridge, CB2 1PZ, UK

Short Summary

Regulations and technological advances over the last decade have led to improved energy efficiency for new buildings. However much of the existing European building stock has poorly insulated fabric leading to low energy efficiency and high carbon emissions. In the UK we have a particular problem with homes built prior to 1930 with un-insulated solid walls. This paper briefly reviews the multiple barriers to retrofitting solid wall insulation in the UK. It then quantifies the whole life (operational and embodied) carbon of a solid-walled dwelling, first in its original state and then retrofitted with one of four solid wall insulation products. The results show that all of the products modelled repay their cradle to grave embodied energy and carbon costs within 13 months of installation through the operational savings achieved. The authors conclude that retrofitting with solid wall insulation can result in considerable whole life carbon reductions. While the barriers remain considerable, greater understanding of the issues will help contractors, home owners and developers to make informed design choices.

Keywords: retrofit, whole life energy and carbon, life cycle assessment, solid wall insulation

1. Introduction

According to the International Energy Agency [1], buildings account for close to 40% of the energy used in most countries, with space heating still the main factor. The IPCC have suggested that buildings have the highest potential for cost-effective reduction of energy among all sectors and in all countries [3]. Reducing heating demand through energy efficiency measures could reduce energy use in the domestic sector alone by 50% or more [1].

Regulation and technological advances over the last decade have led to increasing improvements in the energy efficiency of new buildings, with net zero energy due to become the norm in the UK by 2019. However much of the existing European building stock which will still be standing in 2050 has poorly insulated fabric leading to low energy efficiency and high carbon emissions. In the UK we have a particular problem with homes built prior to 1930 with un-insulated solid walls; 31% of existing dwellings fall into this category [2] and these are responsible for over 30Mt CO_2 emissions per year. The option of demolishing and rebuilding these homes with more energy efficient designs would not only lose our cultural and social heritage, it would also have a high embodied carbon cost.

The Climate Change Act of 2008 committed the UK to reducing carbon emissions by 80% by 2050. A number of policy instruments have been developed to achieve this target, including increasingly stringent Building Regulations for new buildings. In 2013 a financial instrument, the Green Deal, was launched to encourage the retrofit of existing homes. This is expected to increase the up-take of solid wall insulation in particular with the result of reducing carbon emissions, as well as energy use, from existing dwellings. However the process and materials involved in retrofit also have a carbon impact which needs to be included in any calculation of savings. The Government Low Carbon Innovation and Growth Report of 2010 recommended that embodied carbon should be assessed at the feasibility stage of construction projects to inform design decisions [4], and this also, necessarily, applies to retrofit projects.

The multiple reasons for the current slow uptake of external insulation installation are discussed in the following section. The paper then describes a theoretical model simulating the performance of a solid wall house with four options, each with a different insulation product as part of the building's wall construction. For each option, the operational energy and carbon saved during the building's lifetime is compared with the embodied energy and carbon of the product.

2. Barriers to solid wall insulation

Energy efficient technologies can be attractive investment opportunities, not only at governmental and industrial levels but also at household level; they can be net present value (NPV) positive, they have low time payback period, and are most likely to remain competitive in the future (Reddy 1990). Cavity wall insulation and loft insulation programmes have been encouraged by the UK Government for many years, with widespread uptake in both social and privately-owned housing. Solid wall insulation systems have also existed for many years – however, these systems have had very poor uptake, for a number of reasons.

Many of these reasons are technological. One important issue for traditional buildings is that they are "breathing" structures, made of permeable materials and without the vapour barriers and membranes which are standard in modern construction. This permeable fabric tends to absorb more moisture, which is then released by internal and external evaporation. Inappropriate application of impermeable solid wall insulation products can lead in some cases to problems with damp ingress [5]. Other technical challenges can be problems with thermal bridging and the creation of cold spots [6].

Further barriers arise from social and cultural considerations. External insulation systems can change the appearance of the building, while internal systems reduce room sizes. Both are disruptive to the daily activities of the occupants. Economic concerns are also considerable, with not only the cost of installing the insulation and applying finishes and redecoration, but often considerable further building work, such as extending window sills and eaves, needed as a secondary effect of adding the insulation.

In addition, in the UK there is little previous experience of this type of work, either by builders or by home-owners. In a traditionally risk-averse industry this is a considerable barrier to implementation.

These barriers are summarised in Table 1 below.

Table 1: Barriers to growth of solid wall insulation sector

Classification	Barriers to implementation of solid wall insulation
Technological	i. Embodied energy and carbon emission savings in contrast with U-value.

	ii. U-value varies significantly between each type of insulation. The thickness of insulation plays a role in decision making iii. Technical challenges including thermal bridging, the creation of cold spots and potential damp inducement.
Economic/ Financial	i. The need for grants and other financial support as the cost of solid wall insulation can be a market inhibitor. ii. There is a lack of consistency and clarity on the direct and indirect costs of solid wall measures and payback times
Socio-cultural/ Behavioural	i. Change of appearance of the dwellings, especially when implementing external solid wall insulation ii. The reduction in the total area of the living space when using internal wall insulation, as well as the need for redecoration. iii. Both internal and external solid wall insulation disrupt the activities in the household.
Information/ Awareness	i. There is a lack of robust, detailed data on the size of the domestic solid wall insulation market in terms of value, number of installations, trends and forecasts. ii. A low public awareness especially on the options availability and the benefits each option introduces.

3. Whole life energy and carbon for five scenarios

The Energy Saving Trust states that 'where products are very similar in terms of operational performance, then embodied energy aspects should also be taken into consideration' ([6] p.32). The authors have calculated the whole life energy and carbon of a typical solid wall masonry UK domestic building, first in its original state and then retrofitted with one of four solid wall insulation products, in order to assess the carbon payback times for each product.

The tool used to model the building is a whole life cost, energy and carbon tool called 'Butterfly' [7], developed as part of an industrial-academic research consortium led by BLP Insurance and including the Centre for Sustainable Development (CfSD) at the University of Cambridge, the Energy Institute at UCL and UK major contractor, Wilmott Dixon.

The embodied energy (EE) and embodied carbon (EC) are calculated over the whole life of the building ('cradle to grave'), following the methodology and boundary conditions set out in the recently published CEN TC 350 standards on Sustainability of Construction Works [8-10]. Figure 3 illustrates the modules of the Life Cycle Analysis framework as set out in these standards; those which are outlined in blue/bold form the embodied impacts. Only module B1, Use, incorporating B5 and B6, are currently the focus of regulation in the UK.

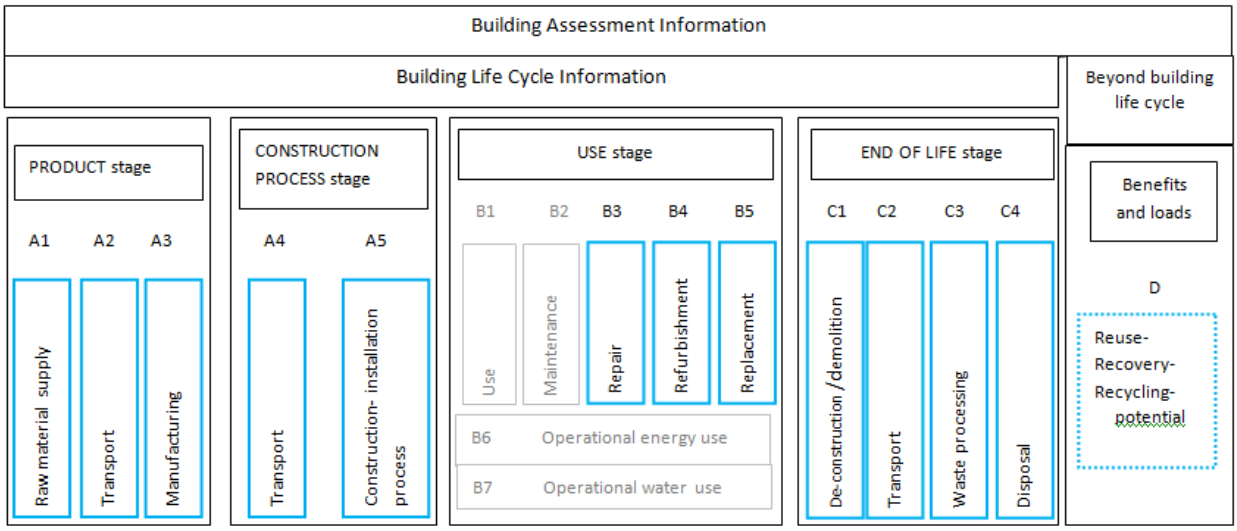

Fig. 1: Life cycle stages from BS EN 15978:2011 Sustainability of construction works — Assessment of environmental performance of buildings — Calculation method [8]

The model considers the building broken down into assemblies (external wall, for example), each with their constituent components (plasterboard lining, for example) and the quantities of these are calculated using assumptions of typical construction methods and systems. These can be overruled by the user when actual figures are known. The embodied energy and carbon of each component is calculated for modules A-C and aggregated to give the total 'cradle to grave' embodied energy and carbon for the building. The construction phase is an exception to this method, since the energy and carbon is not easily attributed to each individual component, and so benchmarking data from construction projects has been used [11].

The operational energy and carbon is calculated using a SAP model, which considers the U values of the building fabric, heating systems and other energy use parameters of the building.

The baseline building used in this experiment is a traditional solid wall masonry semi-detached 2 storey house of 76m^2 internal area. The model was run for five different external wall insulation conditions, the first base case with no insulation and the other four cases retrofitted with different products, including two which are used externally and two internally, with one mineral and one oil-derived product in each category. These are labelled options 1-4 and each is described in more detail below [12].

Option 1: ThermoShell rock mineral wool (External use)

> This product incorporates a rock mineral wool slab with thermal conductivity of 0.038W/mK, containing a water repellent additive to ensure that no water is able to pass through the slab and reach the substrate during installation and construction. However mineral renders and rock mineral wool insulation are breathable, allowing moisture to permeate through the system in use.

Option 2: OPTIMA system with ISOVER glass wool product (Internal use)

> The OPTIMA System consists of a metal frame, ISOVER glass wool insulation with a thermal conductivity of 0.035W/mK, a vapour retarder and air tightness layer. To avoid condensation damage in the structure, the vapour retarder and air tightness layer are installed on the inner facing surface of the insulation layer (i.e. the warm side).

Option 3: ThermoShell EPS Board (External use)

ThermoShell EPS Board is a graphite impregnated expanded polystyrene bead board with a thermal conductivity of 0.032W/mK. The boards can be either adhered and mechanically fixed or just mechanically fixed to the substrate and then overlaid with a mesh and a render system.

Option 4: Speedline Thermal Laminate Plasterboard (Internal use)

This is a composite product of 12.5mm tapered edge gypsum plasterboard factory bonded to polyisocyanurate foam (PIR) insulant with a thermal conductivity of 0.022W/mK. The PIR foam is faced on both sides by a multi-layer kraft paper and aluminium foil to create a vapour resistant product which can be either adhered or mechanically fixed to the wall.

The wall build-up modelled for each of the 4 options includes an external cement render layer and an internal plasterboard layer, and all options have a total thickness of 350mm; the difference between the options is therefore only in their thermal performance. Each of the four solid wall insulation options produce a u-value similar to that of a standard insulated cavity wall as shown in Table 2. The full external wall assembly is modelled in the programme under the ID code for each option, with only the external walls changed.

The additional embodied energy and carbon 'cost' of the solid wall insulation was then measured against the operational energy and carbon 'saving' due to the decreased u-values of the building envelope. In each case the carbon payback time was calculated, defined as the length of time from when the building starts operating to the point at which the operational carbon savings surpass the additional embodied energy and carbon.

Table 2: Comparison of external wall options

ID code	U-value (W/m^2K)	Description	Operational carbon (regulated) (tCO_2e/yr)	Total embodied carbon (tCO_2e)	Relative embodied carbon (tCO_2e)	Payback (mths)
2355	2.09	Solid wall, no insulation	3.93	33.23	-	-
2356	0.29	Option 1	2.36	34.41	1.18	9.0
2357	0.28	Option 2	2.35	34.65	1.42	10.8
2358	0.26	Option 3	2.33	34.56	1.33	10.0
300	0.20	Option 4	2.27	35.07	1.84	13.3
200	0.25	Cavity brick and block with 100mm cavity fill mineral wool insulation	2.32	32.31	-0.92	-

The percentage contribution of each life cycle stage to the total embodied carbon of a whole new-build dwelling is given in Table 3 below (from [11]). For the solid wall insulation products, stages B2-5, which include the replacement of components, will be zero for a retrofit design life extension of 60 years, since correctly installed this is also the design life of the insulation systems.

Table 3: Percentage contribution of each life cycle stage to the whole building embodied impacts

TC350 stage	Embodied carbon (%)	Embodied energy (%)

A1-3 Product	50	54
A4 Transport	9	10
A5 Construction	3	5
B3-5 Refurb and replace	17	26
C1-4 End of life	21	5
Total A-C	100	100

4. Discussion and conclusions

As can be seen from the results of the modelling in table 2, all four insulation products have very low payback periods, and are very similar to each other. In particular it is clear that the embodied carbon of external wall insulation is low compared to the operational carbon saved over its lifetime. This is an important finding for both designers and policy advisors interested in influencing retrofit of domestic buildings. While the addition of other energy technologies may appear more exciting and innovative, it is important to assess all options not just on the potential carbon saved but also on the initial carbon cost [13].

It is also important to consider, as the authors have here, the full life cycle impacts of a retrofit product. Here again solid wall insulation is a sensible choice for carbon reduction, since not only does it have relatively low initial embodied carbon, where correctly installed it is expected to last for at least 60 years, the standard extended design life of the building in which it is installed. This means that the repeat carbon costs of reinstallation over the life of the building are not an issue, unlike products which have a shorter design life such as most services components.

However, as discussed in section 2, a number of barriers still exist to the installation of these systems in the UK. The extra cost of installing external systems due to the additional work required, and the loss of space from installing internal systems in already small houses, are both considerable concerns. The lack of expertise and knowledge for both installers and home-owners is important, as are the valid fears of incorrect installation leading to damp problems. The Green Deal should go some way towards alleviating the economic barriers, leading to an increase in uptake and subsequently a greater experience of and confidence in the technology. As demand increases, the focus on manufacturers and specifiers will be to produce thinner systems, without huge increase in embodied carbon.

This paper concludes that the embodied carbon impact of retrofitting solid wall insulation to existing UK homes is very low compared with the carbon saved during the building's lifetime. The carbon payback time is calculated at around one year for each option, with only small variations between the four products studied. Even with the acknowledged variation between actual energy saved compared with that as modelled here by the Standard Assessment Procedure (SAP), the payback is likely to be very much shorter than the lifetime of the product. It is therefore clear that the take up of this insulation should be encouraged for the 31% of UK homes which currently have solid walls, in order to reduce whole life carbon emissions from the building stock. Since the embodied carbon of the four typical products chosen were similar, the choice of product used is likely to be dependent on other issues, such as whether the disruption and loss of space for internal insulation, or the expense and changes to dwelling appearance for external systems, are more acceptable.

This paper concludes that there are undeniable technical arguments for applying solid wall insulation. While the barriers remain considerable, the increase in uptake which is likely to result from

the Green Deal will lead to greater understanding of the issues, which in turn will help contractors, home owners and developers to make informed design choices.

5. Acknowledgements

The authors would particularly like to thank Gary Sutton, SIG Energy Management and SIG plc for their input to and support of this research. The tool used to calculate the whole life carbon was funded by the Technology Strategy Board Low Impact Buildings Programme; the consortium was led by BLP Insurance and included the UCL Energy Institute and contractor Willmott Dixon.

Short Summary

Scope of the paper is the environmental system declaration and improvement of environmental properties of the prefabricated TES EnergyFacade retrofit system on product level. It is the fundamental step towards the description of ecologic quality of a smart envelope refurbishment method. The task is a comparison of various dependencies between the technical requirements and the material effect, which is relevant for the environmental characteristics. The outcome shows a high influence on environmental impact results from different technical and functional requirements to facade elements.

Keywords: Refurbishment; energy efficiency; resource efficiency; system declaration; environmental product declaration; environmental impact; life cycle assessment; reference service life;

1. Objective

Sustainably built and modernized buildings must be economically, socially and ecologically sustainable. In addition to organizational and technical aspects, as well as the optimization of the planning and construction process, fire protection, or the hygro-thermal building physics, is therefore the life cycle-oriented consideration of ecologic quality of vital importance for the development of new modernization solutions [1]. The ageing building stock in Germany and most of Europe is in a change phase. An amount of around 45% of the existing buildings from the age class of 1950 to the eighties of the last century is dedicated to a fairly renewal, that goes beyond ordinary maintenance and repair. The building performance neither fulfils the actual technical and functional requirements nor the demand of owners and tenants.
The currently usual answer to this need for renewal is the application of external thermal insulation compound systems made of mineral fibre or for economic reasons polystyrene hard foam. The installation of these systems is little ergonomic, dependent on weather, will be more difficult with increasing insulation thickness and leads to dust and noise pollution for an extended period of time. These market dominating insulation systems are manufactured from non-renewable raw materials and are energy-intensive in the production and assembly. In polystyrene rigid foam there are risks in terms of the environment and human health, especially by contained hazardous flame retardant which can reach different pathways into the environment.
Energy efficiency measures must be out of social, environmental and process planning considerations carefully considered and compare different solutions; it must be ensured a balance between the environmental impact of the manufacturing phase and the reduction of environmental impacts during building operation. Even if the energy efficiency related refurbishment, mainly targets towards reduction of greenhouse gas emissions in the building operation, so the LCA of a reorganization measure itself, i.e. the primary energy use or greenhouse potential in production, as well as possible risk and hazardous material loads may be considered during production, processing, use and end of life.

Hence it remains a contradiction between improving the ecological properties of existing buildings and the use of fossil based resources to achieve the first goal. In order to realize a better energy efficiency of the building stock there is the need to (1) bring down buildings energy demand by changing the heating system and fuel, (2) improving the building envelope (windows, wall, windows, ground floor, roof) and additional (3) minimize impact from refurbishment by conserving useful substance of the existing fabric, prolonging service life, choice of durable and multifunctional (flexible solution) by consequently use an off-site process before facade elements are assembled and wrapped around the existing fabric.

Scope of the paper is the preparation of basic environmental system declaration and record of environmental properties of the prefabricated TES EnergyFacade retrofit system on product level. TES is synonymous with Timber-based Element System for the energy efficient refurbishment. It is the fundamental step towards the description of ecologic quality of a smart envelope refurbishment method. The task is a comparison of various dependencies between the technical requirements and the material outcome, which is relevant for the environmental characteristics. The main objectives for a practical application of reduced environmental impact are defined by König et al. in [2]. The impact for the most influential life cycle phases – production and end-of-life – has to be quantified for sustainability benchmarks. This information is required in certification systems and supports decision making.
TES EnergyFacade elements consist of a timber-framework construction with highly insulated cavities. The modular framework is produced off-site and assembled with an adaption layer onto existing structures or exterior walls. The cladding material and windows can be chosen as like. They will be mounted onto the wall elements and that should be done off-site as well. Due to the high level of prefabrication, the on-site process is short and inherits minimal waste production.

The dominant parts of the system have not the highest environmental impacts, because they are from renewable resources. Rather, it will be revealed that these parts make a positive contribution to the environmental impact by avoiding a high percentage of carbon. This remains very similar in various construction structures, as the dominant shares are of renewable resources. The disposal can take credits from the energy generation from wood to a substantial extent. The burdens are mainly on the account of the mineral components on the system.

2. Methodology

2.1 Facade Construction Parameters

Life-cycle optimized construction systems have four important basic requirements: the objectives are to maximize the lifespan of important components such as the primary structure [2] [3] [4], minimizing the flow of material [5], increases the possibility to reuse and recycling, as well as maximises the decommissioning. The necessary and variable components of the system are described as input variable. In a poly-hierarchical model, they are networked with the requirements and further the critical dependencies with the impact on the choice of material are derived.

There is a definition of functional properties of layers for TES element and a definition of the essential principles to ensure the design characteristics of this new facade construction [7]. TES is a self-supporting facade structure similar to semi-balloon framed timber structures with support for vertical loads and horizontal anchoring against wind loads on each floor level. Each element has a structural framework and within this framework there is the insulation which improves thermal properties of the existing exterior walls. The enclosure of framework is necessary for structural bracing and functional properties of the element as moisture safety, wind- and airtightness. For safety reasons specific panelling layers for fire safety can be applied. These mineral-based layers encapsulate and protect the insulation and structural parts of the elements.
The compulsory and variable components of the system are set as input dimensions and represent the subgroup of the *TES core* and *Adaption layer* as it can be seen in Figure 4. The structure of the timber framework consists of the wood studs that are positioned in a regular distance and butt-joint perpendicular to sill-beam and wall-plate. On this side of the element oriented towards the interior a panelling is applied for structural and airtightness reasons. Towards the outside a mineral- or a

wood-based panel is fixed. A gypsum fibre board is exemplary for a fire safety layer. The partition cavities will be filled with thermal insulation like cellulose fibre.

2.2 Robust construction model

Robustness in life cycle engineering delivers constructions with minimised environmental impact at full serviceability at appropriate durability and technical functionality.
In a poly-hierarchical model, the technical parameters of the TES construction are connected with the environmental requirements derived from the objectives listed in this specific order:

a) Construction design decision leads to,
b) Differentiation of life span and
c) Influences dismantling behaviour.

For life cycle durability and service life, only qualitative empirical values can be derived from existing structures e.g. lifetime of dry wooden walls. It applies to the composition of the structures that so far no composite materials are provided in rule-compliant elements. Exceptions are the sill and the sealing of the window frame.
A selective dismantling process is possible on the element level on-site, a demolition is not necessary. All joints between the existing building and the TES are done by screws. Entire elements can be disassembled and transported for further waste management. The layers and timber framework of individual elements have to be separated and recycled off-site. The joints between the framework and layers of the element are durable and e.g. staples, nails are reversible only to a limited extent.
All relevant considerations need to be evaluated and optimized for the finding of design patterns. Hence the aim is at demonstration of appropriate layer composition instead of the detailing of smaller parts of the timber facade system. This assumption is explained with the influence of the joint part in relation to the element area. Basic assumption is an average small facade of a 4 storey town house building with eight apartments. The length of all horizontal joints is roughly 320 – 520 meters including the length of the basement and the roof eaves. This sums up to an amount of 2,2 to 3,5 m³ of wood required for all horizontal joints plus ten percent for all vertical joints. Assumed that average facade area is about 450 m² it is only 0,005 m³ of wood per square meter of the facade needed for the joint. The TES element itself requires about 0,036 m³ of wood per square meter.

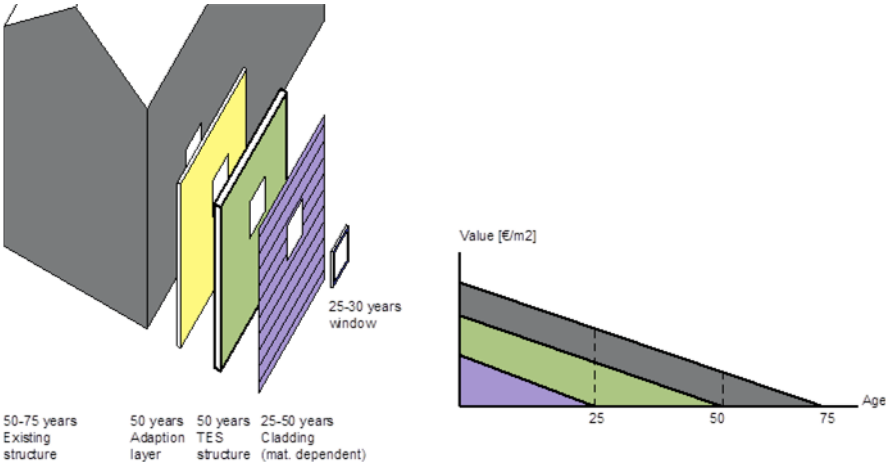

Figure 1 Differentiation of life span of TES element layers.

It is shown as an example that it is more worthwhile from an LCA perspective to optimize the structure of the element. The shape of the joint has an influence on the construction process and the later removal and thus the recovery at the end of life. These other objectives are integral in the whole life-cycle approach, and in particular in the development of the jointing.
Further goals are to maximize the lifespan of important components such as the timber framework structure, and give ability to reuse and recycling, as well as maximizing the dismantling. This is necessary to a higher degree for the exterior parts and layers compare Figure 1. The durability of

the wooden elements and the protection of the structure against climate exposure are done in compliance with hygrothermal requirements and moisture management in closed timber frame components. Thus the TES elements fulfil the requirements of use class 1, in which the wood or wood-based product is inside a construction, not exposed to the weather and wetting [8].

2.3 Life cycle assessment methodology

General LCA methodology is according to the basic rules of building life cycle assessment following the requirements and steps of ISO 14040 and ISO 14044 standard [9] [10].
Functional unit is one square meter of TES element with all layers of the timber framed element but without existing wall, cladding and other integrated components like windows. Up to now the inflow side does not include a more detailed insight in the accompanying parameters, anchoring, tie-back, and gap layer. The core element inventory, which are layers b and c see Figure 3, cuts off negligible secondary materials e.g. tapes, nails, and screws.

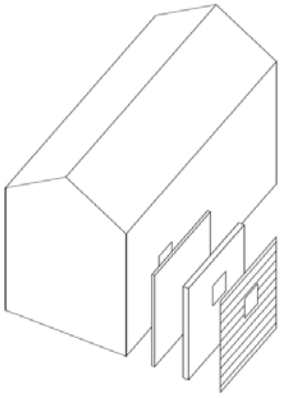

Figure 2 Assembly process of adaption layer, core element and cladding at existing structure (left to right).

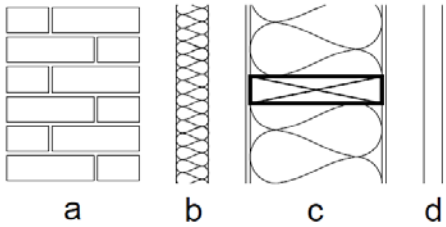

Figure 3 Cross section of existing structure (a), gap layer (b), core TES element (c), cladding layer (d).

System boundaries include the production with raw material extraction, transport, and processing into semi-finished products. The system includes the production of the raw materials and the provision at the factory gate; this is the cradle to gate part according to EN 15804 [11]. The off-site production of the conducted elements is a second factory process, but it is attributable to the construction process and related to phase A5. The transport and assembly flows in A4 are cut off from the “second” factory gate. There is still no data available for life cycle module A4-5 energy and material flows for mounting TES on existing buildings. The subsequent life cycle modules B, C and D are not examined in this article.

2.4 Data for life cycle assessment

The assumptions are set for the entire production phase of TES facade elements. They consist largely of semi-finished products for which already environmental product declarations (EPD) are available. There are so far no detailed data recorded of energy consumption and local material flows in the manufacture of TES elements. Therefore comparative figures from the off-site production of timber frame construction elements will be used, similar to new building off-site processes [12] [13].
Material input flow indicators are divided into the primary energy sources of renewable primary energy content (PER) and non-renewable primary energy content (PENR). A delicate subdivision is not possible here according to the conventions of the EN 15804, because neither the used nor currently available data from the ökobau.dat conform to this standard [14]. Upcoming EPD available on the basis of EN 15804 is also not fully well suited and have only values of the specific products. It is resorted also to EPD for the data base because there are no suitable generic records in the ökobau.dat.

Data for wood-fibre insulation material are selected on an EPD basis [15]. For the wood-fibre insulation material and other wood-based materials, the carbon sequestration is estimated on the basis of the density and the usual humidity and receives a flat-rate reduction of ten percent as either from the manufacturer unspecified base material or necessary glue is included in the final product.
The choice of the impact categories consists of accepted indicators in certification processes. Hence refurbishment will reduce the greenhouse gas emissions, is therefore an important reference value on the material side of the global warming potential (GWP). In addition the carbon sequestration (Cseq) of renewable materials is shown on the basis of the standard TC 175WI [16]. This advantage is evoked already in the global warming potential calculations for cradle to gate. But thermally recycled wood loses this advantage and gets CO2-neutral on the only material side at the end of the entire life cycle. Because the advantage of a CO2 absorption in wood in structure is an essential climate protection contribution, it is included informative in this investigation as a positive environmental impact.

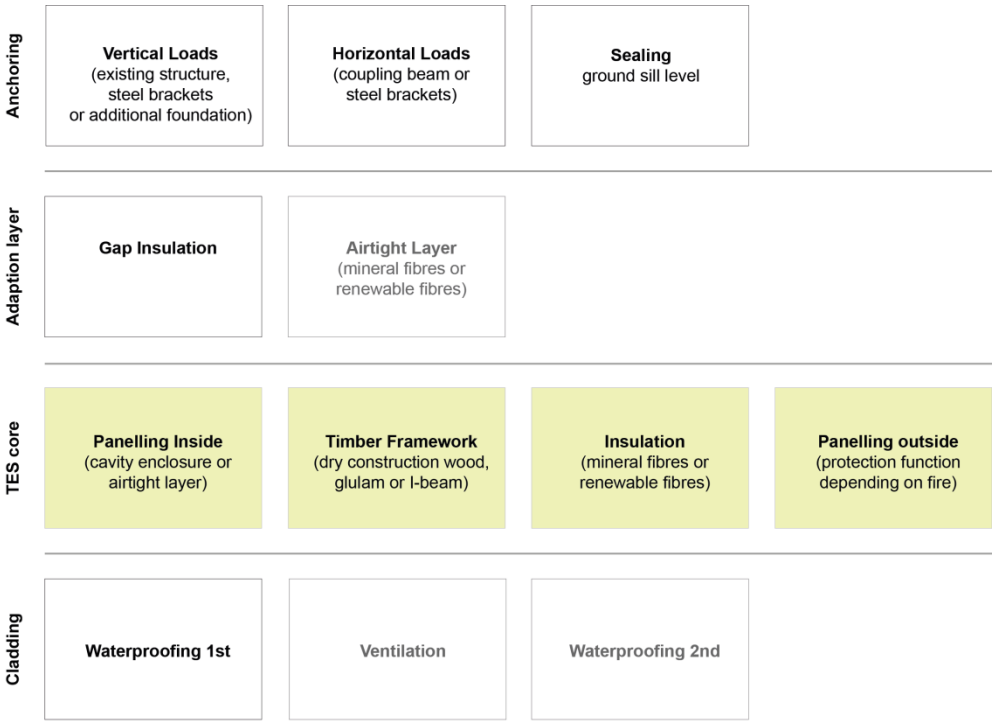

Figure 4 Matrix and basic functional unit description of a general TES system with the core parts highlighted in third row.

2.5 Demonstrators and Examples

The studies are based on nine different wall constructions that are already implemented in different projects. The projects were in Germany, in Norway and Finland. The thickness of the insulation, which is realized with these elements, is between 200 and 300 mm. The thickness of the adaption layer must be added yet, it is between 50 and 80 mm. The TES cross-sections have resulting U values of 0.14 to 0.24 W/m²K. Together with the existing walls thermal properties, total U-values can be reduced thus down to 0.10 W/m²K. By such measure the heat transmission of the facade of existing buildings can be reduced to the level of a retrofit passive house.

Table 1 Properties of TES element case A.

	Position	*Material description*	*Dimension [mm]*
1	functional layer	gypsum fibre board	25
2	gap for adaption	mineral wool	98
3	back_panelling	OSB	12,5
4	insulation	mineral wool	250
5	structure	glue laminated timber, dry	250
6	front_panelling	wood fibre board, soft	12,5

3. Result and discussion

3.1 TES solutions compared to conventional systems

The results focus on the material input and related burdens and benefits. One goal is to compare the full TES systems with the benchmark of conventional retrofit systems for facades. Another objective is taken also on the bandwidth of the inflows of primary energy and the outflow indicators for the global warming potential. Moreover, very good and very bad solutions of a TES facade can be identified and better valued. The averages for the primary content and the global warming potential give important indications of the performance of the entire system. They are also orientation values for the whole spectrum and the degree of deviation.
All TES elements compared in nine cases have the similar layer structure, only the functional layer is not included in all cases. Soft insulation is used for heat insulation and to compensate the gap. The supporting structure is made of solid wood or wood-based materials. The back side panelling requires only airtightness. The front side usually braces the element and additionally meet fire protection requirements on the front in the cases A, D, E, F, G and H.

The primary energy expenditure for TES production is high, if you look at the pure numbers in Figure 5. The ratio of renewable primary energy (PER) versus non-renewable primary energy (PENR) content is 815 MJ to 603 MJ on average. Compared to that, the primary energy content of ETICS are rather small, they have a ratio of 7 MJ PER versus 331 MJ PENR.
The renewable primary energy content of TES contains also the share of the calorific value of wood material in addition to the energy of production; it is therefore similar to or higher than the non-renewable primary energy. The fraction of the calorific value of a square meter of TES is at least 212 MJ or 55 kWh and thus over a quarter of the average renewable primary energy demand.

Table 2 Indicator overview of all nine examples with averages and standard deviation.

	Min	*Max*	*Average*	*SD*
PER	492.21	1318.37	815.38	275.74
PENR	338.27	1191.28	603.38	249.30
GWP	-0.43	-63.89	-33.78	16.67
CSeq	38.32	81.00	50.82	12.16

The benchmark of ETICS is according to the environmental system description (ESD) of the industry. It is therefore an aggregated ESD of German ETICS association and indicates PENR 331.18 [MJ/m²], PER 7.07 [MJ/m²], and GWP +14.48 [kgCO2eq/m²] [17]. The ETIC system compared is from expanded polystyrene insulation material and contains therefore prevailing fossile energy and causes greenhouse gas emissions. Meanwhile, the TES facades have a carbon sequestration potential of an average 50 kgCO2eq that is almost equal between different cases as it can be seen in Figure 6.
The GWP of nine different cases of TES is on average at -33 kgCO2eq. This value is by a factor of four below the reference value of polystyrene-based ETICS.
This shows the low environmental impact of TES facades despite their high resource demand and minor U-values. Despite high primary energy consumption, a result of the reasonable amount of

wood mass with a high calorific value, the remaining GWP of TES is still lower than for ETICS. It should be noted in particular a necessary improvement of resource efficiency in the production of the TES elements and its raw materials. However this universal statement based on the figures lacks a more detailed examination of material properties that cannot be done here.

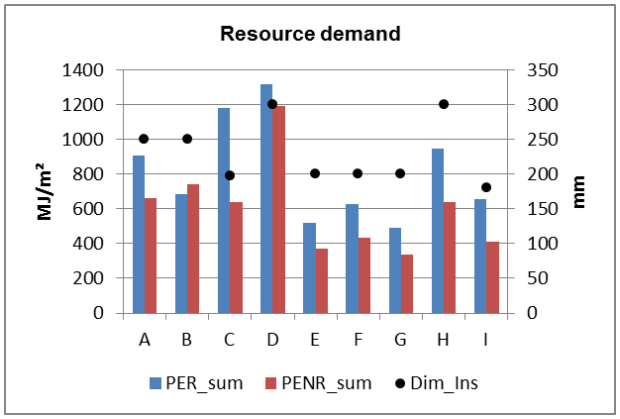

Figure 5 Resource demand of construction compared to thickness of insulation and TES element.

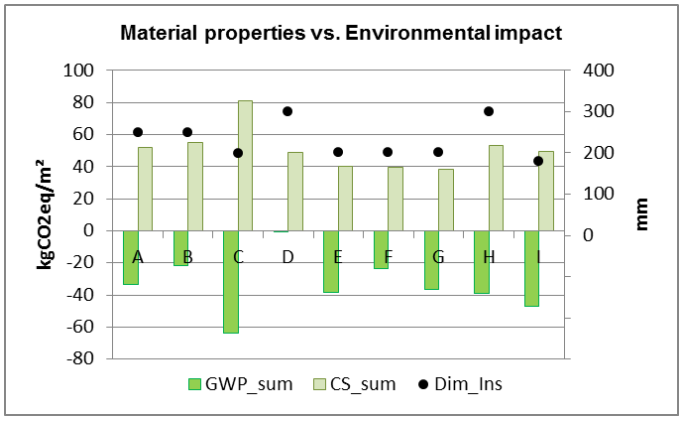

Figure 6 Environmental impact versus the carbon sequestration related to thickness of insulation in a TES cross-section .

3.2 TES layers environmental impact en detail

The analysis of the element layering is most suitable as a method and applied here. The inflow indicators by PER, PENR and carbon sequestration together with the outflows or emissions of GWP are individually calculated for each component layer. The correlation between the insulation dimension and the GWP is assessed. The sensitivity of the influence of layer materials is checked in a dominance analysis. Finally the evenness of material compositions graphs show how important certain layers are for the total amount and to the degree of environmental impact.
In principle, all layers are variable, with regard to the dimension as well as with regard to the materiality. In order to handle the possible diversity it is necessary to consider the requirements matrix and to ensure the correct choice of environmentally-friendly construction of the system. The choice of the layers in the context of the design principles makes it possible to evaluate them separately and to assess environmental impact of layers. By comparing the individual inflows and outflows makes clear, this parameterized layer affect the result of each indicator. On one hand facades such as TES can avoid or replace materials with high environmental impact in contrast to other constructional parts of a building like foundations. This is not always a simple task for wood-based materials because fasteners, adhesives, or encapsulating materials can influence the outcome (structural, safety). If the influence can be reduced the overall result will get more stable in relation to the environmental impacts. Further research will be done on this topic and first results are show in the presentation.

In Table 1, the review of the TES is given as an example element in case study A. By the global warming potential be considered it is apparent that there are positive and negative values in case A. The functional layer and the insulation are on the positive ordinate axis because they do not have carbon storage in cradle to gate phase. The wood based materials from the back panels to the front panels are on the negative ordinate axis due to their carbon storage, see Figure 6 and Figure 9. They avoid carbon emissions and contribute to a reduction of global warming therefore they have a bonus expressed in negative values for the cradle to gate phase.

It is expected that the insulation and the studs have the highest proportions and the strongest influence on the distribution of primary energy. This can be confirmed from a general perspective with the numbers in Figure 7 to Figure 8. There is also a correlation expected between the insulation thickness and the primary energy parameters. Regression of the insulation thickness with the PER and PENR is available (Lin. R-squared = 0.62). Further it is expected that there is a strong negative CO2eq for GWP as mostly wood and wood-based materials are in use. This is true

for almost all investigated facade cases; compare Figure 9 to Figure 10. Mainly a mineral based panelling of the TES front side will have influence as well as non-renewable insulation. The GWP scattering at the Back_Panel layers is very low. The Back_Panel layer is only thin regard the entire cross section. Greater deviations rise with the front panelling, the Front_Panel layers, because technical requirements for fire protection or bracing reduce variability of material and dimension parameters. The carbon sequestration information will behave similarly to the GWP.

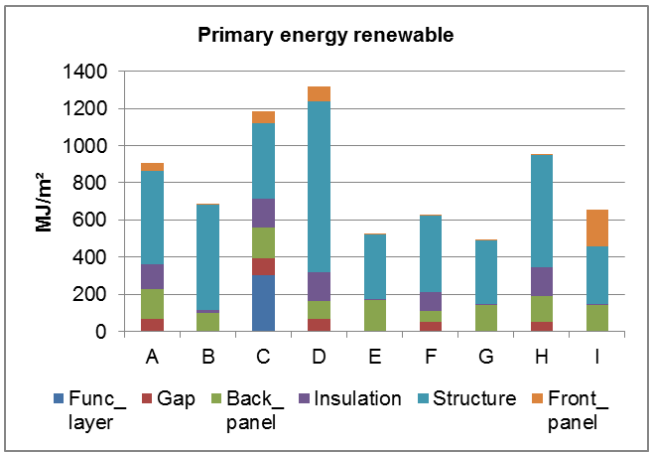

Figure 7 Renewable primary energy content of nine different TES facades, separted by layers.

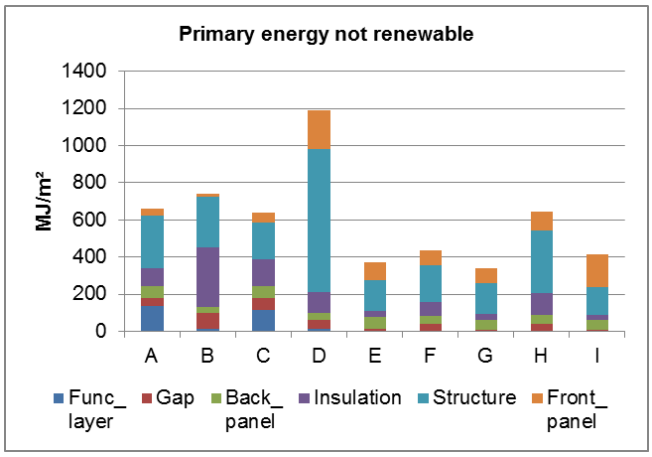

Figure 8 Non-renewable primary energy content.

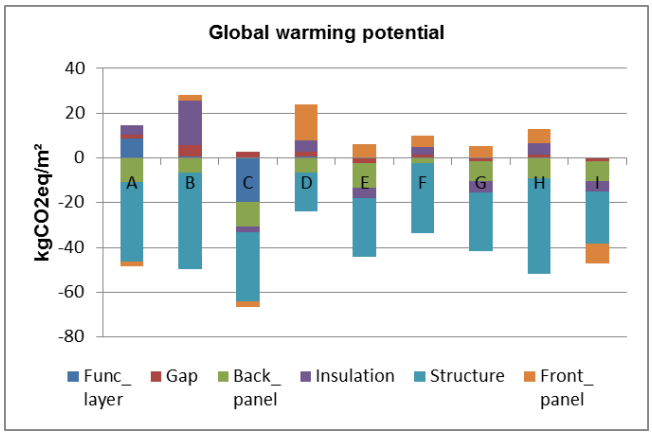

Figure 9 Global warming potential.

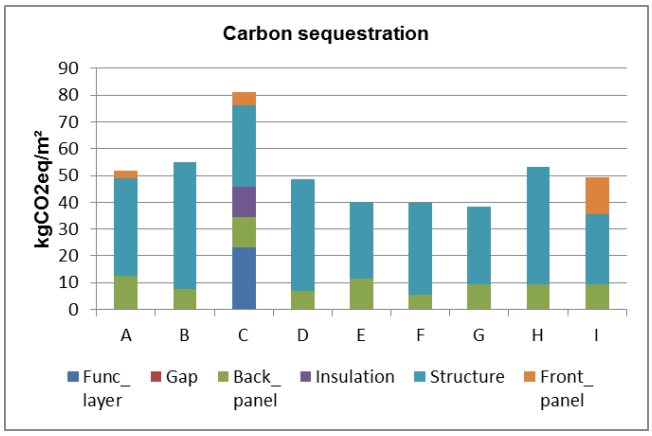

Figure 10 Carbon sequestration potential.

In the further course this article you look closer to some features. They are related to particular element production techniques and the use of certain materials associated.

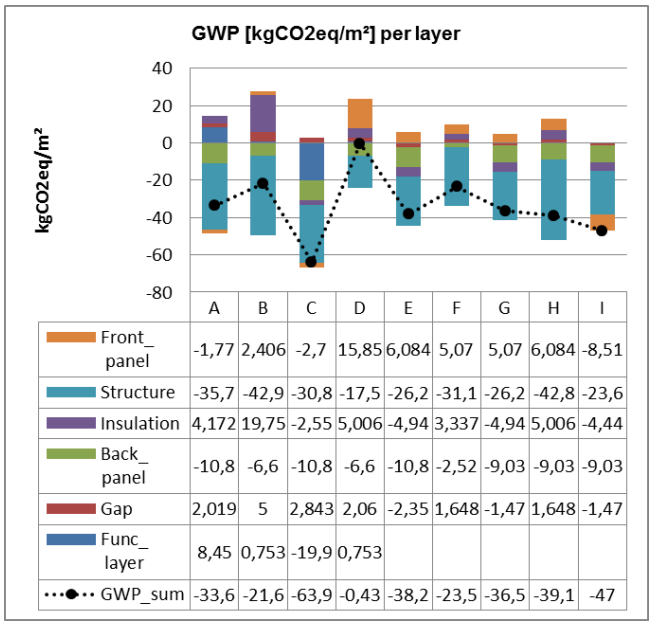

Table 3 Main material groups used in the nine cases.

Functional layer	A; B; C; D	airthightening foil or board
Insulation	A; B; D; F; H	mineral or glass wool insulation
	E; G; I	loose fill cellulose fibre insulation
	C	wood fibre insulation
Front panelling	A; D; E; F; G; H	mineral-based building board (gypsum based or cement bound)
	A; C; I	wood based panelling

In facade case C a functional layer (= shell) is included for airtightening reasons. For this layer, there is a small reinforcing effect of negative GWP, compare Figure 9.
In Figure 9 GWP shows also a distinct greenhouse potential at facade of case D, whereas the

other cases all have a smaller proportion of the positive GWP variants. The same applies to the primary energy content from case D. There is a GWP score of almost zero instead of a negative for case D. It should be noted that the load-bearing structure in this case is laminated veneer lumber (LVL). The used insulation material is mineral-based. In sum, this leads to a below-average score in all impact categories.

For its positive performance the cases C, H and I have low GWP. Another good performance in GWP value has facade case H despite high insulation thickness and not renewable insulation material. This is due to the high proportion of wood in the load-bearing structure. The layers have almost no greenhouse gas emissions with the exception of case H, because it has a mineral based insulation and front panelling. Case I is very balanced over all component layers.
Figure 12 indicates the positive influence of the structural framework on the negative GWP while the front panelling and the insulation do not have this. The structure also has the highest deviation of all scores. The even distribution of the other layers impacts apart from the front panelling is seen also in Figure 12. There is also a spike from the insulation material in this diagram. Reason for this result is a high amount of GWP for the glass wool used.
The influence of insulation and its material is a significant burden while the influence of insulation thickness is comparable low.

	A	B	C	D	E	F	G	H	I
Front_ panel	-1,77	2,406	-2,7	15,85	6,084	5,07	5,07	6,084	-8,51
Structure	-35,7	-42,9	-30,8	-17,5	-26,2	-31,1	-26,2	-42,8	-23,6
Insulation	4,172	19,75	-2,55	5,006	-4,94	3,337	-4,94	5,006	-4,44
Back_ panel	-10,8	-6,6	-10,8	-6,6	-10,8	-2,52	-9,03	-9,03	-9,03
Gap	2,019	5	2,843	2,06	-2,35	1,648	-1,47	1,648	-1,47
Func_ layer	8,45	0,753	-19,9	0,753					
GWP_sum	-33,6	-21,6	-63,9	-0,43	-38,2	-23,5	-36,5	-39,1	-47

Figure 11 Global warming potential in detail compared to the total sum.

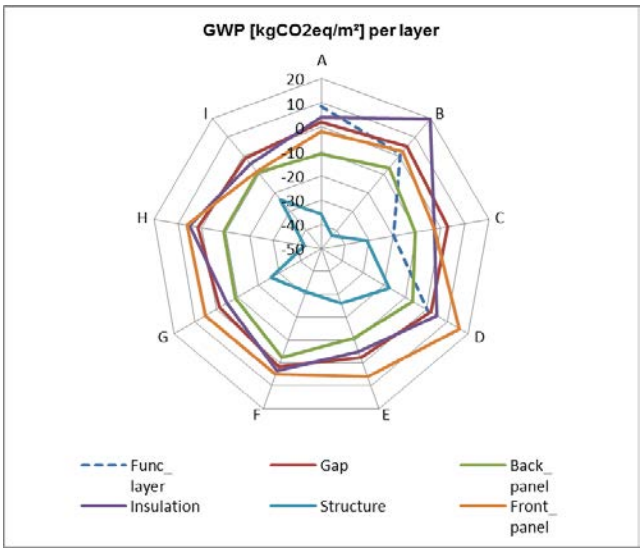

Figure 12 Dominance and evenness of GWP related to layers.

As mentioned before the module A4-5 is based on a very general assumption. It is given that the life cycle module A4-5 holds 20-30% of the total impact of module A1-3. In addition, the module A4 has a relatively high share in the module A4-5, approximately 30%. The other 60% can be allotted to phase A5 construction and phase A5 waste management in equal shares.

4. Conclusions

The TES system is analysed to, which features most of the modernization projects are sustained and what features constitute individual solutions. This inquiry is necessary to be able to use the catalogue of requirements for all projects as universally as possible. The dominant parts of the system have not the highest environmental impacts like the timber framework as structure. Rather, they make a positive contribution to the environmental impact by saving a high percentage of carbon. This remains very similar in various constructions, as the dominant shares are of renewable resources. But right selection of structure and insulation material can influence the positive properties of TES EnergyFacade to a large extent.

To sum up, it can be stated only the front cladding and insulation can deteriorate the GWP balance because they have values on the high emission side of the GWP which is a positive figure. The wood framing and the panelling of the back are renewable materials with negative figures and absorb more CO2 than the production emits. The functional layer is not always required, but it can contribute a slightly negative influence on GWP. The environmental impact of the insulation layer in the adaption layer of the gap is in contrast, constant low and almost negligible.

All TES EnergyFacade solutions are relatively homogenous regarding their global warming potential. The deviations depend severely on the material of the studs and the insulation and are more obvious on the inflow side than on the impact. The panelling has only minor influence.

The TU Munich has developed an eco-balance calculation tool for the TES facade elements and it will be expanded with complementary information. It is an extension to previously disregarded components (e.g. anchoring bolts), as well as characteristic values for the end-of-life scenario have to be captured. The cladding layer as well as integrated elements will be shown only exemplary, because they are individual chosen in each project and they are separate EPD or even ESD and therefore kept outside the system boundary. Another interesting aspect is a deeper insight in the necessary amount of energy and waste for off-site construction and the missing values for flows resulting from on-site processes. The assembly of a TES element wrap around on existing buildings is very different from new building with timber constructions and will cause further environmental impact that has to be diminished.

5. Acknowledgements

TES EnergyFacade, run from 2008 to 2009, and still running SmartTES, from 10/2011 to 09/2013 are funded in the European ERA-Net Woodwisdom-Net by the German federal ministry for research BMBF, represented by PTJ.

Short Summary

The renovation of old buildings is actually the challenge to cope with increased effort in order to reduce climate global change, channeling more investment and awareness in this sense, defining more experimentations and find innovative solutions. The difficulty of carrying out an intervention on the existing buildings necessarily arise from the lack of information on the existing structure and the lack of coordinated processes between the multidisciplinary skills involved, as well as a difficulty to optimize the process that would make it even more competitive on the renovation work instead on the new construction.
Naturwall is an innovative energy saving system for existent buildings by using wood in multifunctional components able to mitigate the environmental effort in building management. The project meant to introduce an industrialized design method in the renovation of existing build environment that highlights opportunities gave by "off site" production and parametric design approach, without neglecting the aesthetical values and the possibility to change the architectural image of residential and non residential constructions. The project aims to create a representative model of solution that will be promoted in Italy and widespread in other similar context.

Keywords: wood, prefabrication, retrofit, building, urban renewal, renovation,

1. Introduction

The renovation of existing buildings is driven by new European rules and projects on energy efficiency. The recent Smart City program, EU climate action "20-20-20" or the last EPBD directive 2002/91/EC are promoting initiatives in the field of renovation, introducing new issues and perspectives in the use of materials and components performed for this goal.
The aim to achieve energy saving in buildings is a complex process, especially if buildings are very ancient. From the last report of Buildings Performance Institute Europe (BPIE), regarding the situation of building sector in EU 27 [1], are shown the performances of the amount of old construction characterized by poor energy saving potential. Our purpose has been the development of a whole process system in the field of renewal strategies to be used in every architectural field. Starting from the relief phase, we would optimize the process detailing envelope with digital data to be used in the entire process to define components that fit perfectly on the existent wall surface, reducing the risk of adaptability of the system and the work during the yard, We meant to achieve the reduction of energy cost optimizing the total cost of the operation, complying actual energy standards and reaching the opportunities related to renovation of social housing and industrial heritage, which needs smart solution in economic terms. In the report made by Copenaghen Economics for Renovate Europe in 2012 is highlighted how “energy savings associated with energy efficient renovation of buildings outweigh the up-front investment costs

needed to under-take the projects" [2]. The reducing of energy demand in public bills for example reflect a decrease in need for subsidies and permit the achievement EU's 2020 energy targets and reductions of greenhouse gases at a lower cost. Renovation opportunities could be a real benefit for EU economies and society, especially using a strategy that maximize the investment in energy saving convey an amount of extra benefits regarding the quality of health and urban climate (air pollution, etc...). Energy efficiency could seen as possibly the most cost effective way of reducing GHG emissions. Energy efficiency measures account for two-thirds of the 3.8 GT of abatement in 2020, with renewable energy contributing about 20 % [3]
Some economical studies [4] believed that efficiency offers an enormous "win-win" opportunity. Thus means that through an appropriate and strict energy conservation policies, it's possible both save money and reduce negative issues. This approach refers to the amount of externalities such as harm to human health, climate change and constraints on the foreign policy objectives of energy-importing countries that could be amplify with correct investments in energy efficiency. A true retrofit requires a fact-based, benchmarked, quantitatively oriented, energy efficiency retrofit with a clear payback analysis on an integrated multicomponent effort with performance guarantees. [5]

1.1 Renovation problem in Italy

In Italy, the introduction of energy regulation, within standards coming from European energy legislation, has led to further actions oriented towards buildings retrofit. This approach is not well sustained by a renewal claim about functional and formal features, but only considering faster energy saving strategies. In the most case this has solved by installing a thermal insulation on the building envelope, which permit to fulfil the target points without valorise the economical and architectural value of building heritage.
The situation of built environment in Italy could be understood by the outcomes of two national studies. The first is an outline from ISTAT (National Institute for Statistic) survey in 2001, which shows the highest number of existing houses built before the energy crisis of the '70s (more than half of the total amount) and how much is the consumption of those buildings (about 250 kWh/m2 compared to 100 kWh/m2 of buildings built in the '90s).
Considering the improvement of energy efficiency of residential buildings built among 1950 - 1980 (resulting from a widespread housing development), may suggest the obvious benefits about reduction of climate-altering gases in Italian urban areas through retrofit strategies and the reduction of management cost for public administration.
The second important data coming from an EU project called TABULA [5], in which Italian part was conducted by Politecnico of Turin, it displays for Italian country an existing built environment not efficient, wide and varied to be tackled through redevelopment actions. This research defines the typology of Italian buildings heritage and their features, explaining some furthering action to improve their supply and energy performances.The last frame is a research conducted by Legambiente, and called "Tutti in classe A", which present the top level in Italian energy rating, confirming the worse insulation of buildings actually made in Italy.
All those documents explain us how much wide is retrofitting field of work in our country. Thus was highlighted by first international convention Re- Build, held in Riva del Garda (TN) in September 2012, which has shown the huge percentage of heritage to be restored and re-used, promoting governments initiatives in the recovery and regeneration assets, emphasizing the need to revise intervention processes on urban areas, stimulating the research of structured path between governance, business and local communities.

2. Naturwall – a sustainable way for the envelope retroffitting

The target of the Naturwall method is primarily focused on the building's energy efficiency improvement and, as direct consequence, the reduction of GHG emissions. "Energy efficient buildings poses special demands on the quality and performance capabilities of the facade" [6] In the field of renovation and refurbishment high energy retrofitting results and greenhouse gases reduction could be achieved by using multifunctional facade systems. Smart facade solutions using the surface of the building envelope as "active skin" confirm the increasing number of experience in this sense (TES EnergyFacade, enVELOP system, PHI-Wood façade, GAP façade system, etc..). The last number of Zuschnitt [7] shows some innovative way to recover buildings with wood prefab systems. Thus permit to reach to achieve high energy performances and sustainable features on existing buildings.

Our system would recover power from sun by using PCM systems or simple strategy to overstock renewable energy (PV, water, etc..). We verify the behaviour of Naturwall system with mathematical models by using energy evaluation software; after tested it on laboratory, we will prompted it on a real case study. The first application will be upon an industrial building envelope, which needs to be recovered and insulated. Finally, we study its application on a residential multi-storey building located in Turin (Italy) to verify the efficiency of the solution in terms of architectural renovation and energy saving.

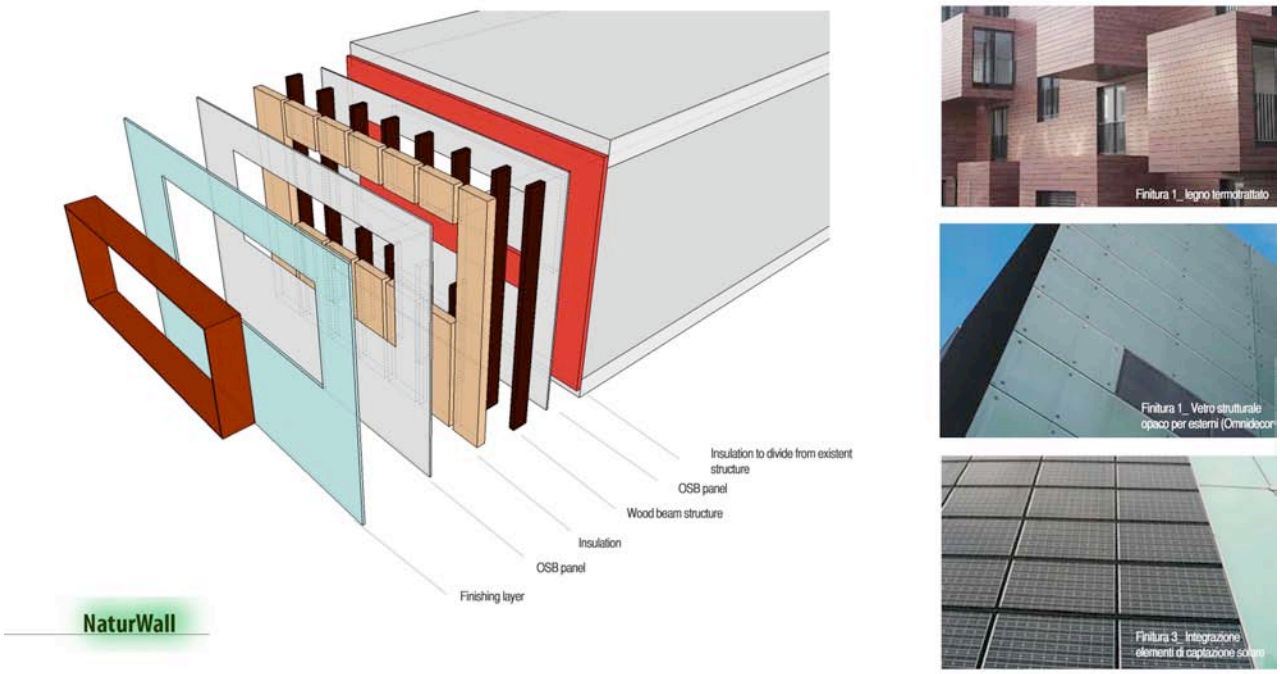

Fig 1: Naturwall facade system schematic design

The main target of that element are:

- Self supporting timber frame structure, coming from local forestry management
- Precision and quality of a customized prefabricated building system
- Application of different cladding materials – especially use of solar active systems (PCM, Photovoltaic, etc..
- Spatial intervention or expansion in a coherent modular system
- Integration of technical systems and sensor for monitoring performances
- Static behavior: wood elements are lighter than other construction material and guarantee better seismic performances.
- Responsive design to project objectives, an off-site process permit to control the quality of the final result, elements are industrialized products (made by using CNC machinery);
- Management of the yard: the setting in construction phase is more simple and there is the possibility to work, in the case of retrofit projects, without move outside the users, reducing implementation cost.
- Use of local material, especially wood coming from certified forest

A core task of energy efficient building design is to reach the required indoor environmental quality with a minimum of primary energy demand and a simple energy supply system. [8] Naturwall have several advantages, especially in the use of natural and local material, which reduce the embodied energy in the process and the carbon footprint of the products.

2.1 Multidisciplinary integrated workflow

Naturwall research meant to introduce a new settlement in renovation design approach maximizing benefits of integrated design and off-site production. This means achieving energy requirements

paying attention on the whole process. It is almost different from simple "recovering" strategy, Naturwall aims to define housing components able to activate dynamic and adaptive processes referred to the stresses coming from the external environment.
Facades play a fundamental role in the city renovation projects especially if the intervention runs up on buildings without remarkable architectural meaning and poor energy saving quality.
Naturwall prefab elements combine a self-supporting structure with insulation infill and panelling, which can be made by wide range of cladding materials (e.g. timber boards, timber panels, glass, aluminium etc.). High precision components like windows are easily integrated due to the modularity.

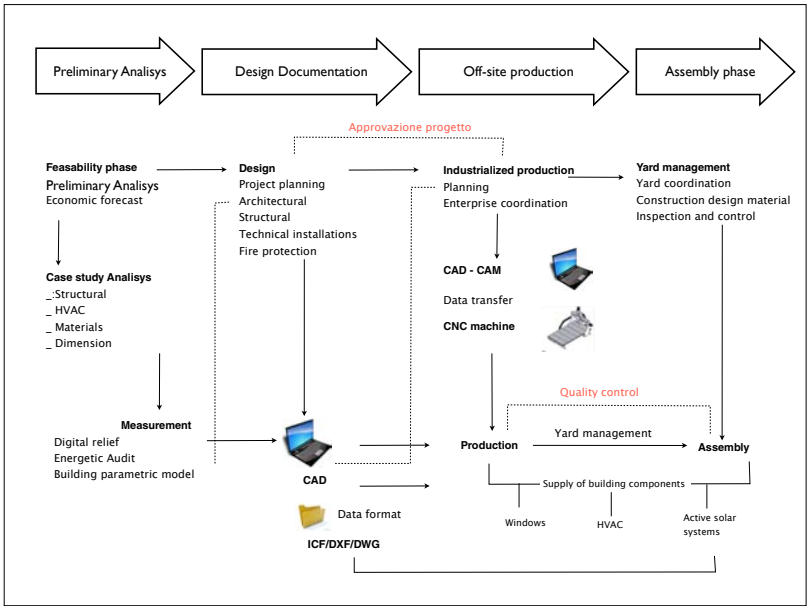

Fig 2: Naturwall workflow process (A. Spinelli, 2012)

Despite the use of wood in construction is increasing in Italy, the use of lightweight components in the intervention on the built environment remains an area of interest and research in our country. The aim of this project it's to propose a reflection about the opportunity gave by using industrialized system in the retrofitting approaches in urban spaces. permitting a deep renovation of the heritage that now shows problem of maintenance. The situation of the context, especially in urban dense areas, is very important to define a strategy that conceive the operative condition and time costing of the retrofit operation. One of the purpose of this research is the connection among design phase and construction, through the re-organization of the whole process with: digital measurement, planning off-site fabrication, on-site assembly, defining the instruments and phase necessary to bring the renovation to the end, evaluating all the issue and pay-back return. The Naturwall project take into account different ways for the application of that innovative component on the building. In particular, three main installation type have been considered: components applied on exiting envelope, components applied instead the existing envelope or components added to extend the building. All these types of installation request a preliminary survey of the building in order to put in evidence the critical points and study the best solution for the building renovation.

2.1.1 The role of relief phase

A specific relief phase, based on a dedicated methodology able to investigate in details the starting condition of the building, is necessary in order to collect important features and parameters necessary to conceive the component with respect to its performance, but also in order to reduces cost, resources and times in the whole design and fabrication process. During the production phase is important the availability of reliable and detailed measurements regarding the building. Since precision and reliefs devoid of errors are at the base of each solid design and correct inventory of the current state of a building, nowadays the simple 2D representations are no longer sufficient to serve the purposes of the field of architecture especially in the detailed metric measurement of the external facades. In the last few years, the employment of 3D laser scanning systems for the survey of exiting building - also complex - have been considerably increased due

to the advancement achieved by the recent hardware and software solutions. This technical improvements has boot a consequent decrease in the laser scanning services cost, that today are almost comparable with the traditional survey techniques. In addition, comparing the traditional survey techniques, the high level details achieved by laser scanning survey permits the correct dimension of the components during the off-site production phase achieving high precision (as an example, technical compartment for windows could be measured with a total error less than 5mm). Because the digital fabrication process based on CAD/CAM programs work mainly in two-dimensional mode, the 3D scan data allows the generation of any number of 2D representations such as plans, sections or views to understand the possible critical points during the fabrication process and design the component correctly. It is therefore possible to compare the measured data with the desired renovation project, detecting early warning of potential design errors and eliminating them even before the construction phase. This reduces the high liability risk of the requalification project, while the stringent requirements in terms of accuracy and profitability become calculable. In addition, the relief data could be directly imported in CAD/CAM programs and directly charged into CNC production machine, reducing the time necessary for the fabrication. Another advantage of the adopted method is given by the deformation analysis conducted on the façade, which allows to extract different important parameters in order to plan the most suitable installation program and conceive the proper support structure devoted to the component installation (bracket, trestles, etc.) with a consequent reduction in terms of resources and time

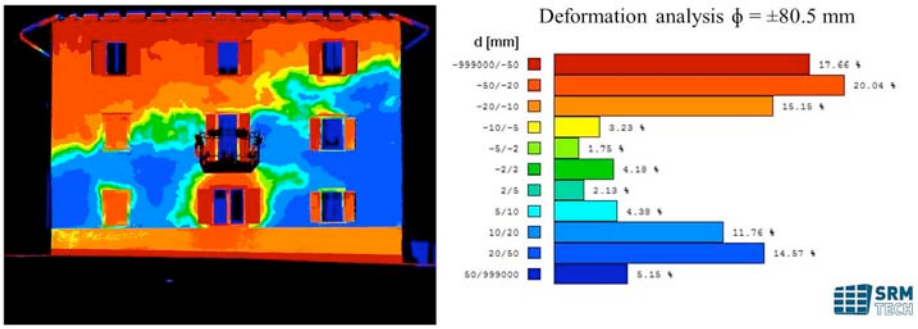

Fig 3: Deformation analysis of the west façade of an existing building (traditional '900 architecture) in Trentino, Italy.

during the place on the yard due to unforeseen critical points. As an example, in figure 3 is reported the deformation analysis on an existing building in Trentino Region where façade planarity error is higher than 20 mm in the 84% of the total surface.

2.1.2 The role of design phase

The designing phase could be focused as the main part of the process; the modern methods for measuring described above (i.e. Photogrammetry and 3D laser scanning) generate precise data of the target buildings in 3D-models, which could used for designing prefabricated components for renovating, and finally, for maintenance program. The dataflow matches the requirements of the digital process chain, from site measuring, planning to prefabrication. To exploit the best value of industrialized process we need to improve our instruments of investigation and communication. BIM method, for example, is an intelligent model-based process that helps professionals and enterprises achieving business results by managing more accurate, accessible, and actionable insight throughout project execution and lifecycle.

"The digital age has radically reconfigured the relationship between conception and production, creating a direct digital link between what can be conceived and what can be built", [7] the use of control machines within help of computer code permit to overcome the limit of standardization, variable information flow coming from design allows the manufacturing of components of various shapes, without any loss of time in production phase. The easy machinability of wood account this material for digitally controlled processes, thus provide an opportunity to incorporate the properties of material and inputs coming from construction and fabrication requirements, as parameters into the process. [8]

Timber design can be defined as the most modern method of construction in the market in terms of contemporary 'information society'. No other systems could explain better the relationship between technology, fabrication methods and architecture. [9] With an integrated design, you not only

evaluate the systems by themselves, but also as part of the overall energy consumption picture so that every action reinforces the others.

2.1.3 The role of production phase

When we manage a retrofit process, a shorter assembly on-site and fewer restrictions due to construction work compared to conventional renovation methods is a valuable quality for owner-occupied flats or buildings under operation. Some case studies made in Europe shows how it's possible to make a renewal project within inhabitants living in the "under construction" building.
In the timber construction sector, advanced methods of prefabrication are very successfully used in a contemporary practice to make new energy efficient buildings, and are consistently gaining market share.
Prefabrication allows the integration of building components such as windows, building services systems and ready-made surfaces of the facade elements in the controlled and ergonomic working environment of the factory. A flexible workflow from design to production allows for customised fabrication of single building parts to take into account the specific needs of individual buildings, e.g. size, unevenness etc.
Builders are actually prepared to achieve higher work productivity and manage rapidly the entire process, especially the assembly that is controlled from a strict design phase, which define the dimension of all pieces and modules. All parts of the system could be optimised in the workshop, e.g. material flow and efficiency, machine employment, etc . The work load on-site is minimised to the handling of just-in-time provided parts. This avoids organisational work, unproductive time, preparation work and enhances the productivity of the whole process.

2.1.4 The role of monitoring phase

In combination with an accurate metric measurement and deformation analysis of the building façade, a thermal analysis is conducted in order to evaluate environmental condition and characterize the building from the energy point of view. These analysis is important not only for the proper refurbishment of the façade in order to improve energy saving performances of the building, but also to realize a measurement campaign that characterize the performances of the installed components during their lifecycle. The survey methodology combines the most recent techniques for survey and modelling of the existing buildings with the thermal analysis (eventually merged on the 3D data volume), giving a sort of structural analysis and performance estimation of the building that will be suitable for a correct production of the components as cited before. By this way, a continuous improvement of the product in function of the different building environment conditions and landscape characteristics could be done.
In the economics of the operation, get feedback on the functioning of these modules and their performance, in order to improve their features on subsequent projects, is a key point; through the insertion of sensors it's possible to evaluate the parameters in a dynamic and active way, changing the characteristics of the housing envelope and the management system refer to geographical site and also provide real-time assessments of behaviour in various situations of intervention. This would ensure a performance audit of the housing within dynamic systems, allowing managing more accurately the service life of the building.

3. A refurbishment case study in Piedmont

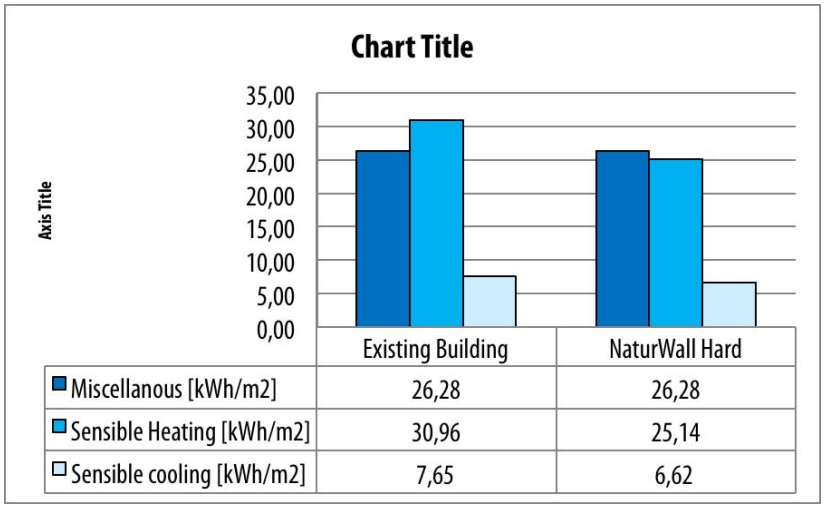

Fig 1: 4 Naturwall Case study model. Located in via Pietro Cossa in Turin. On the right the plan of the main floor.

Naturwall becomes a real program of intervention within Territorially Agency of Home (ATC) endorsement that has sustained our initiative permitting to develop some case study models to verify the feasibility of this retrofit strategy. Choosing a building more responsive to the average characteristics of the buildings made in the post Second World War period, we define a smart requalification process that combine Naturwall with other renewable systems to reduce the impact of those buildings towards "Net Zero Energy" home goal. The building is part of an expansion project in the suburbs of Turin in the '60 and are characterized by a poor energy saving envelope and low architectural value. By using Autodesk Design Builder© software tool we put in the baseline data coming from a preliminary energy audit and we studied the behaviour after introducing our new envelope system. The scope is to analyse how it works before and after the application of the Naturwall façade system. Evaluating the apartments of one floor, after calculating their annual consumption related to heating, cooling and electricity consumption, we simulated the addition of the new facade.
We use in this Naturwall system composed with local timber structure, cellulose insulation and ventilated glass facade (for external layer). Our intervention as be considered as a passive way to reduce consumption without using active systems, like as new technical installations or renewable energy.

The main results shows immediately a considerable percentage reduction of heating and cooling consumption and the increase of performances in energy saving envelope.

	Without retrofit	With Naturwall = Transmittance= 0,138 W/m^{2}K)
U_ Wall 1	0,486	0,11
U_ Wall 2	0,563	0,113
U_ Wall 3	0,561	0,113
U_ Wall 4	0,49	0,113

The table above shows the differences between transmittance values of the walls (that define the perimeter of the apartment) before and after installation of Naturwall system, the new partition have a behaviour in line within standards of new energy regulations in Italy.

The table above shows instead the reduction in term of energy consumption for square meter before and after the installation of Naturwall system. The amount of decrease it's around 15% of total energy consumed for square meter. Considering only the annually cost referred to heating and cooling consumption it represents an added value gain of 321 € for apartment. If we consider

electrical costs (Miscellaneous) the percentage drops to 6%.

4. Conclusion

Naturwall is a retrofit technological system that means to achieve energy savings requirements and restore contemporary building architectural aspect. Our building needs a restoration process to upgrade their performances and reduce the management costs and impact on the environment. With a deep preliminary study on the existing it's possible to make a detailed frame for the requalification process, inside of which can be define some work scenarios, finding the best solution for restoring quantifying the added value of regeneration. Materials, products, components and building techniques used in new buildings need to be further developed and adapted to the constraints of existing buildings. In terms of added value, the new envelope introduce a permanent solution that can be evaluate on a long financial term and achieving some incentives from Government, like as photovoltaic installations, we could widespread that practice of intervention. Multifunctional elemnts, including energy production installations, distribution and storage technologies, shall be integrated into the envelope system for building retrofitting.
For the final step of this research we are defining the cost of the component and its assembly phase on the yard, to develop a real payback return plan of the investment. Naturwall is an eco sustainable system, by using local wood materials to increase the ecological amount of the product and give new opportunities for woodworking local chain on out territorial land and develop a model for other country and define new business for enterprises in retrofit programs.

5. Acknowledgements

The outcome of the work had been possible thanks the work of Natural House (an italian PMI which offers wood construction services) and SRM TECH S.R.L (an Italian PMI which offers innovative solutions for real estate retrofit and refurbishment). The work was co financed by Fondazione Goria (Master dei Talenti della Società Civile).

1. Short Summary

Calculations carried out for renovations of generic single family buildings in Austria, Denmark, Norway, Portugal, and Switzerland show that the most significant reductions on greenhouse gas emissions and primary energy use are obtained by switching to a heating system based on renewable energies, yet that significant synergies exist when combining this with energy efficiency measures on the building envelope.

Keywords: Building renovation; cost-effectiveness; greenhouse gas emissions; energy efficiency; energy need; renewable energies; reference buildings; life-cycle-costs; insulation measures; renovation packages

2. Abstract

Energy use in existing buildings is a major source of energy consumption and greenhouse gas emissions in Europe. Until now related standards and regulations have mainly focused on energy efficiency measures reducing energy need; however, measures based on renewable energies might to some extent reach environmental objectives more cost-effectively. Consequently, there is a need to investigate the balance between these two types of measures, and related implications for design of and target setting in standards and regulations.

Calculations were carried out with a tool taking into account generic building characteristics of residential buildings in Austria, Denmark, Norway, Portugal, and Switzerland, related climate conditions, prices and emission factors of different energy carriers, as well as costs and effects of different renovation measures comprising both measures reducing energy demand and measures to use renewable energy. Results of these calculations show that a combination of measures reducing energy demand with measures to use renewable energies does not lead to large differences in terms of cost-optimal efficiency levels of the building envelope, compared to a situation when the energy carrier remains unchanged. At the same time, calculations show that the number of building elements included in building renovation determines energy performance of the building and cost-effectiveness of the building renovation more than the efficiency level of a single building element. Furthermore, a switch to renewable energy sources has been found to reduce emissions more strongly than energy efficiency measures.

As heating systems based on renewable energies usually have lower energy costs, it could be expected that the cost-optimal energy efficiency level of the building envelope is already reached at a lower ambition level, if a switch to renewable energies is carried out. However, the results

show that if measures reducing energy demand are combined with a replacement of the heating system, there are to a large extent synergies and not trade-offs between measures reducing energy demand and renewable energy measures, as demand side measures reduce peak capacity of the heating system which reduces initial investment costs more strongly for renewable energy systems than for conventional heating systems. At the same it can also be shown that in order to reduce the impact of buildings on primary energy use and greenhouse gas emissions, it is advisable to promote the renovation of several elements of the building at the same time and in particular to switch also to renewable energies, rather than setting higher energy efficiency levels for individual building elements.

3. Introduction

Standards and regulations for building renovations have focused until now mainly on energy efficiency measures reducing energy needs; however, measures based on renewable energies might to some extent reach environmental objectives more cost-effectively. Consequently, there is a need to investigate the balance between these two types of measures, and related implications for design of and target setting in standards and regulations for building renovation.

4. Method

4.1 General approach and framework conditions

Calculations are carried out with a tool taking into account generic building characteristics of residential buildings in Austria, Denmark, Norway, Portugal, and Switzerland, related climate conditions, prices and emission factors of different energy carriers, as well as costs and effects of different renovation measures comprising both energy efficiency measures reducing energy needs and measures based on the use of renewable energies. Calculations of energy needs take into account energy performance of the building envelope, outdoor climate, target indoor temperature and internal heat gains. Greenhouse gas emissions and primary energy use are calculated by taking into account conversion efficiencies of the heating systems and emission factors as well as primary energy factors of the energy carriers including up-stream emissions or energy use. The life-cycle-cost and cost-effectiveness calculations are carried out dynamically with the annuity method.[1],[2]

Table 1 shows the energy prices used in the calculations. Prices refer to assumed average prices over the next 40 years. The table contains empty cells, as only data actually used for calculations is indicated. By default, a 30% price increase for energy prices was assumed for the 40-years period compared to prices from 2010, if no official national projections on energy prices were available which is compatible with the price increases suggested to take into account by the EPBD regulatory framework.[2] A real interest rate of 3% per year is used.

Table 1: Assumed energy prices for households, including taxes.

Parameter	Unit	Austria	Denmark	Norway	Portugal	Switzerland
Oil	EUR/kWh	0.12	0.15	-	0.13	0.1
Natural gas	EUR/kWh	-	-	-	0.09	-
Wood pellets	EUR/kWh	0.08	0.08	0.1	0.3	0.08
Electricity	EUR/kWh	0.21	0.33	0.24	0.18	0.2

Emission factors and primary energy factors used include upstream emissions associated with the production, transport and delivery of these energy carriers. Country mixes for electricity are based on the sources of electricity consumed and not on the national production mix.

4.2 Reference buildings

Generic reference buildings which were investigated refer to single family residential buildings with a relatively low energy performance before renovation. Table 2 summarizes the assumptions made related to the generic reference buildings.

Table 2: Assumed characteristics of reference buildings for Austria, Denmark, Norway, Portugal, Switzerland before renovation.

Parameter	Unit	Austria - SFH	Denmark – SFH	Norway - SFH	Portugal – SFH	Switzerland SHF
Gross heated floor area (GHFA)	m^2	242	108	113	156.2	210
Façade area (excl. windows)	m^2	185	90	146	114.94	206
Roof area pitched	m^2	181	130	54	80.63	120
Roof area flat	m^2				5.43	
Attic floor	m^2		108			
Area of windows to North	m^2	10	5.86	2	2.66	3.3
Area of windows to East	m^2	9.1	1.3	1.7	8.6	8.3
Area of windows to South	m^2	10.0	13.92	13.6	5.55	13.2
Area of windows to West	m^2	9.1	3.2		10.69	8.3
Area of ceiling of cellar	m^2	145	108	51.1	74.4	80
Average gross heated floor area per person	m^2	60	27	28.3	31.24	60
Typical indoor temperature (for calculations)	°C	20	20	20	min 20 winter / max 25 summer	20
Average electricity consumption per year and m^2 (excluding heating, cooling, ventilation)	kWh/ ($a*m^2$)	22	44	26.5	23.51	22
U-value façade	$W/(m^2*K)$	1.4	0.46	0.5	1.1	1
U-value roof pitched	$W/(m^2*K)$	0.9	0.386	0.4	2.5	0.85
U-value attic floor	$W/(m^2*K)$		-			1
U-value roof flat	$W/(m^2*K)$		-		2.5	1
U-value windows	$W/(m^2*K)$	2.9	2.6	2.7	3.9	3
g-value windows	Factor 0.0 – 1.0	0.76	0.75	0.71	0.88	0.75
U-value ceiling of cellar	$W/(m^2*K)$	0.97	0.9	0.5	1.56	0.9
Energy need for hot water	kWh/m^2	14	22	26.5	24.5	14
Energy need for cooling	kWh/m^2				1.8	

4.3 Renovation packages

For each of the reference buildings investigated, series of measures are defined and applied in calculations as renovation packages.[1],[2],[3] Starting from the reference case, which implies some rehabilitation measures without improving the energy performance, nine renovation packages are investigated denominated M1 to M9 which have progressive ambition levels related to the resulting energy performance of the building. Renovation packages distinguish themselves both by the number of building elements included in improvement of energy performance, and in the thickness of the chosen insulation or in the U-value of the chosen window. A replacement of the heating system is assumed in all cases. For each reference building, combinations with three different types of heating systems are considered.

For the generic calculations in Austria, the following renovation packages on the building envelope are investigated:

- Reference: In the reference case, the wall and the windows are repainted, and the pitched roof is refurbished. These measures do not improve the energy performance of the building.
- Renovation package M1: The wall is insulated with 12 cm of mineral wool.
- Renovation package M2: The wall is insulated with 20 cm of mineral wool.
- Renovation package M3: The wall is insulated with 40 cm of mineral wool.
- Renovation package M4: Additionally to M3, the roof is refurbished including membrane, roof battens, shuttering, gutter and 14 cm of mineral wool insulation
- Renovation package M5: Additionally to M3, the roof is refurbished including membrane, roof battens, shuttering, gutter and 30 cm of mineral wool insulation
- Renovation package M6: Additionally to M5, the cellar ceiling is insulated with 8 cm of mineral wool.
- Renovation package M7: Additionally to M5, the cellar ceiling is insulated with 12 cm of mineral wool.
- Renovation package M8: Additionally to M7, the windows are replaced with new windows with a wooden frame and a U-value for the entire window of 1.0.
- Renovation package M9: Additionally to M7, the windows are replaced with new windows with a wooden frame and a U-value for the entire window of 0.7.

For the generic calculations in Denmark, the following renovation packages on the building envelope are investigated:

- Reference: In the reference case, the joints in the wall are repaired and windows are repainted. These measures do not improve the energy performance of the building.
- Renovation package M1: The cellar ceiling is insulated with 8 cm of rock wool.
- Renovation package M2: The cellar ceiling is insulated with 12 cm of rock wool.
- Renovation package M3: Additionally to M2, the roof part of the building is insulated with 14 cm of granulate on attic floor.
- Renovation package M4: Additionally to M2, attic floor is insulated with 30 cm of granulate on attic floor.
- Renovation package M5: Additionally to M4, windows are replaced with new windows with a wooden frame and a U-value for the entire window of 1.6.
- Renovation package M6: Additionally to M4, windows are replaced with new windows with a wooden frame and a U-value for the entire window of 1.
- Renovation package M7: Additionally to M4, windows are replaced with new windows with a wooden frame and a U-value for the entire window of 0.7.
- Renovation package M8: Additionally to M7, the wall is insulated with 12 cm of rock wool.
- Renovation package M9: Additionally to M7, the cellar ceiling is insulated with 30 cm of rock wool.

For the generic calculations in Norway, the following renovation packages on the building envelope are investigated:

- Reference: In the reference case, the wall is refurbished and windows are repainted and repaired. These measures do not improve the energy performance of the building.
- Renovation package M1: Windows are replaced with new windows with a wooden frame and a U-value for the entire window of 1.2.

- Renovation package M2: Windows are replaced with new windows with a wooden frame and a U-value for the entire window of 0.8.
- Renovation package M3: Windows are replaced with new windows with a wooden frame and a U-value for the entire window of 0.7.
- Renovation package M4: Additionally to M3, the cellar ceiling is insulated with 8 cm of mineral wool, plasterboard.
- Renovation package M5: Additionally to M3, the cellar ceiling is insulated with 12 cm of mineral wool, plasterboard.
- Renovation package M6: Additionally to M5, the roof is refurbished by insulating the ceiling of the attic floor with 20 cm of mineral wool.
- Renovation package M7: Additionally to M5, the roof is refurbished from the outside with an insulation of 43.5 cm in an airtight construction.
- Renovation package M8: Additionally to M7, the wall is insulated with 15 cm of mineral wool in a ventilated construction.
- Renovation package M9: Additionally to M7, the cellar ceiling is insulated with 40 cm of mineral wool.

For the generic calculations in Portugal, the following renovation packages on the building envelope are investigated:

- Reference: In the reference case, the wall is refurbished by cleaning with vapour and preparing the surface to apply a new coating system, the pitched roof is repaired by replacing the cover material (clay tiles) and the wood windows are repainted. These measures do not improve the energy performance of the building.
- Renovation package M1: The roof is insulated with 5 cm of XPS.
- Renovation package M2: The roof is insulated with 8 cm of XPS.
- Renovation package M3: Additionally to M2, the cellar ceiling is insulated with 4 cm of XPS.
- Renovation package M4: Additionally to M2, the cellar ceiling is insulated with 5 cm of XPS.
- Renovation package M5: Additionally to M4, the compound wall is refurbished with 4 cm of ETICS – EPS.
- Renovation package M6: Additionally to M4, the compound wall is refurbished with 6 cm of ETICS – EPS.
- Renovation package M7: Additionally to M4, windows are replaced with new windows with a metal frame and a U-value for the entire window of 2.7.
- Renovation package M8: Additionally to M4, windows are replaced with new windows with a metal frame and a U-value for the entire window of 2.5.
- Renovation package M9: Additionally to M4, windows are replaced with new windows with a metal frame and a U-value for the entire window of 2.3.

For the generic calculations in Switzerland, the following renovation packages on the building envelope are investigated:

- Reference: In the reference case, the plastering of the wall is restored, the wall is repainted, and the roof is refurbished, yet all those measures do not improve the energy performance of the building.
- Renovation package M1: The wall is insulated with 12 cm of mineral wool.
- Renovation package M2: The wall is insulated with 30 cm of mineral wool.
- Renovation package M3: Additionally to M2, the roof is insulated with 12 cm of mineral wool.
- Renovation package M4: Additionally to M2, the roof is insulated with 36 cm of mineral wool.
- Renovation package M5: Additionally to M4, the cellar ceiling is insulated with 10 cm of mineral wool.
- Renovation package M6: Additionally to M4, the cellar ceiling is insulated with 16 cm of mineral wool.
- Renovation package M7: Additionally to M6, windows are replaced with new windows with a wooden frame and a U-value for the entire window of 1.3.
- Renovation package M8: Additionally to M6, windows are replaced with new windows with a wooden frame and a U-value for the entire window of 1.
- Renovation package M9: Additionally to M6, windows are replaced with new windows with a wooden frame and a U-value for the entire window of 0.8.

5. Results

The following graphs summarize the resulting cost effectiveness, greenhouse gas emissions and primary energy use of renovation packages with different heating systems. For each reference building investigated, graphs show the relationship between greenhouse gas emissions or primary energy use and life cycle costs, on a yearly basis and specific per m^2 heated area. In each graph, three different curves are shown, representing the application of the different renovation packages on the building envelope in combination with the installation of different heating systems. Each dot in the curves represents the application of a different renovation package. The point with highest emissions or highest primary energy use represents the reference case. As more measures are added to the renovation packages, emissions and primary energy use decrease.

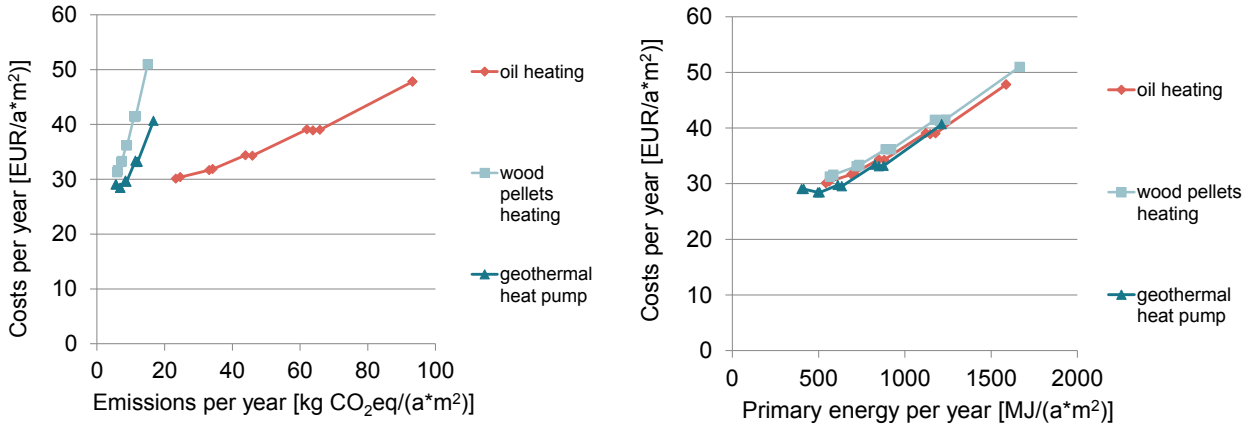

Fig. 1: Comparison of cost effectiveness of energy efficiency renovation measures for different heating systems and related impacts on greenhouse gas emissions and primary energy use in Austria

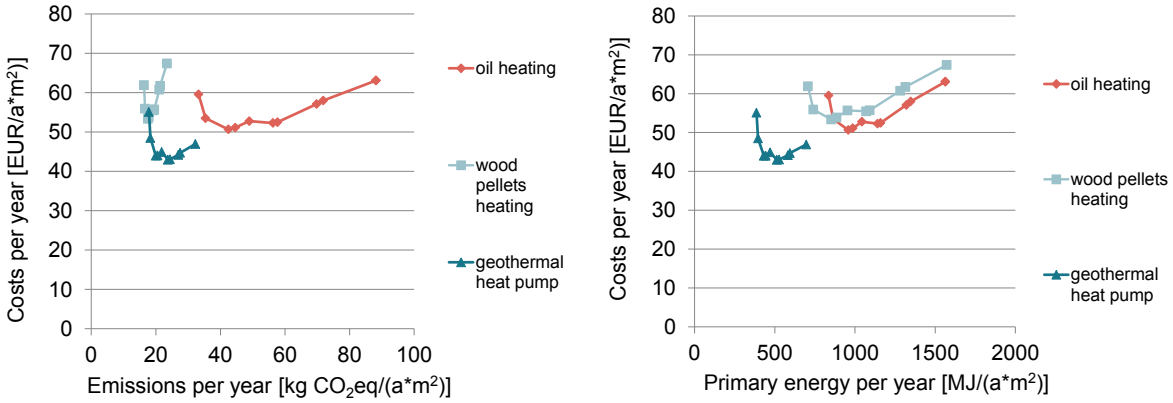

Fig. 2: Comparison of cost effectiveness of energy efficiency renovation measures for different heating systems and related impacts on greenhouse gas emissions and primary energy use in Denmark

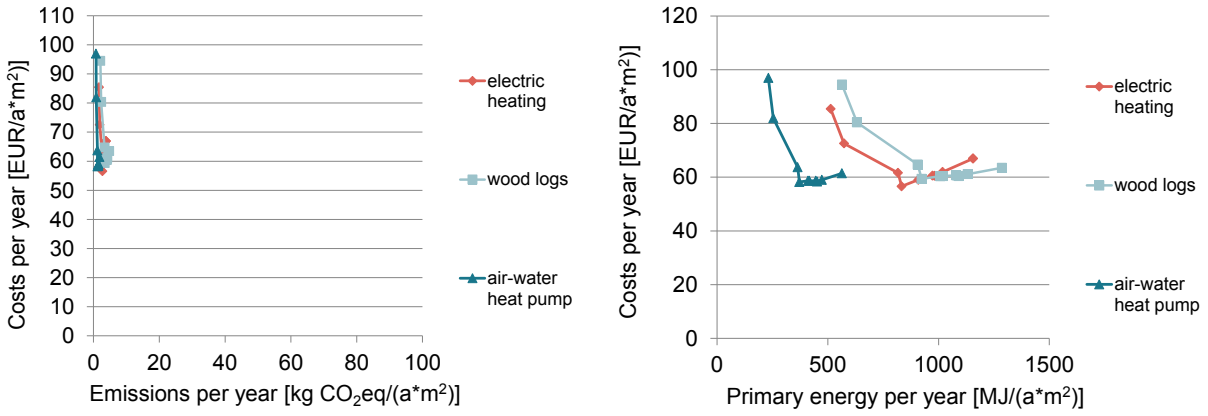

Fig. 3: Comparison of cost effectiveness of energy efficiency renovation measures for different heating systems (note: the systems here are electric heating, wood logs and air-water HP) and related impacts on greenhouse gas emissions and primary energy use in Norway

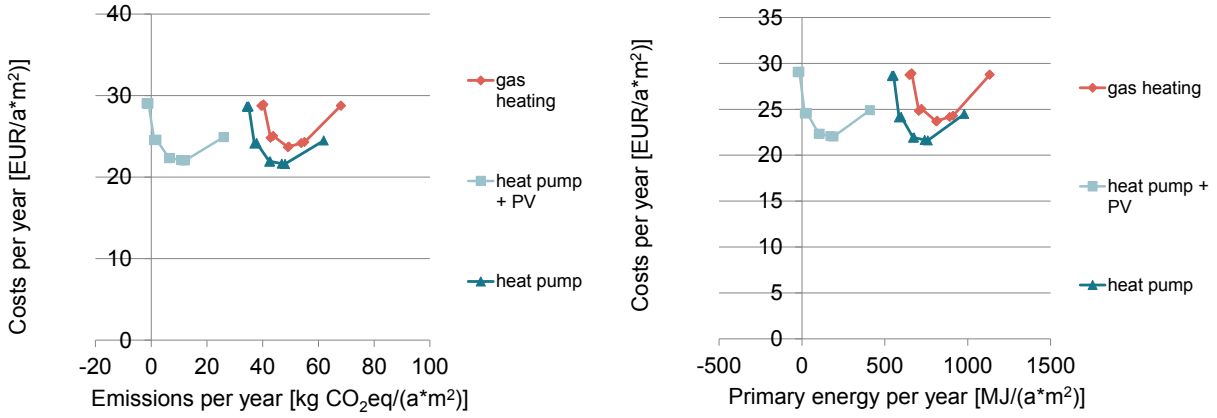

Fig. 4: Comparison of cost effectiveness of energy efficiency renovation measures for different heating systems (note: the systems here are gas heating, heat pump + PV and heat pump) and related impacts on greenhouse gas emissions and primary energy use in Portugal

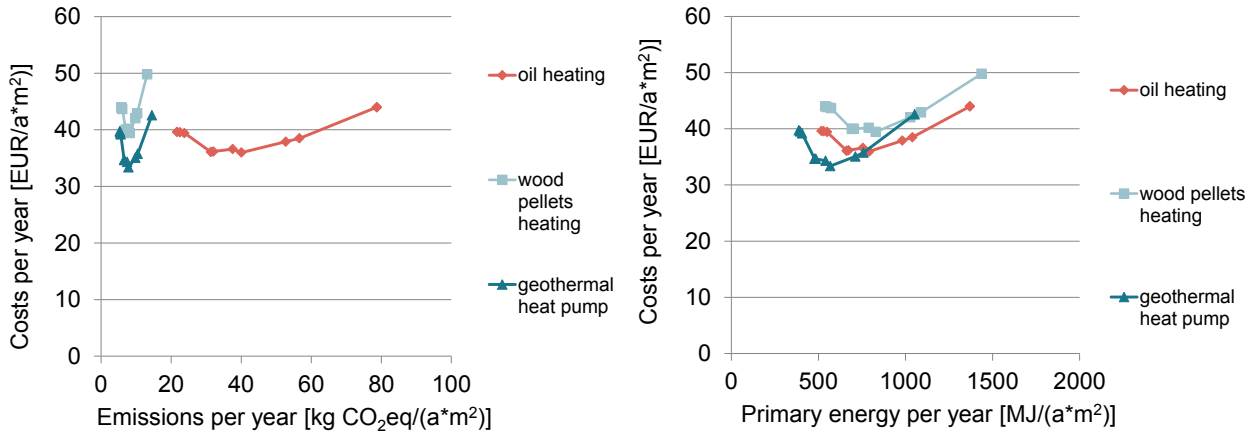

Fig. 5: Comparison of cost effectiveness of energy efficiency renovation measures for different heating systems and related impacts on greenhouse gas emissions and primary energy use in Switzerland

In the graphs as shown in Figures 1 to 5 it can be recognized that a change of the heating system shifts the curves significantly towards lower primary energy consumption and greenhouse gas emissions. The effect is more pronounced for greenhouse gas emissions than for primary energy use if switches from fossil fuels and renewable energy systems are considered. It is observed that a switch from fossil fuels to renewable energy sources reduces emissions more strongly than energy building envelope efficiency measures. However, as compared to a switch to renewable heating systems building envelope efficiency measures might have a larger effect on the reduction of primary energy consumption. As a particular case are the low greenhouse gas emissions for all curves for the building in Norway, because in Norway the electricity mix is mostly free of greenhouse gas emissions, and for the calculations in Norway no fossil fuel based systems have been taken into account. Instead electric heating is assumed as conventional energy system.

When looking at the shape of the curve, it can be seen that they are similar for all curves for a given building. If a renovation package is cost optimal, i.e. if the related dot is closest to the minimum of one of the curves, it is usually also close to the minimum in the other curves. This shows that the cost-optimal ambition levels for energy efficiency measures on the building envelope do not differ strongly for different choices of heating systems. However, note that the cost optimum may be quite different across the different heating systems, particularly with regard to greenhouse gas emissions as well as with regard to primary energy consumption.

At the same time, it can be seen that within a single curve, there are usually some renovation packages, as symbolized by individual dots, which are close together in the curve, whereas between others there are larger differences. The large differences refer to changes in the number of building elements taken into account by the renovation packages, whereas changes in the thickness of insulation or in the U-values of the windows lead only to small differences for the related renovation packages both in terms of costs and greenhouse gas emissions or primary energy use. This shows that the number of building elements included in building renovation determines energy performance of the building and cost-effectiveness of the building renovation more strongly than the energy efficiency level of a single building element.

6. Discussion

As heating systems based on renewable energies usually have lower annual operational energy costs than conventional heating systems, it could be expected that the cost-optimal energy efficiency level of the building envelope is already reached at a lower ambition level, if a switch to renewable energies is carried out. However, the results show that if measures reducing energy need are combined with a replacement of the heating system, there are to a large extent synergies and not trade-offs between energy efficiency measures reducing energy need and renewable energy measures. This can be explained by the fact that demand side measures reduce peak capacity of the heating system which reduces costs more strongly for renewable energy systems with higher initial investment costs than for conventional heating systems. For heat pumps, there is an additional synergy between energy efficiency measures and renewable energy measures, as heat humps work more efficiently if the energy need is lowered by energy efficiency measures on the building envelope. It could also be shown that in order to reduce the impact of buildings on primary energy use and greenhouse gas emissions, it is advisable to promote the renovation of several elements of the building at the same time and also to switch to renewable energies, rather than setting high energy efficiency levels for individual building elements. The results underline in particular the importance of changing to a renewable energy based heating system and to combine this with energy efficiency measures on the building envelope in order create synergies.

The findings are specific to the reference buildings investigated, yet these reference buildings are drawn from different countries and take into account different framework conditions, which strengthens the conclusions derived. Nevertheless, the results remain sensitive to several assumptions, in particular to energy prices and the energy performance of the buildings prior to renovation. The results could be further tested and refined by pursuing the research on the input data, by extending the comparisons to more reference buildings for other building types, energy characteristics, countries, or climate zones, and by taking into account also other renovation

measures which are not investigated here, for example ventilation, solar thermal energy, building automation or energy efficient devices.

7. Acknowledgements

The research has been carried out within the framework of Annex 56 of the Energy Conservation in Buildings and Community Systems programme of the International Energy Agency. Support from the Swiss Federal Office of Energy is gratefully acknowledged. The authors gratefully thank Jørgen Rose, Julia Maydl, Karin Anton, Karl Höfler, Kirsten Engelund Thomsen, Manuela Almeida, and Marco Ferreira for providing data on reference buildings and national framework conditions. The authors furthermore gratefully acknowledge the use of a tool for calculations developed by the Eracobuild project INSPIRE and related input by Claudio Nägeli, Davide Maneschi and Sonja Kallio.

Management and financial tools for housing regeneration

Paola Piermattei

Short Summary

Social housing stock in Italy is actually in a profound state of decay; it shows multiple critical elements that range from poor overall energetic performance, to traditionally lower class occupants with related difficulties in solvency to the scarcity of available economic resources needed to act on it in adequate manner.
The concept of a building as an energy consumer is well understood and has been ingrained in all plans linked to energy saving. Limiting energy consumption has become the key point of all policies, laws and regulations issued in the past ten years. We can add to this the paucity of available economic resources.
Based on what I have outlined, is important to identify the possible economic and managing tools that can generate usable resources to requalify social housing. This becomes possible by linking together the building's potential characteristics switching from an energy consumer to an energy producer view, analysing the technical capabilities that come from the exploitation of renewable energy sources (i.e. photovoltaic). The revenue that comes from the sale of the energy produced by the building can create an interesting investment opportunity, albeit without the profit margins that come with traditional investments, and with a longer ROI.
The concept of the building as an energy producer is one that generates a worthwhile reflection in the search for new paradigms needed to close the gap between the need to intervene and the scarcity of economic resources for residential housing.
Due to the evolution of technical solutions for building envelope ever more performing in terms of thermal comfort, and building systems (in particular for thermal and electrical photovoltaic systems), the possibility of having surplus energy with respect to the building's consumption resalable on the market has grown. This surplus (there are a number of case studies on the subject in Italy and abroad; we mention here the pilot study in the town of Reggio Emilia in the FRESH European framework) represents the keystone to radically change the concept of all that purports to the production and management of the housing. The operators who will be capable of working in this revolution are, thus, companies that deal with energy. Escos (Energy Service Companies) in particular come into play both in new developments and in requalification through third party financing operations, bearing the full cost of the operation and obtaining a revenue from the energy bill before and after the operation.

Keywords: Social housing, energy management, economic and financial processes, public-private partnership

1. Introduction

The research, policies, strategies and operational tools that revolve around the theme of "social housing" are going through a period of profound change in Italy. The term "social" is changing its meaning in relation to both the building stock of reference, and to the target users, and to any operational possibilities for the planning and implementation of interventions.
The term is used to indicate housing designed and built to satisfy the basic need of housing in

relation to a user group that is not able to access the free market. They are traditionally houses built by the state using non-repayable economic resources.
Because of the conditions of low solvency of the user group, and the inability for the public administration to make a return on rents, blocked by the fair rent mechanism, social housing is usually considered in terms of the budget as an item of expense necessary to cope with a social emergency.
It is necessary, however, to distinguish between the interventions of Economic and Popular Construction (Edilizia Economica e Popolare - ERP) and those that are more generally referred to as social housing, intended for the poorer part of the population, constructed by a special agreement between the builder (usually a cooperative) and the public administration. In this case, the rents are still controlled, but provide higher figures than those of the ERP.
Most ERP interventions took place in the period of economic boom in the years '50-'70, in an age of widespread speculation and employed technical solutions aimed at solving a problem of quantitative emergency rather than directed towards quality building. The urgent need to renovate this heritage to make it functional at least with respect to the starting conditions of use is strongly felt and necessary today.
To this situation is added the need to deal with the environmental emergency, with the demand for evermore efficient performance parameters relating to fuel economy, the performance of the building shell in terms of thermal insulation, and the operation and building organism in both winter and summer.
Welfare policies in Italy in recent years have come to a grinding halt because of the ongoing economic crisis. The public administration presently does not have access any more to its traditional channels of procurement; non-repayable resources are disappearing, and, again because of the economic crisis, the portion of the population that might require accommodation in a subsidised rent setting is constantly growing. The central problem today is therefore the difficulty in redeveloping and managing the social housing assets; the reasons for this difficulty have to do not only with the need to improve technical performance, but above all with the scarcity of available economic resources.

2. The crisis in the social and economic sector

2.1 From the lower-middle and middle classes to the grey users

Until a few years ago the target users for social housing were made up exclusively of people belonging to social categories at risk, with no income, who accessed ERP rankings more easily the more their general living conditions were considered to be precarious. It was a social class that, all things considered, was homogeneous and stable, in which the conditions of poverty and lack of cultural education went hand in hand, very different from the lower-middle and middle classes who could usually access the private building market.
The crisis and the ongoing economic uncertainty has impoverished and rendered unstable segments of the population that previously formed the backbone of the Italian social fabric, creating a new category of user and one that is difficult to place within well-defined boundaries.
It is a group of "grey" users, with changing and undefined characteristics, no longer economically stable, borderline, which can live in relative economic ease at times and at others slip below the poverty line. This user category has features in common with the bourgeoisie from which it comes as well as with the target users of affordable and popular housing, among which the most significant is the lack of economic stability required in order to gain access, for example, to a traditional bank loan.
The presence of this group of users, which is so fragile and numerically increasing, makes the question very complex and problematic. The crisis affecting the social housing sector is closely connected to the crisis that is affecting the construction industry in general, also with respect to the private housing market.
The marked difference that existed one time between users who took advantage of lodgings at controlled rents and those who turned to the free market of renting and buying is no longer so clear. The separation between the lower middle class and 'grey' users is increasingly blurred, because entering into crisis is the whole area of the middle class, increasingly devoid of fixed points and security with respect to the labour market.
The data for the annual CENSIS report on the situation of the country in 2012 show a worrying and

widespread situation. The collapse of the economic capacities of the middle class is evident (there has been a collapse of the share of wealth of the middle class of between 50,000 and 500,000 euros, and including real estate, which declined from 66.4% to 48.3%.), and this occurred in favour of the already well-off segments of the population (the proportion of households with a net financial wealth of more than 500,000 euros in fact doubled, from 6% to 12.5%). The social divide has increased at the expense of middle-income classes. Over the past ten years, in fact, net financial wealth has gone from 26,000 to 15,600 euros per family, a reduction of 40.5%.
It is important to consider that one of the characteristics of the grey band is a capacity to produce income albeit in a discontinuous manner. So it is not only the population that is traditionally not solvent that is the recipient of affordable and popular housing, but people who are working on a casual basis, that is, not constantly enough to gain access to the free market (for example, to get a bank loan), but at the same time with an economic power that exists even if it is variable depending on the labour market. The grey band is the place where we find the “jobseekers”, identified by Censis 2012 as a segment of the population that is increasing (+34.2% between the first half of 2011 and the first of 2012), active, relatively young (between a quarter are 35 and 44 years old, another quarter in the older brackets, while the others are under 35) which is currently being pressed by the current economic situation due to the lack of job prospects.
The expansion of this user category is also invading segments that up to a few years ago were destined for the private market, broadening the question to what is defined as current residential construction, i.e. the portion of the housing stock typically allocated to the main house of the middle class.

2.2 The collapse of public and private investment in the construction industry.

Everything that has to do with building in Italy, and not only social housing, has suffered a sharp decline in recent years in terms of the economic resources available and possible investments. The collapse of the private housing market has affected a sector that traditionally was able to drive the overall economy of the country in a very strong way, contributing significantly to the stagnation of the current economic crisis. This situation is fully described at various territorial levels. The European Commission Communication to Parliament and the Council of 31/07/2012 (COM2012 433 final) on the Strategy for the sustainable compatibility of the construction sector and its enterprises underlines (referring to the Eurostat press release 169/2011) the presence of a severe crisis in the construction sector, with a drop in the carrying out of building and infrastructural works of 16% occurring between January 2008 and November 2011. At local level, referring to the city of Rome, a relevant indicator of this situation is provided by the decrease recorded within the private housing market. From the note published by the Territorial Agency for the Valuation of the Real Estate Market in the first quarter of 2012, a decline of 20% in sales compared to the data of the previous quarter was witnessed.
If the construction market is in crisis, equally in crisis is the situation regarding access to public resources that can be spent on housing and in particular on social housing.
Public resources currently available and in the process of disbursement cannot alone solve the problem because they are not sufficient to put in place extensive programs of intervention on the housing stock. The concept is disappearing of the disbursement of resources in the form of non-repayable grants, because those provided are not sufficient. These resources also, where available, are not always adequately used. Given the conditions of low solvency in the user group, both in relation to that which traditionally was the recipient of ERP housing and considering the grey band, more solvent but variable, it is not possible to consider the construction and management of social housing as a profitable investment in relation to the absorption of rents. In some cases, the resident population in social housing is not only not able to bear the cost of the rent, however reduced, but not even able to pay energy costs, generating the complex phenomenon of fuel poverty.
One of the key issues is therefore related to the possibility of attracting investors interested in operating in a segment of the housing stock that traditionally has been unprofitable; the very investors plunged into a comprehensive crisis by the economic crisis. If the public administration is no longer able to bear the costs for the redevelopment of social housing, it is equally complicated to turn to forms of public-private partnership. It is necessary to attract the interest of someone willing to invest in a sector that does not pay, a supposed “cold work” to use the term from project financing, destined, that is, at least apparently, to not produce income.

3. Energy management as a resource

3.1 From consumption to energy production

To the question of the possibility of having a space to live, we have to add that of lowering the consumption, and therefore the costs, related to the energy management of the building. In Europe, social housing is made up of approximately 25 million housing units, of which more than half have an energy consumption of over 150 kWh/sq.m/year. In Italy, the social housing stock is traditionally "dated" in time and built between the early 1900s and the '50s and '60s. 80% of this stock needs energy upgrading.
The policies of the last decade have made great strides in this direction dealing with the issue of limiting consumption, with the aim of creating building structures that are as self-sufficient in terms of energy as possible, all the way to considering the building not as a consumer but a possible energy producer.
Because of changes in the energy market in fact, the ability to produce energy independently of the networks of national production has been made possible by the spread of large-scale technologies related to solar energy. The spread of procedural and economic mechanisms for the autonomous management of energy, the presence of state incentives for the diffusion of these same tools, and a growing widespread awareness of environmental issues, is leading to an increasingly large number of individuals choosing to operate in this field.
The concept of energy sustainability is now closely linked to economic sustainability; we assume the cost of installing plant capable of producing energy because this has advantages at an economic level that are perceptible albeit in the medium and long term. The market also is rapidly absorbing the growth and spread of new products able to operate in this way.
At the basis of the concept of economic sustainability is that of self-financing; creating a building structure that is autonomous in terms of its needs regarding plant operation means becoming independent of the traditional channels. It is precisely the energy market operators, primarily the ESCOs (energy saving companies), private companies which invest by paying the costs relating to the intervention, in the expectation of a financial return that comes from the management of the same, that are able to offer possible solutions as regards it.
Thinking in terms of energy production may represent an element of interest for those who are able to make a profit from the management of the same, freeing themselves from the condition of being resident users. A structure with high energy efficiency also improves its functioning (and therefore its performance in economic terms) if the general conditions of the same, the shell and plant, are optimal.
This kind of operation is possible through the use of appropriate management and budgetary tools. The intervention of the ESCOs is in this sense a great opportunity. They have an interest in improving the energy functioning of a building because they can achieve a profit from the management of the same, through instruments (such as energy performance contracts) that guarantee the ESCO a profit that comes directly from the collection of the energy saving. In layman's terms, the more a building consumes less and produces more, and the more the energy bill is lowered, the more the ESCO is able to earn. The redevelopment of the building stock, with the consequent increase in technical and energy performance, offers, in this sense, an interesting perspective.

3.2 The European Project FRESH and the pilot case in Reggio Emilia

A case study in this sense is represented by the European Project FRESH (Financing Energy Refurbishment for Social Housing), which has just ended and whose results are being evaluated, which in Italy was carried out through a pilot case in the Municipality of Reggio Emilia.
The project opened up a discussion whose aim was precisely that of reflecting on the relationships between the various parties involved in operations of third-party financing with the help of an ESCO. In particular it has used, analysed and implemented the forms of contract that can be stipulated in these cases. The EPC (Energy Performance Contract) contract is proposed as a large-scale solution (but applicable and improvable in line with specific cases) for energy upgrading in social housing.
The project was carried out with a number of experiments that took place through contracts in

several states of the European Union on upgrading the energy efficiency of buildings destined to social residential use. In particular, the countries involved were France, Italy and the UK. The buildings chosen as pilot projects were built in the ‘80s, with the prevailing construction technology based on the use of concrete with a high consumption of resources in the phase of use.
The Italian pilot project consisted in entrusting the provision of energy services in a building for public residential use under the management of the Reggio Emilia ACER located in the Municipality of Reggio Emilia. It is a small building (a total of 13 apartments), built in the ‘80s. The building envelope was made with precast concrete panels with an interposed insulating panel; the air conditioning plant, run on natural gas, did not ensure adequate performance in energy efficiency.
The call for tenders involved the renovation of the heating system in order to obtain enough savings in fuel consumption that could repay the intervention itself as well as the cost of the energy service made up of the conduction of the air conditioning systems (inclusive of extraordinary maintenance) and the operation and maintenance of heating systems, as well as ancillary services including the provision of fuel for the heating plant in winter.
The main objective of the intervention was to achieve in the first year of activation energy consumption savings of 35% in terms of primary energy use as well as a reduction in energy costs of at least 35% of the expenditure currently incurred. The project is now finished, with satisfaction on the part of the users both in terms of savings and quality of life.
The profit for the service contractor, in this case, comes from the retention of a portion of the energy savings achieved through the redevelopment. From the collection of that fee, which occurs for a given number of years stated in the contract, also comes the coverage of costs incurred in the intervention. It is obvious that the success of such operations depends on the ability to use the technologies available on the market and to organise both technical and managerial competences.

4. Open issues and possible strategies

4.1 Self-reliance and economic sustainability

The goal of economic sustainability, understood as self-reliance, can be pursued only through a careful reflection on the instruments currently able to operate in this way.
The open questions on the subject, which have to be answered in the near future for this revolution to become feasible at the operational level, involve various aspects.

4.1.1 The operators in the energy market: problems and potential

The first aspect concerns the operational difficulties encountered by those working in the energy market.
The problems deriving from the spread of forms of partnership involving the intervention of ESCOs are of a different nature. On the one hand, a low diffusion of the phenomenon corresponds to a lack of knowledge of the same. The disbursement of a loan granted to an ESCO by a bank, for example, can no longer be connected to the existence of any guarantees (as is the case in traditional lending mechanisms), but to the obtainment of the promised results in terms of improvement in energy performance. The evaluation of this type of factor presupposes the presence of adequate technical knowledge, not yet possessed by the operators present in the market.
The skills required of an ESCO, on the other hand, range from the technical to the managerial and financial, since the ESCO proposes to manage the operation overall. The purely technical and financial aspects, moreover, are more closely connected than in the past for other management operations of the housing stock, given the close connection between the savings achieved and the use of technical equipment capable of generating precisely those savings. To this is added the difference in performance compared to operations carried out in the construction market. In the phase prior to the start of the economic crisis there was a period of great speculation, with very high earnings for builders and investors. Currently the instruments connected to third-party financing with the help of ESCOs provide longer payback times with earnings that are lower and diluted over time.
To this is added the relationship with users; they, while no longer entering the game as potentially paying customers, are the recipients of the interventions, and have to be assisted in order to work together to make the right choices. Given that users traditionally resident in social housing do not

have the appropriate skills to fully understand such complex interventions, there is a need for great transparency and simplicity in communicating what is actually being accomplished.

4.1.2 Possible public resources to guarantee private investments: the Funds

The need to entice ESCOs to enter a market that is traditionally unprofitable led to the birth of funding mechanisms through Funds, particularly the funds of the Cassa Depositi e Prestiti (Deposits and Loans Fund). The ESCOs are considered, in this case, as possible beneficiaries such as private citizens and condominiums, or as public bodies, for certain types of intervention relating to the improvement of the building shell and plant through appropriate and/or innovative technologies.
The Cassa Depositi e Prestiti is a joint-stock company 80% controlled by the Ministry of Economy and Finance. It is subject to minimum reserve requirements by the European Central Bank as all banks are. The resources it channels through the funds therefore are not grants, but real investment arrangements that foresee the interest of a bank and the possibility of a return, through which it is possible to finance the fund itself. Such a return, albeit non-speculative and with low margins, must be present. Since 2009 the operations of the Cassa have extended to the possibility of financing projects of public interest such as those related to social housing.
Among the available and active funds and the financing channels promoted by the Cassa Depositi e Prestiti is the revolving Kyoto fund. This fund has an initial budget of 600 million euros. The fund is called “revolving” insofar as it is fed with the instalments of the repayment of loans, and has been available and operational since 16 March 2012. It can be used and combined with other incentives, such as those relating to the issuance of Green Certificates, Third and Fourth Energy Account, and incentives for the production of electricity and heat. Between 2012 and 2013 the objectives of the fund have remained essentially the same with a few variations. The request for funding in the years 2012 and 2013 was very high, and exhausted very shortly after the activation of the requests, which could be made through an IT portal.
The same concept forms the basis of the European Energy Efficiency Fund (EEEF), connected with the European objectives of 202020. In this case too, possible recipients are the ESCOs but also the social housing associations. The concept behind this type of instrument is that of attracting public and private capital to promote partnership initiatives aimed at solving environmental problems.
The importance of this modus operandi is fundamental from the point of view of seeking to create forms of guarantees for investors operating in sectors of high risk and collective interest; the impulse coming from the public administration in terms of incentives is very important to create the initial lever to trigger a mechanism of this sort. The same concept is at the basis of the operation of the incentives for the production of energy from renewable sources, which have increased energy production from photovoltaic sources enormously in recent years. The report “Statistical data on electricity in Italy in 2011,” by Terna shows, in terms of net production, a decline in thermoelectric production (218.5 TWh against 221, -1.1%) and hydroelectric (47.2 TWh against 53.8, -12.3%), and a significant increase in the contribution of the other renewable sources of wind, solar and geothermal (25.8 TWh against 16, +61.2%).
Among these photovoltaic is the most relevant technology, because of the enormous increase of production recorded which is equivalent to +499.2% (10.7 against 1.9 TWh) which has far exceeded the already very considerable result of 2010 (+177%). In 2011 the number of operating photovoltaic systems reached 330,306 (of which 174,329 were connected to the grid in the last year of reporting).

4.2 From the building to the city

The idea of energy self-production involves not only the operative possibilities on single buildings, but more widely the satisfaction of a need of a collective character.
The analysis carried out on the possibilities of intervention on a building stock that is problematic both in terms of the intrinsic characteristics and the conditions of the users, such as those of social housing, reveals potential for use by reasoning on a different scale, that of the city.
Going up in scale, in fact, and considering the possibilities for energy production no longer from the single building but from the block, the sector, the small size of the neighbourhood, we enter into the logic of the smart city understood as a set of individuals working collectively to solve single

problems.
From the point of view of energy production adding together the energy production of groups of houses rather than focusing on the efficiency of individual buildings is undoubtedly more productive in terms of the amount of energy produced and possibly residual energy as a surplus to be placed on the market. If it is this surplus that acts as a lever to move from the concept of a building as energy consumer (with the resulting energy savings in various forms), to a building as a structure that is energetically as independent as possible (aiming for the solution of the passive house at zero consumption), to a building as producer of energy (deciding how to use the energy produced) and as a producer of economic resources, it is necessary to find a way to develop collective strategies to help this become possible. The conditions of the built heritage in Italy involve an urban core that often is very compact, and for this reason concentrating on the production efficiency of a single building is not always convenient precisely because it operates within a built context in which the technology linked to solar collection cannot always be effective. The energy efficiency of a technological solution can be influenced by the relationship with other buildings, in terms of orientation, shadows, management issues, the shape of the building itself. The same house if transported to an empty space with the right exposure could make much more energy if it were not wedged in a built-up area that is often very compact; but at the same time the presence of a compact built-up area, with buildings similar in their original constructive technology, and numerically significant, allows choices to be made that are more convenient by adding together the energy production of a number of units.

5. Conclusions

Thinking in terms of buildings as potential producers and not just as consumers of resources, and using the earnings resulting from the management of the energy produced from the buildings for the redevelopment of the social housing stock, can bring benefits both in terms of the quality of life of the resident users and in terms of new investments to be made on the market, generating a potentially effective economic induced activity.
The social housing sector has been, in recent years, the subject of numerous research projects in Italy and abroad, mainly aimed at the development of innovative solutions especially at the technical level. These solutions, without adequate financial resources to allow their large-scale diffusion, risk remaining examples of an excellent technological level but destined to have a low take-up in practice, limiting themselves to the development of prototypes of a very high technological quality and high-impact innovation, but without the possibility of becoming widespread on a large scale. Within this framework, it is important therefore to consider the connections between technical possibilities and the management-economic ones that can be used to promote the redevelopment of the social housing stock in a concrete way.
To summarise and conclude, the two main issues that need to be developed in the near future relate to:

- The need to make interesting and appealing to the eyes of a private investor possible redevelopment interventions on the existing. This need might be addressed by linking redevelopment to the introduction of systems and technologies for the production of energy. The ultimate goal is that of redeveloping in a sustainable manner, considering the economic aspect, above all related to energy production linked to the introduction of photovoltaic systems. At the basis of this type of intervention is the overturning of the common way of thinking about the house as something that consumes resources, focusing rather on the fact that through the introduction of appropriate technologies it is possible to produce energy resources which, if managed correctly through the use of appropriate management tools, can be transformed into opportunities to produce economic resources. These opportunities range from the possibility of using the energy produced for the running of the home and the services related to it, in order to create a structure that is as independent as possible from the point of energy.
- The need to think in a collective way rather than stopping at the individual instances of the single case. This request comes from considering the request for energy/economic production collectively, no longer being interested in the single building but in groups of houses arranged in blocks, sectors, larger groups than a single building. This is how possible solutions to a problem like the apparently limited one of social housing can be used for the redevelopment of a building and social fabric that is numerically much more

significant and complex. This involves on the one hand the possibility of producing energy in a more rational and efficient way, but the other leads to problems both from the point of view of the management of the service and from the point of view of the management of possible initiatives.

A reflection undertaken to solve a social emergency can be transformed, if properly managed, into a resource capable of generating mechanisms that can also be used elsewhere with potentially beneficial effects for the rest of society.

Catalogue of passive house details for refurbishments

1. SYNOPSIS

The IBO catalogue of passive house details for refurbishments [1] is a comprehensive resource for solutions for refurbishments tasks. Construction and connection details, checked for their physical, ecological and technical properties are offered to designers, the building trades and producers of building materials.
Typical refurbishment tasks like roof space conversion, basement drainage, façade renovation are treated systematically.
Ecological and hygienic aspects are pivotal for the evaluation of innovative solutions. This paper uses examples of façade and basement renovation to demonstrate the comprehensive approach used in [1].

2. INTRODUCTION

Refurbishment of existing buildings to comply with the passive house standard or refurbishments using passive house components may lead to savings in terms of heating demand from 75 % to 90 %. Conventional refurbishment will realize less than half of this potential. Refurbishment with passive house components guarantees a marked improvement of physical safety in terms of condensation and mould development. Most notable benefits are comfortably high temperatures of inner surfaces and good indoor air quality.
The catalogue is structured according to

- building tasks – encountered in buildings from the 19th century to the 80s of the 20th century, mainly in central Europe with a focus Germany and, especially, Austria. In this paper we present two solutions for renovation of base and basement slabs presented
- regular cross section – items are ordered according to building components, detailled as regular cross sections and connections and evaluated. In this paper we present a façade renovation with passive house qualities.

- recurring problems of thermal renovation with passive house components like moisture or harmful substances in existing buildings, basement climate and slab foundations in contact with ground without moisture seal. In this paper we present an climate optimization for a basement

For details of methodology see [1]

3. RESULTS

3.1 Building tasks

Treated are buildings from the 19th century to the 1980s, mainly in central Europe with a focus Germany and, especially, Austria.

Buildings are listed in order of age:

- buildings built before 1918
- buildings built between 1920 to 1950
- buildings of the 1950s and 1960s
- buildings of the 1970s
- massive buildings of the 1980s
- prefabricated lightweight buildings of the 1980s

Fig 1. shows an example of a refurbishment detail in 2 variations for a building built before 1918 with solid brick outside wall and vaulted ceiling.

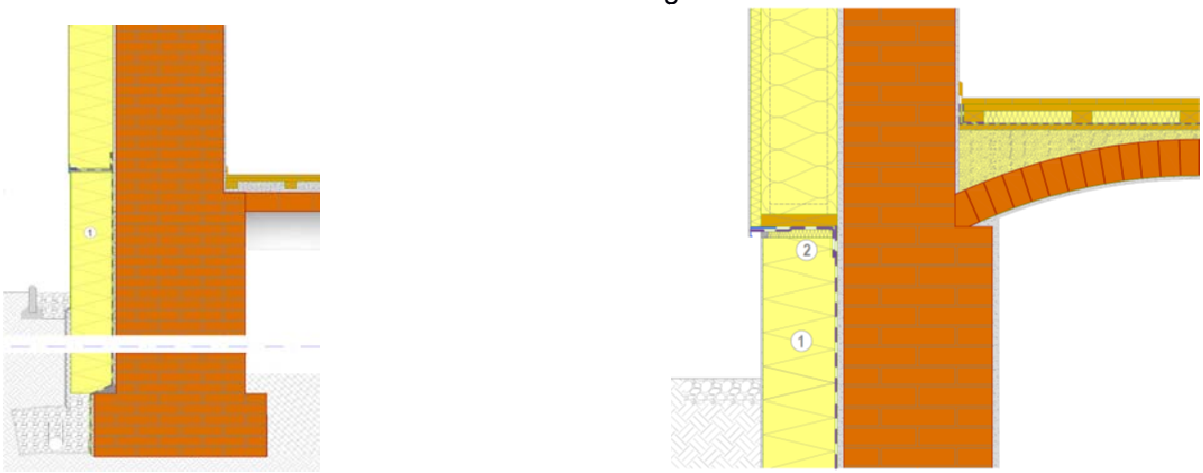

Fig 1. Example of a refurbishment detail: detail with 2 variants for a building built before 1918 with solid brick outside wall and vaulted ceiling (Notice: Variant basement floor insulation is insulated on the perimeter only at those parts of the basement wall which are in contact with outside air)

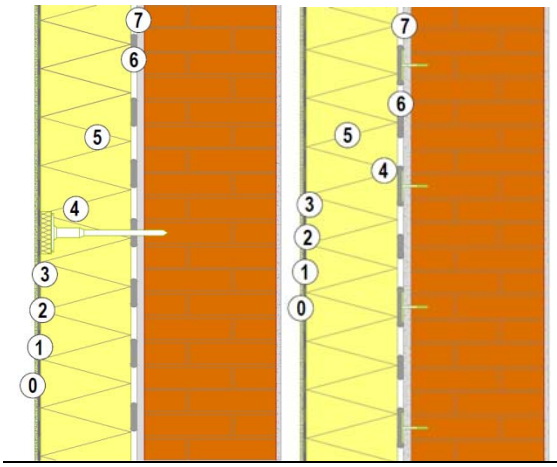
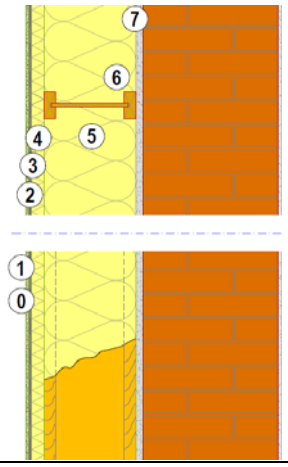
3.2 components of passive house retrofit

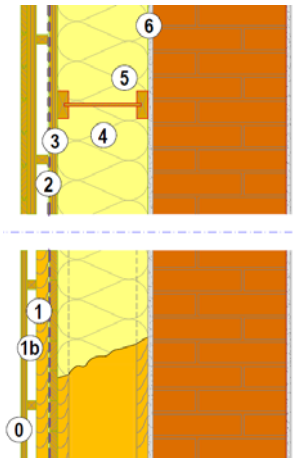
Overview

Items are listed according to building components and detailed as cross sections and connections



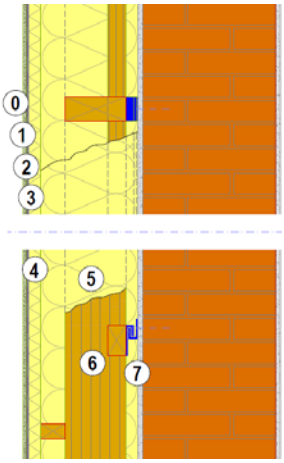


- Insulation materials – Overview and ecological evaluation
- Outside thermal insulation of outside walls



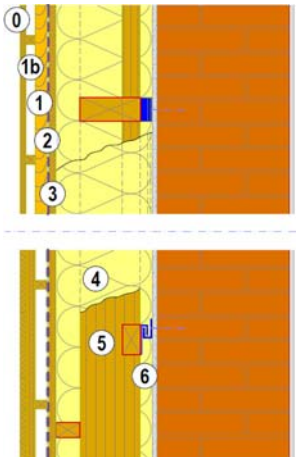
- Inside thermal insulation of outside walls
- Thermal insulation of steeply pitched roofs
- Thermal insulation of flat roofs
- Thermal insulation of uppermost floors
- Basement slabs thermally insulated upper side
- Basement slabs thermally insulated lower side
- Thermal insulation of foundation slabs
- Outside thermal insulation of basement walls in contact with ground
- Balconies and loggias
- Windows
- Ventilation systems

Example: Ecological amorisation in façade renovations

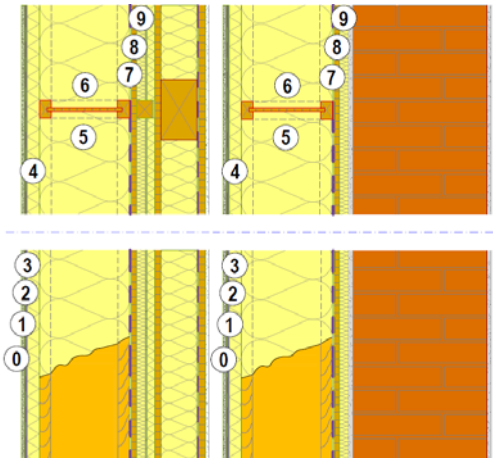


For an outside wall thermal insulation one may consider rear ventilated or composite (ETICS) systems, plastered or non-plastered systems, glued ot mechanically fastened systems (Fig 2). Systems may differ in

- level of prefabrication
- fastening technique (glued or screwed)
- flatness tolerance and tolerance for adhesiveness of existing surface



ETICS	Wood construction built on-site, plastered
	
Wood construction, built on-site, rear ventilated	Prefabricated wood construction, insulation material inserted on-site, plastered



Prefabricated wood construction, insulation material inserted on-site, rear ventilated

Wood construction. Prefabricated including insulation material, plastered

Wood construction, prefabricated including insulation material, rear ventilated

Anchored on-site

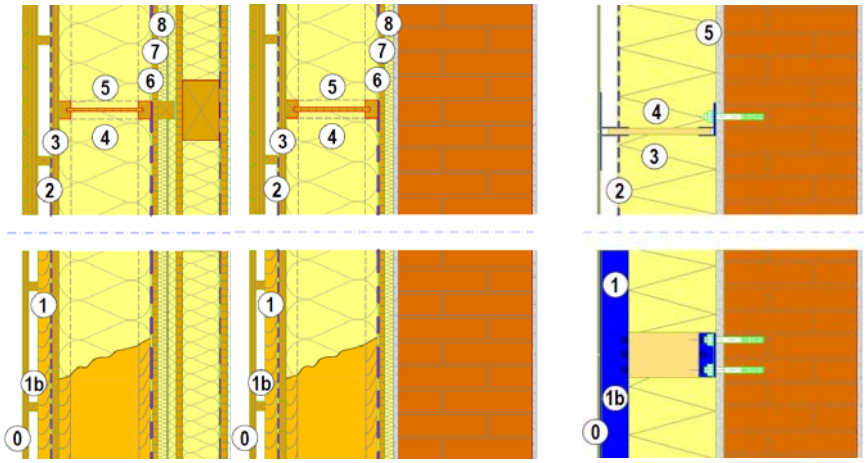


Fig 2: Regular cross sections analysed in detail in [1]

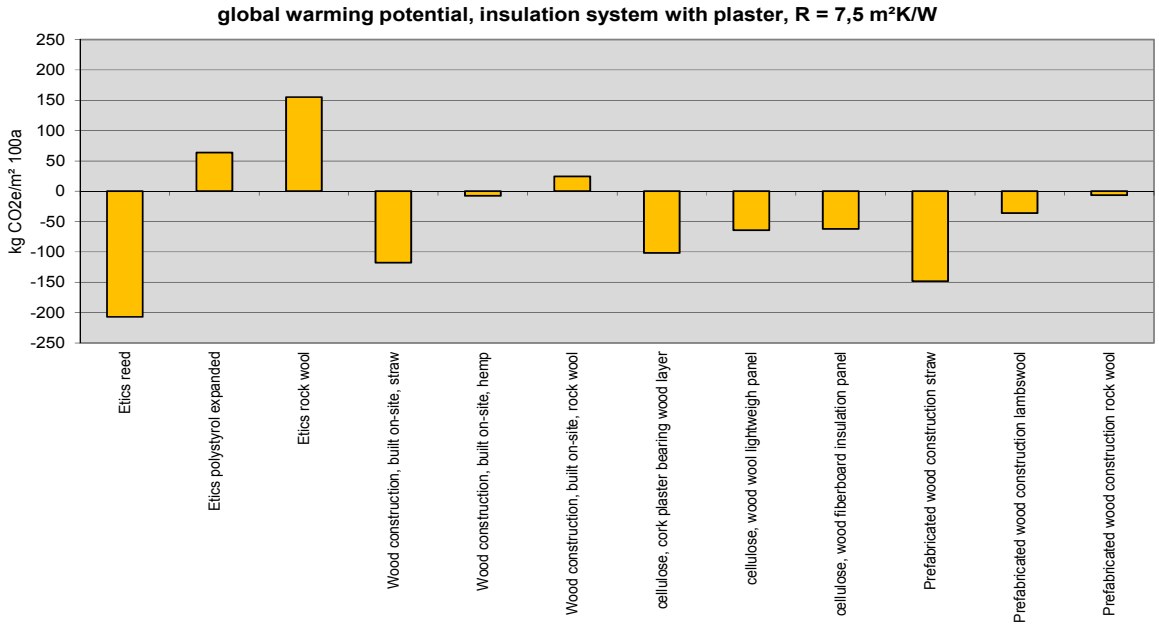
Summary of physical considerations



Thermal insulation must not be ventilated with cold air at the rear side. No cracks or clearances must connect warm and cold areas. As existing walls may not be flat, their surfaces must prepared according to norms and regulations.

Air-injected insulation materials will fit to uneven surfaces. Systems with inflexible insulation materials (ETICS) or prefabricated insulated constructions require filling of rear air gaps which is a disadvantage. Sound insulation will be improved in almost all cases, depending on properties of the existing wall and flexibility of the surface layer. ETICS systems may with inflexible insulation materials may reduce sound insulations properties in some cases. Using thicker layers of plaster or choosing more flexible insulation materials may prevent such problems. Moisture protection of insulation systems is dependent on the finishing/quality of outer surfaces:

- plastered systems allow for high moisture diffusion and hydrophobic properties against driving rain at the same time if modern coatings (silicate or silicate resin plasters) are applied
- rear ventilated systems separate both functions with advantages in moisture diffusion properties

Summary of ecological considerations

Ecological impacts of production of refurbishment components are dominated by impacts resulting from thermal insulation material production (Fig 3). All other required building materials have comparably small impacts resulting from production. Systems produced with minor processed insulation materials show favorable low values.

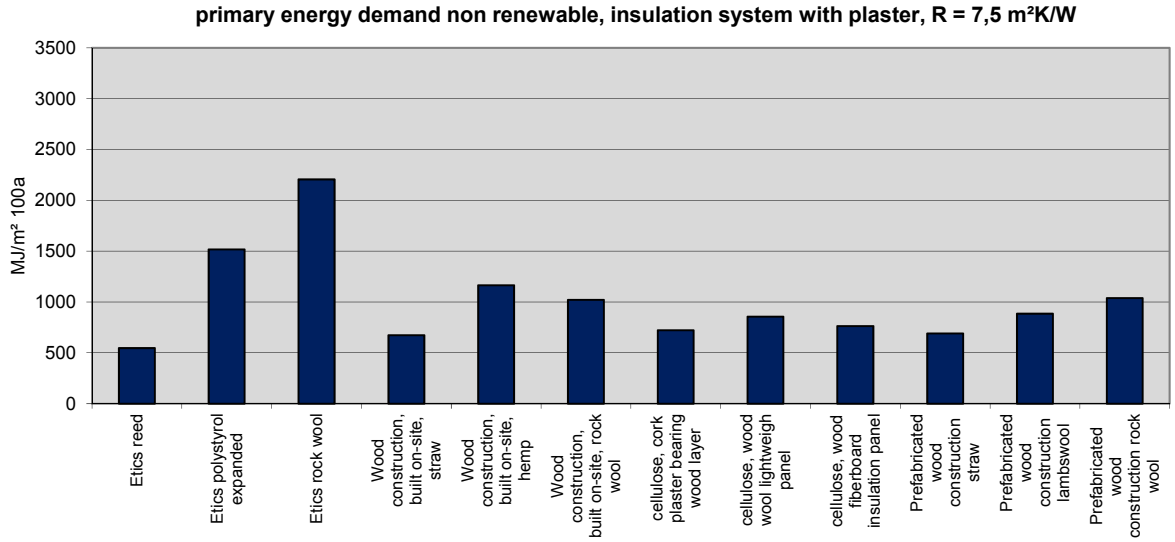


Fig 3: Global warming potential and primary energy demand non renewable of production and maintenance of different insulation systems an different insulation materials, with plaster, 100a

Expenditures for production of refurbishment components are to be balanced against achievable heating energy savings resulting from minimized heat transmission losses.

Fig 4 balances expenditure in terms of global warming potential (GWP100) of production and maintenance of an ETIC system with EPS-F panels (λ = 0,04 W/mK) against heating of a building with natural gas to a level of 20 °C in a typical central European climate varying thickness of insulation

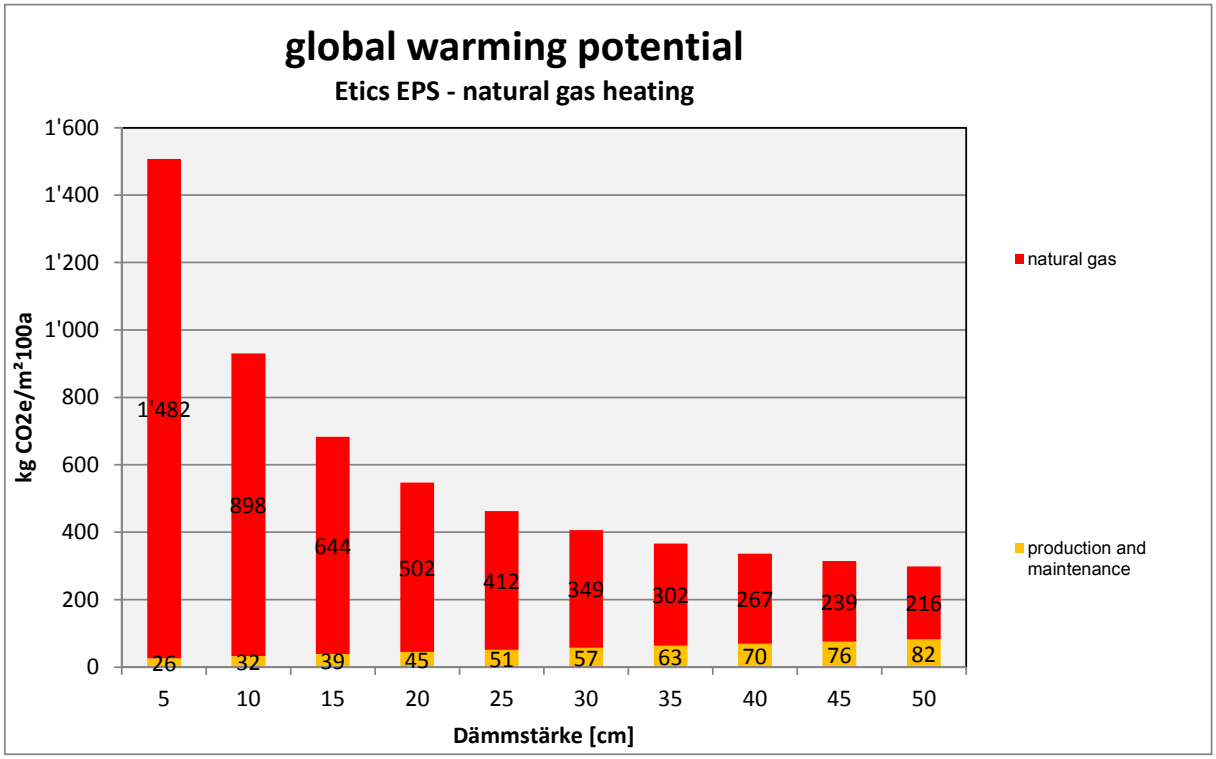

Fig 4: Global warming potential of production of an ETIC system plotted against layer thickness (incl. Exchange of materials within 100 years) assuming heating with natural gas to compensate heat transmission losses

Fig 5 shows decreased values of global warming potential (GWP100) as result of refurbishment depending on thickness of insulation material layers and heating system

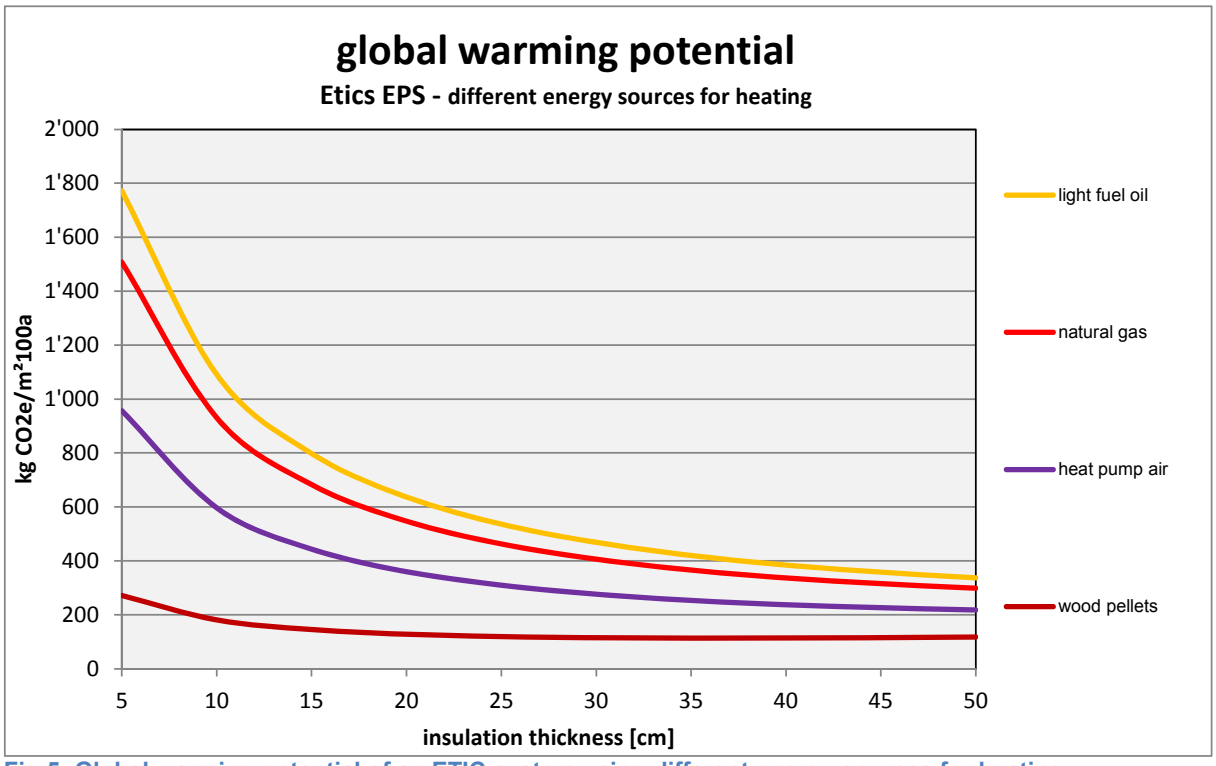

Fig 5: Global warming potential of an ETIC system using different energy sources for heating

Optimum values of insulation material thickness in EPS ETICS are beyond 50 cm in most cases. Only with wood pellets heating and CO_2-neutral combustion there is a minimum of expenditure at 35 to 45 cm insulation material thickness. Thermal insulation with EPS, an ecologically less favorable insulation material, should be applied with thicknesses required for the passive house standard. Optimum thickness is even higher with insulation materials that carry more favorable ecological expenditures of production.

Building site workplace exposure is the sum of exposures resulting from individual components. Protection measures are mandatory especially for air injection of insulation materials incurring considerable dust emissions. Prime coatings may emit large quantities of solvents.

Disposal properties of a construction differs with separability into its components and with their suitability for material and energetically use.

Construction details are evaluated regarding deconstruction, recycling and disposal according to methods developed in [2]. The following table shows results of a disposal rating of selected variants of an outside wall outside thermal insulation. A 30 cm brick work (dressed stone of brick) with inside lime cement plaster is assumed as outside wall.

Insulation material variants listed are installed to this wall:

Plastered insualtion system	**Note**
30 cm ETICS with EPS panels (disposal of brickwork due to contamination)	6,7
30 cm ETICS with EPS panels (recycling of brickwork despite of contamination)	4,9
34 cm ETICS with meineral foam panels	3,3
30 cm I-beam with cellulose fibre, plaster on 4 cm wood wool lightweight panel	3,0
30 cm wood frame with wood fibre insulation, plaster on 4 cm wood wool lightweight panel	1,2
Rear ventilated insulation system	**Note**
30 cm cellulose fibre between I beams with wood shuttering, wood façade on wood lathes	2,6
30 cm cellulose fibre between wood construction1	1,1
30 cm EPS panels fixed with anchors, mounted with dowels in the brickwork, aluminum facade on aluminum substructure	2,0

General topics of thermal refurbishment with passive house components

- Moisture in existing buildings
- basement climate and floor slabs in contact with ground without sealing
  inside insulation in refurbishment
- microbial fouling on façade surfaces
  design aspects
- harmful substances in existing buildings
- disposal options of typical demolition waste

Example: High grade refurbishment with improvement of basement climate

Problems of thermal and hygric conditions in basements can be described as:

- If an insulation is applied to basement ceilings, temperatures in the basement will decrease by several degrees depending on ventilation and thermal bridges
- With absolute humidity remaining constant, relative humidity will increase steeply, mould may develop in certain conditions.
- Moisture contents at the surfaces may vary with sources of humidity (surface water (pavement!) ground water, soil conditions, use-specific sources like laundry including drying) and with ventilation intensity.

Two variants of thermal refurbishment of a base in a building built before 1918 are used to demonstrated our comprehensive evaluation procedures (Detailed drawings see above).

- Variant 1 Umbrella-type insulation. Basement wall insulated until down to the foundation slab, basement ceiling slab is not insulated
- Variant 2 Insulation of basement ceiling slab, base is insulated only partly where in contact with outside air

Technical and physical evaluation

Technical effort for the variant „umbrella-type insulation“ is large

- the whole basement wall has to be excavated, securing of the excavation pit is dependent of soil conditions
- in many cases an excavation of the foundation for insulation and sealing work is not feasable

In the case of the variant „basement ceiling insulation“ the perimeter insulation and the sealing extends only 50 cm above the part of the wall in contact with outside air. The basement ceiling slab is insulated upper side (alternatively: lower side):

- Technical effort is considerable for removing the existing floor in order to install insulating fills and to reinstall a new floor
- Effort to insulate the base at the outside is small

In the variant with basement ceiling slab insulation downward heat transfer ist reduced significantly. In the variant with umbrella-type insulation vertically intruding water can be kept away.

Calculations of hygrothermal behaviour were made using a 3dimensional simulation program Ham4D, which was developed at the Technical University of Vienna, and which is capable of reproducing all relevant humidity and heat flows (simulation period is 100 years). Water content and relative humidity of the umbrella-type insulation variant in a settled state is shown in Fig. 6 and 7:

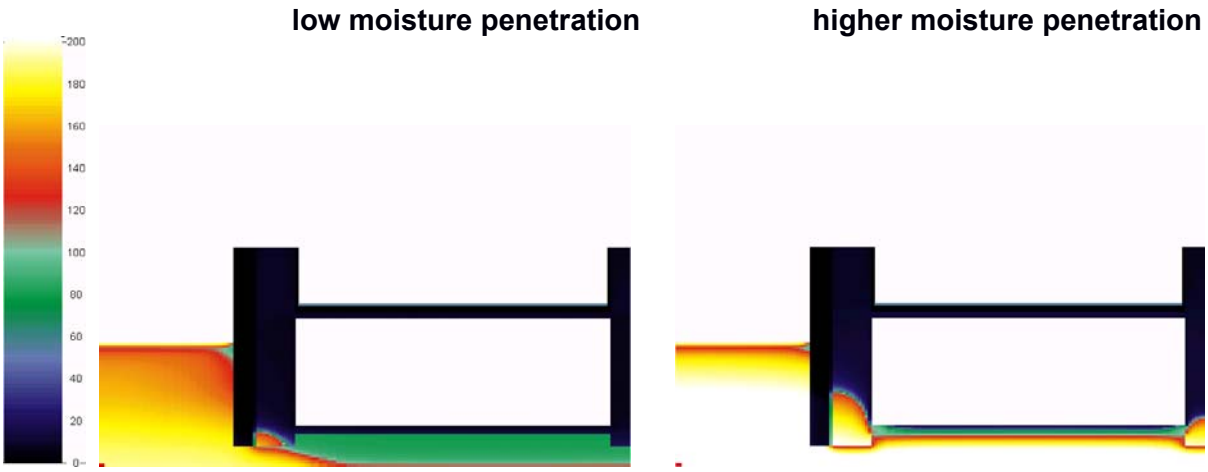

Fig 6: Water content [kg/m³] with lower or higher moisture penetration and an air exchange of 0.1/hr (1 January)

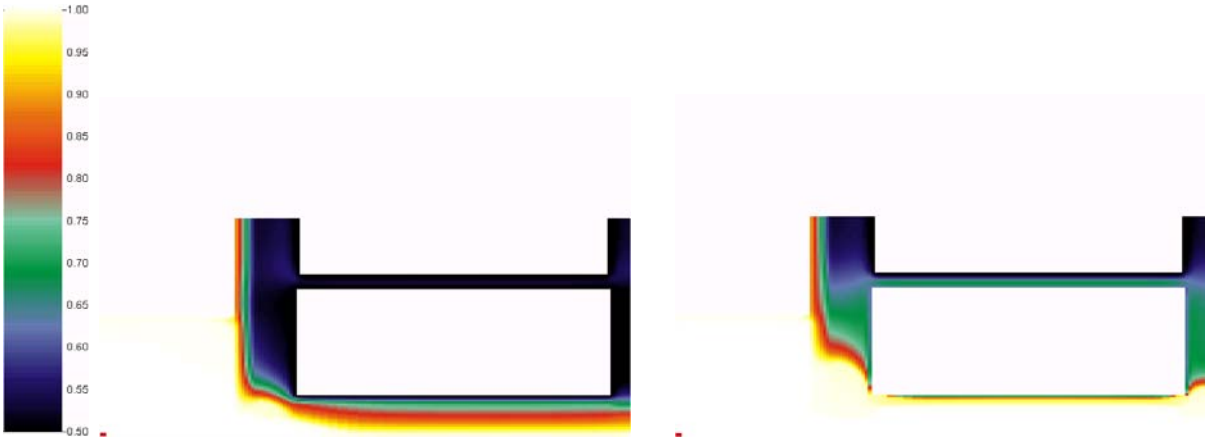

Fig 7: Relative humidity with lower or higher moisture penetration and an air exchange of 0.1/hr (1 January)

In principle relative humidity is directly dependent of brickwork moisture penetration and of air exchange. The refurbishment variants have similar effects on the room climate independent of the level of moisture penetration. In principle thermal improvements of the thermal envelope of the building should be preferred to achieve an increase of temperature in the basement and thus a reduction of relative humidity. All kinds of thermal refurbishments of a basement will increase humidity problems and need to be combined with accompanying measures like an adjusted ventilation of the basement.
An optimal thermal refurbishment of a basement is not only dependent on insulation thickness but also on moisture penetration in the floor in contact with ground and in the brickwork and dependent also from air exchange rates with outside air.
The following comparison (Fig 8) shows relative humidity of a basement at different air exchange rates and different degrees of moisture penetration.

low moisture penetration **high moisture penetration**

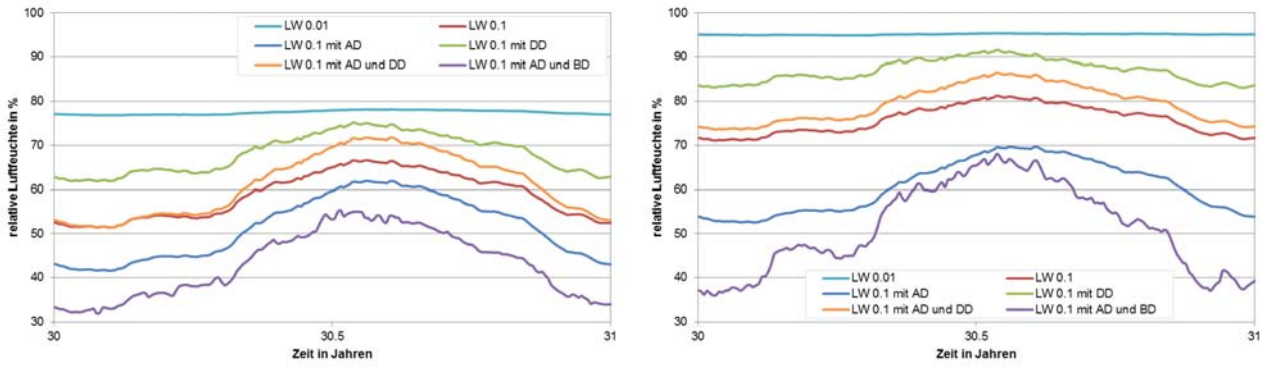

Fig. 8: Relative humidity at different degrees of moisture penetration comparing all refurbishment variants (LW = air change cellar; AD: exterior wall to outside and to ground insulated; DD: basement ceiling slab insulated; BD: cellar slab insulated)

Moisture penetration in a construction has no marked effect on temperature distribution. Only in the variant with floor insulation, with reduced moisture input on account of the additional floor construction, temperature follows a slightly different curve.
The following figure 9 compares temperature curves at different moisture penetration levels in the basement wall

low moisture penetration **high moisture penetration**

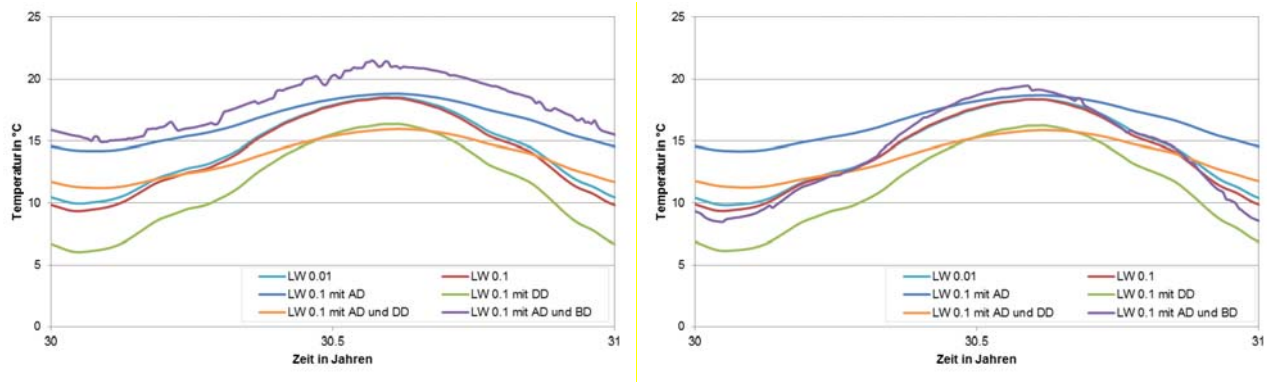

Fig 9:temperature distribution at lower and higher moisture penetration comparing all refurbishment variants (LW = air change cellar; AD: exterior wall to outside and to ground insulated; DD: basement ceiling slab insulated; BD: cellar slab insulated)

Heat flow is calculated for ecological comparisons on the basis of ÖNORM EN ISO 13370 (PHPP 2007) – see fig 10. Balancing expenditures for heating via the basement ceiling against expenditures for production and maintenance of the insulation system, the following environmental expenditures result in a period of 100 years, expressed as primary energy input, non-renewable.

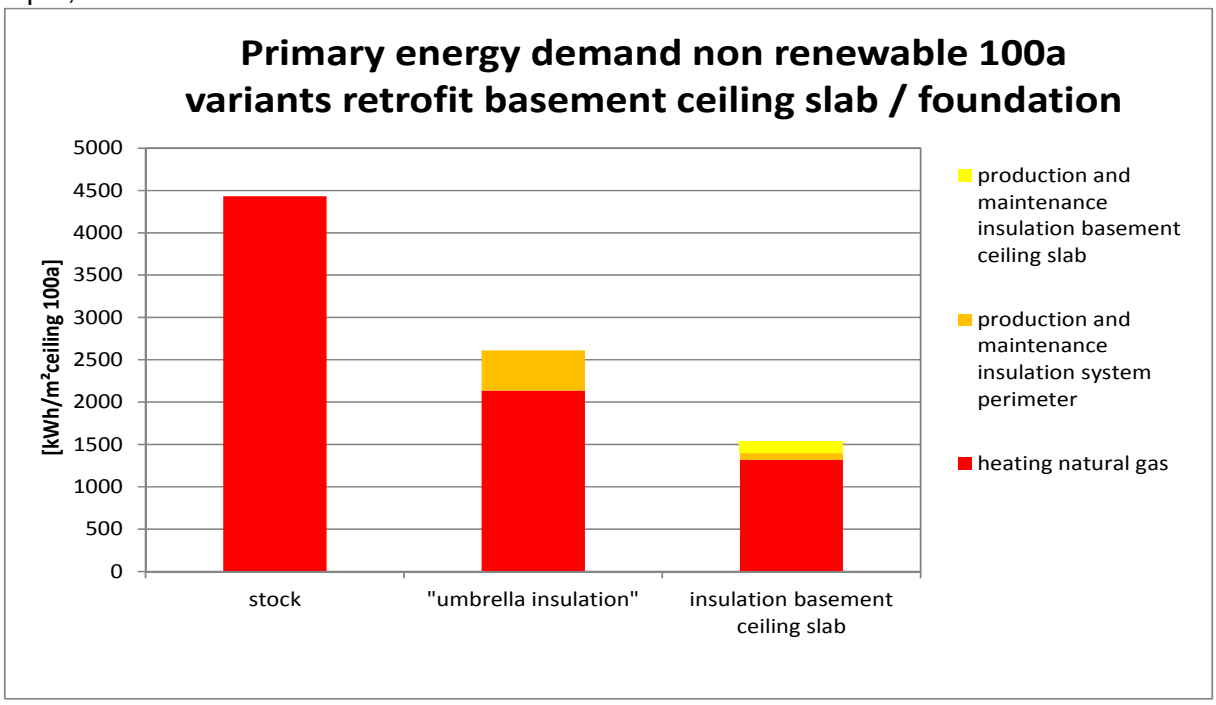

fig 10: Expenditures for production of insulating systems and for heating in order to compensate for heat losses via the basement ceiling

By reference to primary energy demand, non renewable, insulation of the basement ceiling slab plus thermal insulation of the base parts in contact with outside air more favorable than an umbrella-type insulation. Both systems, however, have big advantages compared to the unrefurbished state.
Capabilities of a cellar to store goods and also regarding risk of mould development the variant with umbrella-type insulation is preferable. The variant with basement insulation is most unfavorable, the unrefurbished initial state is in a middle position.
These results give clients a well founded position to choose refurbishment options by ecological and hygrothermal criteria.

Conclusions

On the way to an energy self-sufficient (or energy independent) Austria in 2050 high grade refurbishments of the existing building stock take a crucial role. In the future not only refurbishments with passive house components are relevant but also integration of energy-collecting systems. Integration in the existing building stock and reliable energy yield forecasts also in dense urban settings seems as one of the promising solutions.

Technologies and aspects of high quality refurbishment in non-residential constructions

Chair: Vanessa Gomes
University of Campinas, Brazil

Requirements and solutions for high performance school renovations

Armin Knotzer
Project leader
AEE – Institute for Sustainable Technologies
Austria
a.knotzer@aee.at

Keywords: School renovation; energy-efficiency; ventilation; passive cooling; indoor environment quality

1. Introduction

Schools were mostly built from the 1950ies to 1980ies. Beside educational aspects the existing school buildings are mostly in high need of renovation. While in rural areas an increasing number of schools are closed down, the urban areas lack of space for the increasing numbers of pupils in consequence of growing populations in the cities. So school renovations often are municipality driven projects, they claim governance and expert advice. The renovation process should raise both energy efficiency by high performance retrofit strategies and thermal comfort by proved solutions for ventilation and protection from heat. School owners and users demand short renovation time, high indoor environmental quality and summer comfort of school renovations.
A transnational research approach to strategies and solutions for school renovations was made by the European ERACOBUILD-project School*Vent*Cool. Some results of this project will be presented in the paper.

2. School renovation strategies

Comprehensive and holistic renovation strategies follow an “Integrated Design” approach that covers all relevant aspects. The regularly applied and accustomed procedures of municipalities to retrofit their building stock should be scrutinised. They mostly lead to a typical package of renovation measures setting priorities on the single building level, there on the appearance of the building secondly on insulation or energy relevant measures. In many cases the influence of the location and infrastructure, the indoor air quality, overheating challenges or even educational aspects are not included or discussed within the renovation process. This is suited for a change and was one of the outcomes of School*Vent*Cool as shown in *Figure 1* [1] – renovation of the school building stock starts with the Scope and ends up with Best Practice school renovations.

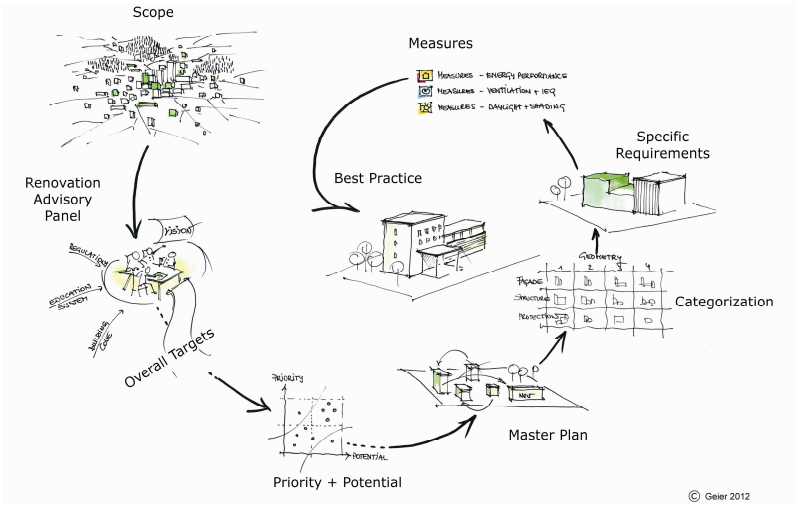

Figure 1 The SchoolVentCool methodology approach

2.1 Scope

The change of the scope from the single building to the entire portfolio avoids measures and investments in a non-selective way. Sustainable property management and development needs a profound knowledge on the existing building stock and is therefore based on a sufficient building stock documentation.

2.2 Renovation Advisory Panel

A future-oriented education system needs sufficient building and organizational structures. A Renovation Advisory Panel with experts and stakeholders from all affected aspects enables a multi-disciplinary perspective for the development of sustainable strategies of school building portfolios.

2.3 Overall Targets

Targets have to be defined in a clear, quantifiable and achievable way. They should address the buildings' functional usage, possible options for educational building utilization, performance, the Indoor Environmental Quality and the outlook to the life-cycle of the buildings. The overall targets provide the „Big Picture“ and general guidelines for all school buildings within the portfolio.

2.4 Priority and Potential Assessment

Target-oriented strategies on the level of the entire portfolio facilitate achieving the “Big Picture”. It is necessary to choose suitable school buildings for renovation that can be made „fit for future“ with feasible means. The degree of priority (urgency and pressure) together with the level of potential (good location, easy to adapt and renovate) shows ranking scenarios for scheduling and expenditures of measures (see Figure 2).

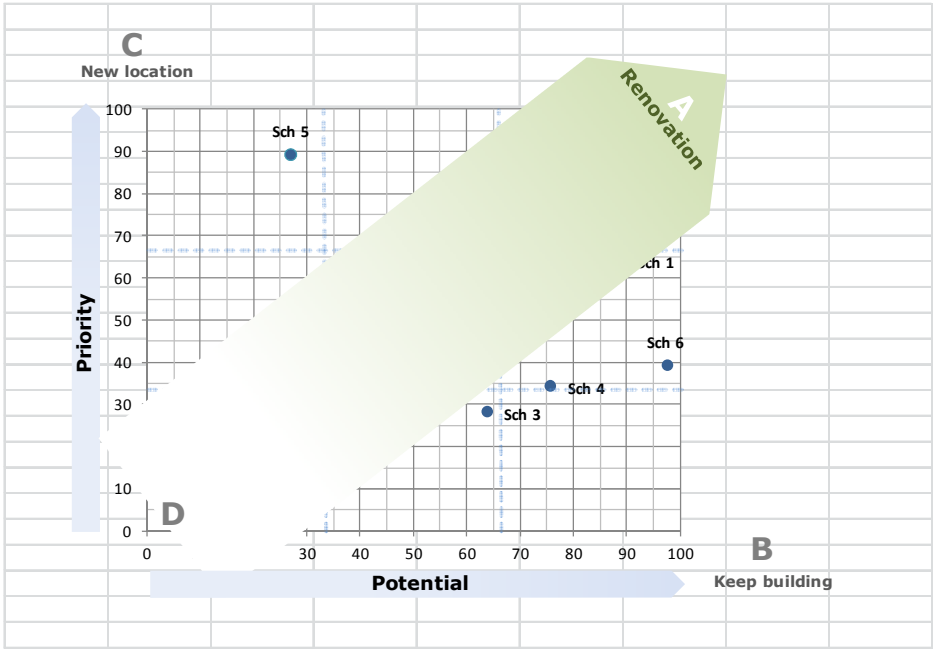

Figure 2 A “Potential-Priority Matrix” supports decision-making within a building portfolio

2.5 Masterplan

The development of a master plan is focused on a cluster of school buildings and the set-up of the

most efficient renovation strategy. That comprises reorganization or switching of buildings, functions or space supply for optimized operation. Additions of stories or annexes, even to sell, to let or to demolish buildings are possible options. Based on the strategic master plan that optimizes space structures and functional use of building structures from a bird's view, it is also necessary to (re-)structure the buildings due to the interior structure – for example a zoning due to the orientation (corridors on the west-side, classrooms on the east-side), the user's needs (comfort temperatures are higher in classrooms than they are i.e. in corridors), the difference of usage profiles and other influencing factors for interior space and room planning.

2.6 Categorization

Every renovation has to tackle the pre-settings of existing buildings that cannot be changed easily. Relevant key characteristics of buildings are indicators for executable or non-executable strategies and measures. The categorization of existing buildings due to a few but relevant key characteristics facilitates the choice of appropriate strategies and measures. (see chapter 4.1)

2.7 Specific Requirements

Now the strategy for the specific school-building with its own environment and conditions has to be developed. Having the vision of the „Big Picture" for the entire building stock very clearly in mind it is easy to deduct the specific targets for single buildings. So the overall targets have to be brought down and interpreted: What does it mean for that specific single building?

2.8 Measures

Basically measures can be separated into: „Passive" ones, like the improvement of the thermal envelope, efficient shading or optimized use of daylight, „active" ones that include efficient mechanical ventilation or heating systems, lighting control or others. Besides constructional or technical options organizational measures are an option too – they have to be planned in strong cooperation with all building related measures and the intended users. But anyhow the point is not to use the best measures, but the most suitable ones.

2.9 Best Practice

The best way to prove theories is to show that they had been realized already. Although every project has its own specific approach – the pattern of the strategy and the subsequent success is always the same. So every best practice example provides the chance to learn and the motivation to keep it up. Last but not least the pupils and teachers benefit from them!

3. Quality Requirements

Following requirements regarding best classroom indoor environment and learning ability are crucial:

- Visual comfort
- Thermal comfort
- Humidity comfort
- Air quality (olfactory comfort)

Beside design quality of the classrooms and functionality regarding educational and social use these four quality requirements have to be taken seriously. For each of them guidelines are existing in nearly all European countries as investigated in the School*Vent*Cool project, but often these guidelines neither are legal obligatory nor put into practice of renovation measures. So these overall quality requirements (see also chapter 2.3) are very important parameters to be considered before single renovation planning.

4. Solutions – prefabrication, ventilation, passive cooling

Based on the knowledge of the specific Integrated Energy Design and so the overall strategy of the renovation process, the quality requirements and the analyses of typological features, a set of solutions could be determined for the single building level.

4.1 School building typology

Analysing the typology of school buildings, a lot of similar constructions appear.[2] Conformities exist in facade structure, floor number, classroom dimension, window areas, entrances, staircases, other facilities. The typology work distinguishes general from focus types, whereas the general types are mainly characterised by the number of stories and the type of façade (see *Figure 3*), the focus types by e.g. window areas, parapet, lintel and room heights regarding a specific interest like space for ventilation ductwork etc.

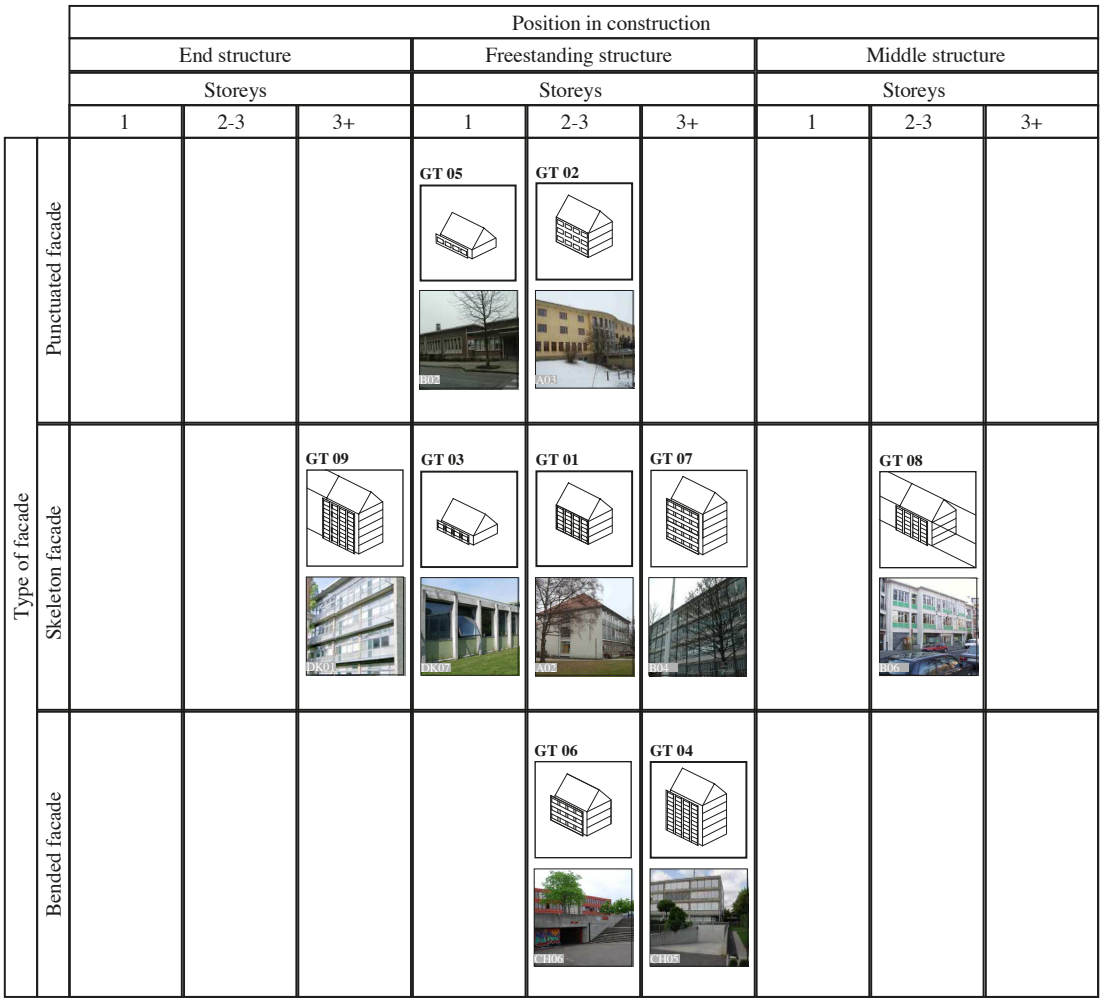

Figure 3 Categorisation of general types regarding the defined key features type of façade, number of storeys and position in construction, visualized with case study buildings (Source: FHNW)

The aim of this categorization work is creating detailed knowledge on pre-conditions of the school buildings leading, for example, to the design and production of prefabricated façade and roof modules. These thorough investigations help to find appropriate renovation measures for the:

- Module system and dimensioning
- Access to and storage space of building site
- Process of transportation and mounting
- Construction of foundation

- Roof adaption
- Renewable energy integration
- System and distribution of ventilation
- Cooling system
- Orientation and size of façade openings

4.2 Prefabrication

Renovation often means disturbance of the building's users, individual and error-prone construction works and dependence on weather conditions. Prefabrication is a very interesting aspect to overcome this challenge. The module manufacture is weather-independent, the construction works on site are short and can be made during summer when pupils are out. The critical path for school buildings is the air ducting system because of the high air volume needed in the classrooms.[3]

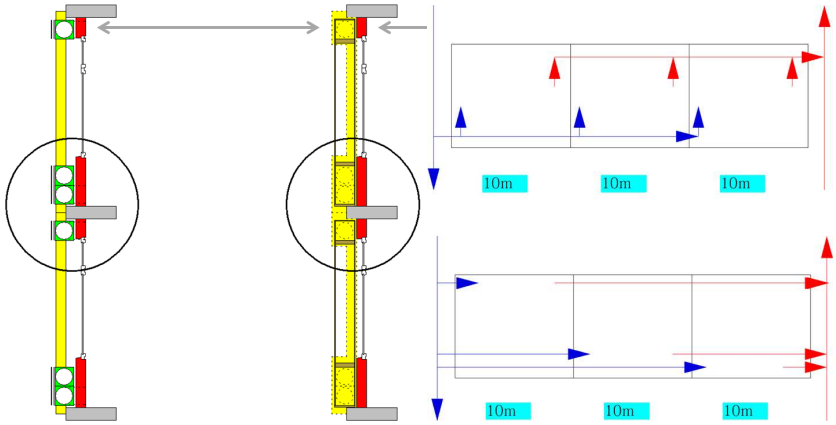

Figure 4 Central ventilation with horizontal air distribution and smaller effect on architecture; Left: Cross section of two façade-Storeys; Right: Elevation of two façade-storeys with horizontal ductwork (Source: FHNW)

Dependent on the existing façade structure the modules can be mounted onto or placed in front of the façade. But in every case the system and distribution of the ventilation seems to be the crucial point regarding school renovations. The question is, how the ductwork could be included in prefabricated modules mounted onto the façade (roof) without disturbing the users and the architectural appearance of the building.

4.3 Passive Cooling

Existing school building stock is mostly equipped with big window areas without acceptable thermal and shading standard.

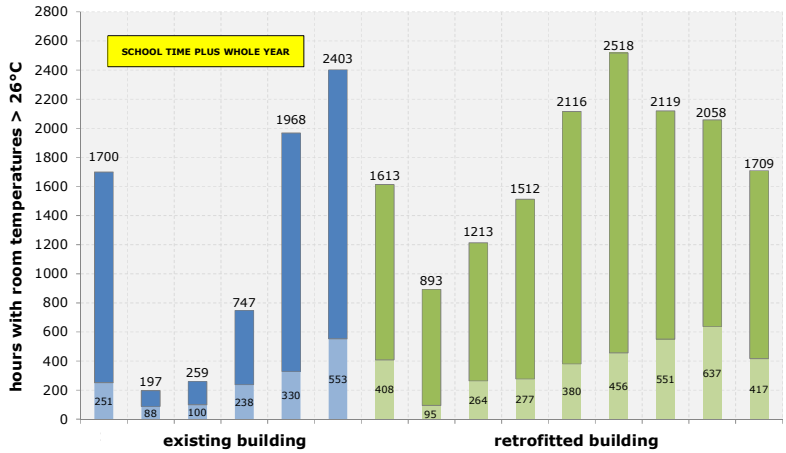

Figure 5 Different scenarios of shading and ventilation systems in an existing and a thermal-energetic retrofitted classroom of the same building

Thermal analyses have shown that thermal standards for summer comfort will be very important in future especially thinking of “summer- / all day schools” [4] – see *Figure 5*. Calculations have shown that the worst case in renovated schools could be one quarter of a year with temperatures above 26℃ in the classrooms, including summer holidays. Passive cooling concepts have to include “intelligent” shading control and (night free) ventilation systems to avoid overheating. At the same time an innovative shading and lighting concept is relevant for the optimal use of daylight and an effective protection from glare. The shading system as underestimated component of the energy system controls both comfortably cool rooms and intelligent usage of daylight.

4.4 Ventilation

A big challenge mostly is the implementation of the right ventilation system for school renovations. Manifold studies during the last decades have shown that ventilation is a vital aspect in getting classrooms to high indoor air quality (IAQ) standards, ensuring pupil’s health and their ability to concentrate during lessons. The way to appropriate ventilation solutions is again determined by the existing school building typology and IAQ criteria. A design criteria list, visualised as design cart (see *Figure 6*), weather centralized or decentralized mechanical or hybrid / natural (including night-) ventilation is best, helps for the decision making process.[5] Important is to think of both, fresh air during lessons and increased free ventilation during the night for cooling down the heat storage mass.

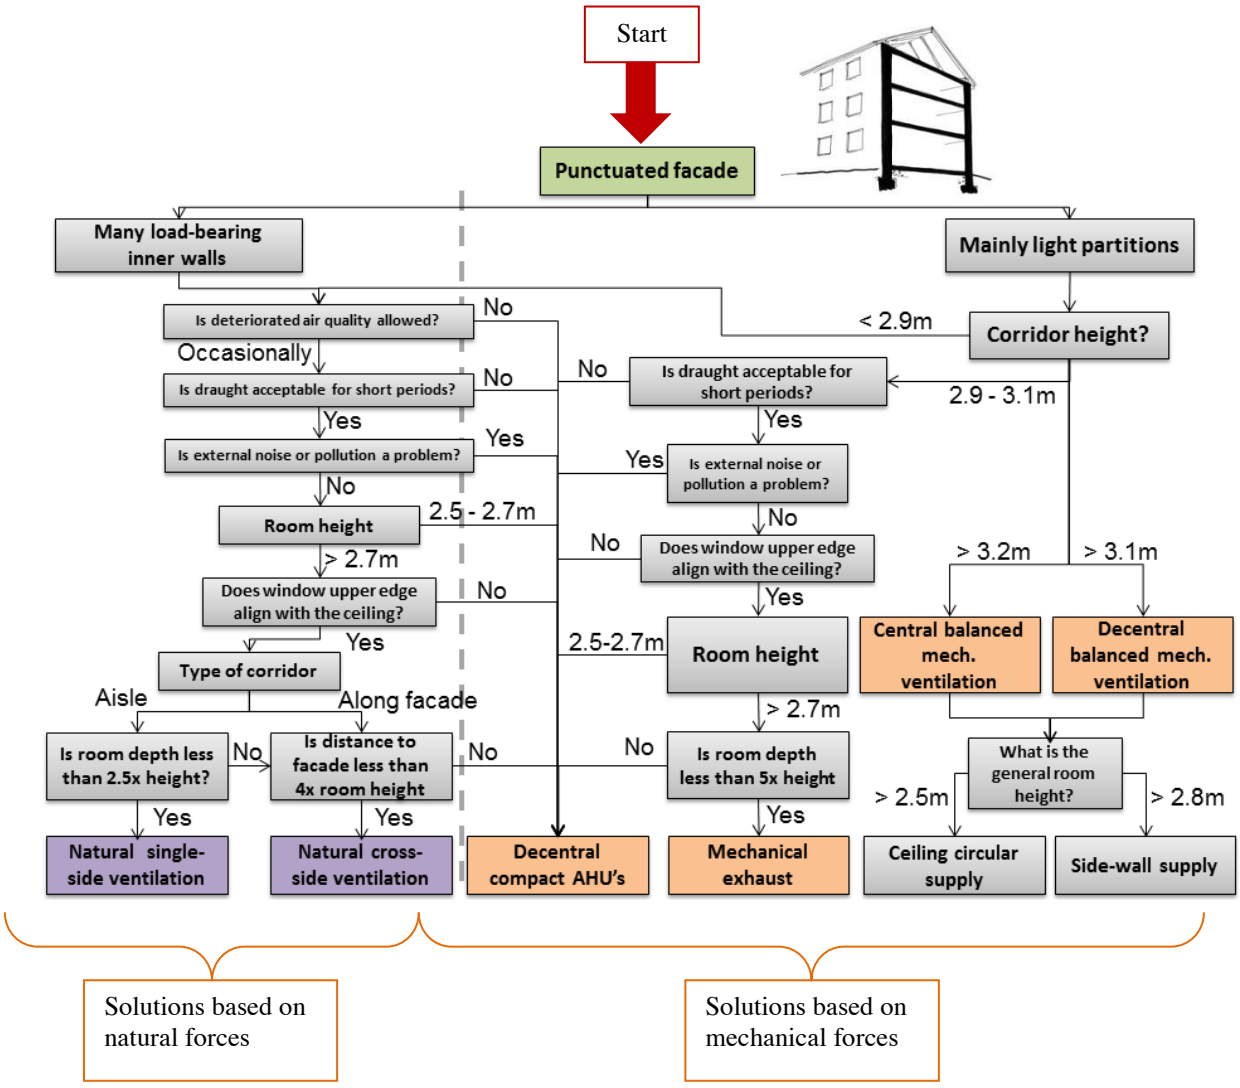

Figure 6 Visualization of the criteria that each solution must fulfil in order to be the recommended solution for a given building typology (Source: DTU)

5. Conclusion

If the scope is clear and the master-plan for the existing school sites done, a range of solutions for school renovations based on typology can be found. Prefabrication or the use of modular design components is a very promising of that. In near future there will be more research activities like concept and component development in this field. As there is very low energy demand for heating in high performance modernized school buildings the importance shifts towards their cooling demand. Passive cooling with (night-/free-)ventilation, intelligent shading and daylight use will raise the indoor environment and educational quality for pupils. These measures should be integrated in the prefabrication processes as far as possible to avoid individual installation mistakes on site and keep the renovation works in schools as short as possible.

Abstract

In the present article we have reflected and compared the results of our investigations on indoor air quality (IAQ) in relationship with heat energy consumption in unrenovated, renovated and newly erected kindergarten buildings. Latvian Energy Development Guidelines for the years 2007-2016 define that heat energy consumption should decrease by 28%, but by 40 % in the time period up the year 2020. Big heat energy demand in buildings is part of Latvia's heritage from the Soviet era. The majority of buildings do not have energy saving mechanical ventilation systems. Our analysis shows, that partial renovation: heat insulation of buildings with windows change, does not give heat energy consumption economy as established. Another target of this study was to evaluate indoor air pollution in kindergartens. Various indoor air pollutants such as volatile organic compounds (VOC) and biological pollutants, emitted from furniture, cleaning agents and floor covering materials, are responsible for respiratory diseases and allergies.

Keywords: Kindergartens; IAQ; VOC.

1. Introduction

For the most part, people live in buildings; thus IAQ is an obviously important determinant of health and wellbeing. To provide IAQ framework (Fromme et al. 2007; Santamouris et al. 2008) requirements are on the footing. Local Latvian laws are based on significant decisions of the European Parliament and European Council, for example, Directive (2002/91/EC) of 16 December 2002 on the energy performance of buildings and Directive (2006/32/EC) of 5 April 2006 on energy end-use efficiency and energy services and the repeal of Council Directive 93/76/EEC. Based on these documents, the Republic of Latvia Cabinet of Ministers created laws for local use. The main ministry that deals with energy issues is the Ministry of Economics. Building and reconstruction must also be provided by the IAQ framework requirements. But does this apply to all cases? We will provide the answer in the present article. We have reflected and compared the results of our investigations on the IAQ in relationship to heat energy consumption in unrenovated, renovated and newly erected kindergarten buildings. Heat energy consumption in public buildings has been explored very little in Latvian scientific research. After partial renovation, the IAQ slowly begins to deteriorate because outdoor air infiltration has stopped. Reconstructed, old natural ventilation and mechanical systems do not provide the necessary air exchange and quality. Residential buildings have the same problem. This unpleasant fact was overlooked for a very long time. Buildings get "sick building syndrome" after some time.

Having clean air indoors is very important for the health of the population as a whole and becomes particularly important for vulnerable groups like babies and children. Various indoor air pollutants (volatile organic compounds, biological pollutants, etc. emitted from furniture, cleaning agents, floor covering materials) are responsible for respiratory diseases and allergies (Wolkoff, 2006; Bernstein, 2007; Carslaw, 2009; Tanaka-Kagawa, 2005). One of the aims of this study was to evaluate indoor air pollution in kindergartens.

2. Materials/Methods

The aggregated information total contained more than 60 000 data indications from the relative humidity of the air, the temperature and indoor concentration of carbon dioxide. IAQ parameters have been defined in the Republic of Latvia Cabinet of Ministers Regulations No. 359, adopted 28 April 2009, as shown in Table 1.

Table 1. Requirements for the Microclimate of Work Premises Depending on Physical Load

No.	Time of the year	Work category	Air temperature (^{0}C)	Relative air humidity (%)	Air movement rate (m/s)
1.	Cold time of the year (average air temperature outside work premises + 10°C or lower)	I[1]	19,0–25,0	30–70	0,05–0,15
		II[2]	16,0–23,0	30–70	0,1–0,3
		III[3]	13,0–21,0	30–70	0,2–0,4
2.	Warm time of the year (average air temperature outside work premises exceeding + 10°C)	I[1]	20,0–28,0	30–70	0,05–0,15
		II[2]	16,0–27,0	30–70	0,1–0,4
		III[3]	15,0–26,0	30–70	0,2–0,5

These Regulations contain legal norms arising from Council Directive 89/654/EEC of 30 November 1989 concerning the minimum health and safety requirements for the workplace. IAQ parameters for kindergarten buildings have also been defined in the Republic of Latvia Cabinet of Ministers Regulations No. 596 “Hygiene requirements for educational institutions when implementing preschool programmes”. They stipulate that the air temperature minimum for children younger than three years is +20.0ºC and older than three years air temperature is +18.0ºC. This requirement does not indicate the boundary of the two indoor environment parameters as relative air humidity and carbon dioxide concentrations indoors, as described in the Minnesota Department of Health Fact Sheet (MDH, 2010).

In this study we used MINILOG GSOFT 40K V7.80 (air temperature logger), EASYLOG 40RF GSOFT 40K V7.80 (air relative humidity logger) and Wöhler CDL 210 version 1.1.6 (air temperature, relative humidity and carbon dioxide quantity) loggers. Loggers have been used in kindergarten rooms approximately 1.5 m above the floor. The gas chromatographic (volatile organic compounds – VOC expressed as carbon) and high-pressure liquid chromatography (aldehydes) method was used for the air pollution investigation. The air polluting substances were absorbed in charcoal tubes in the case of VOC and silica gel cartridges treated with 2,4-dinitrophenylhydrazine (DNPH) in the case of aldehydes. The indoor air concentration levels recommended by the World Health Organization (WHO) were used for the evaluation of indoor air quality: formaldehyde – 0.1mg/m^3 and of VOC – 0.3mg/m^3 (WHO, 2000).

3. Results

We detected indoor air polluting substances – aldehydes (formaldehyde 0.023±0.005mg/m^3; acetaldehyde 0.015±0.003mg/m^3; benzaldehyde 0.004±0.001mg/m^3; propylaldehyde 0.003±0.001mg/m^3) and volatile organic compounds expressed as carbon 0.56±0.11mg/m^3 in kindergartens in the case of floors covered with linoleum and with plastic windows without a ventilation system.

Figures 1, 2 and 3 presents the outdoor and indoor air temperatures, relative humidity and CO_2 concentration level in kindergarten buildings. The horizontal axis presents data of times and date. Minor gridlines disclose the time: first 2:00; second 5:00; third 8:00; fourth 11:00, etc. Major gridlines, for example, zero to eight is the first datum, achieved on 21 February; nine to sixteen is

the second datum achieved on 22 February; seventeen to twenty four is the third datum achieved on 23 February, etc.

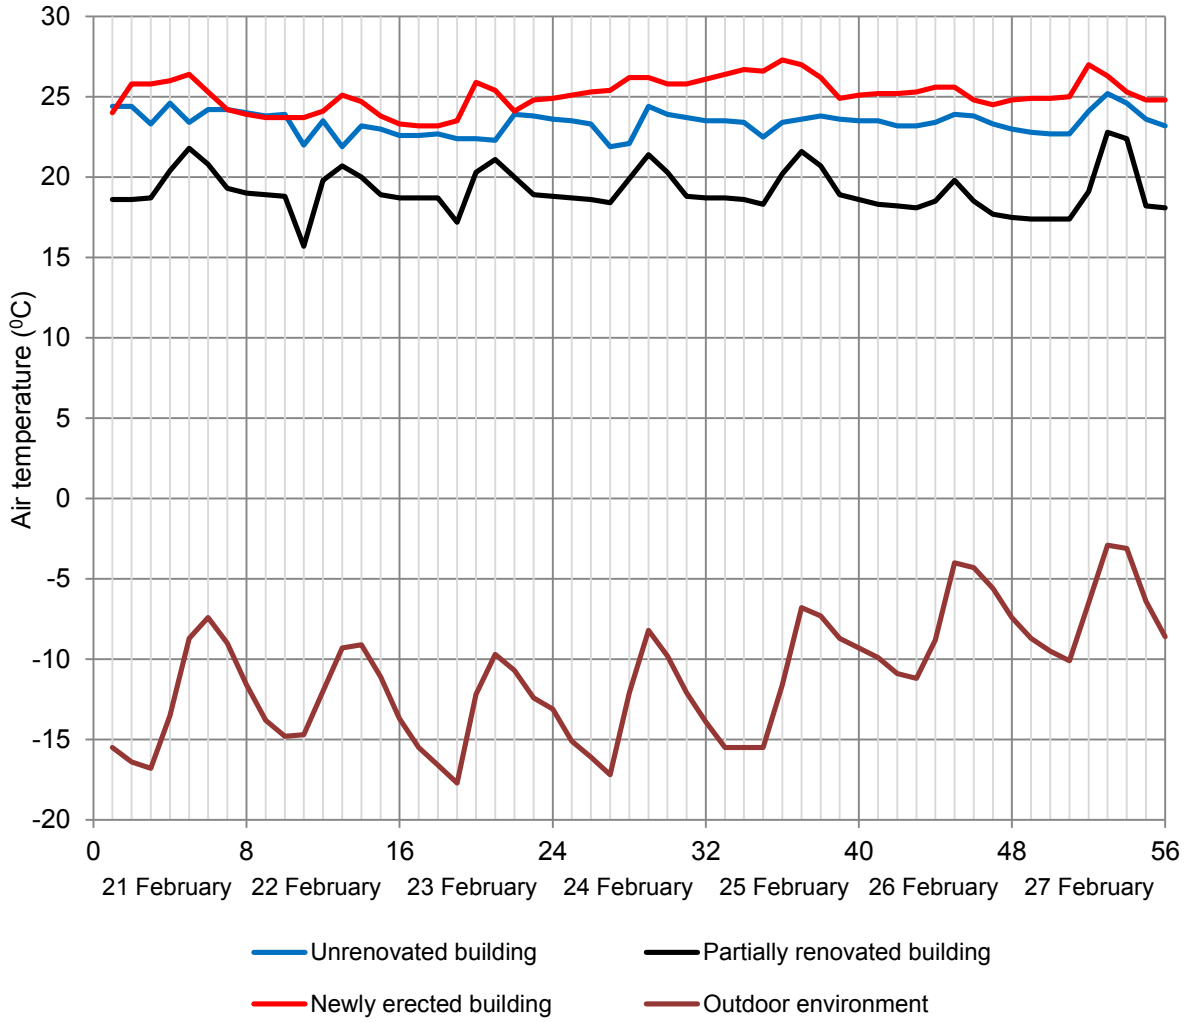

Figure 1. Air temperature in the different conditions of kindergarten buildings and outdoor environment in the year 2011

The newly erected building was built in 2007 and had a heat consumption 339kWh/m^2 in 2008; the partially renovated kindergarten building was renovated in 2004 and had a heat consumption 237kWh/m^2 in 2008; the unrenovated kindergarten building had a heat consumption 130 kWh/m^2 in 2008.

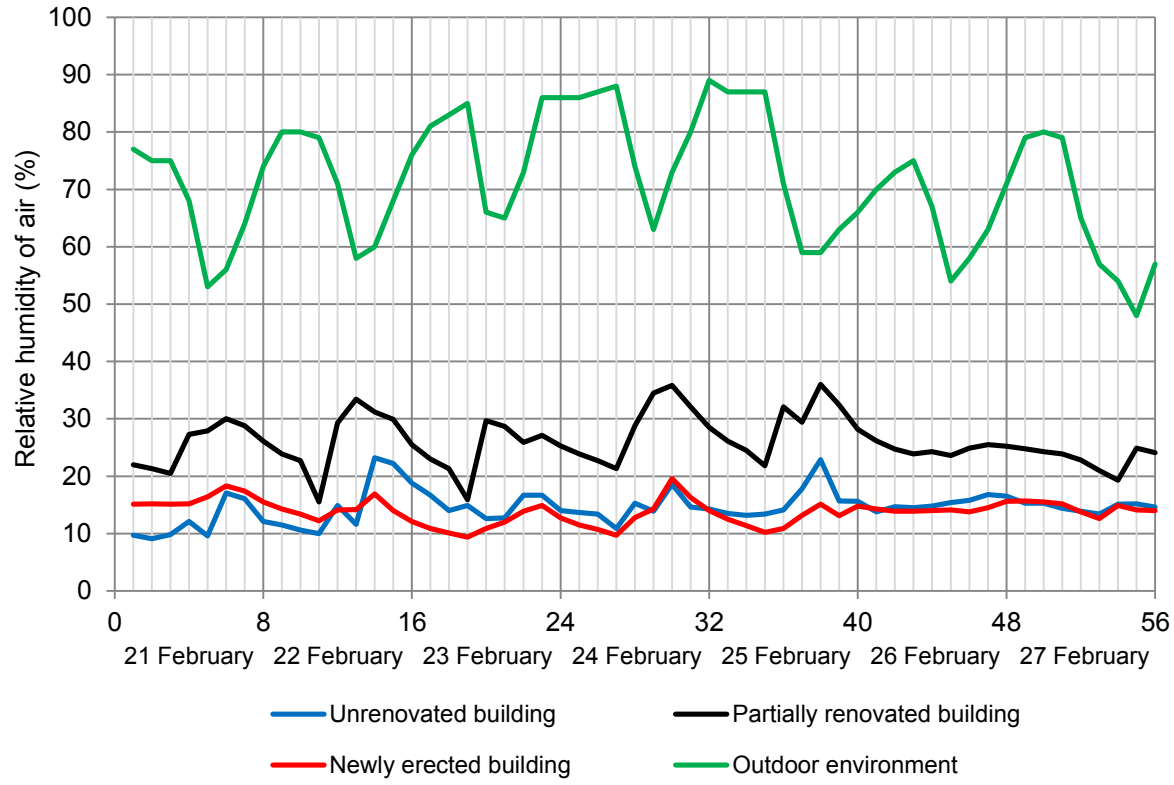

Figure 2. Air relative humidity in the different conditions of kindergarten buildings and outdoor environment in the year 2011

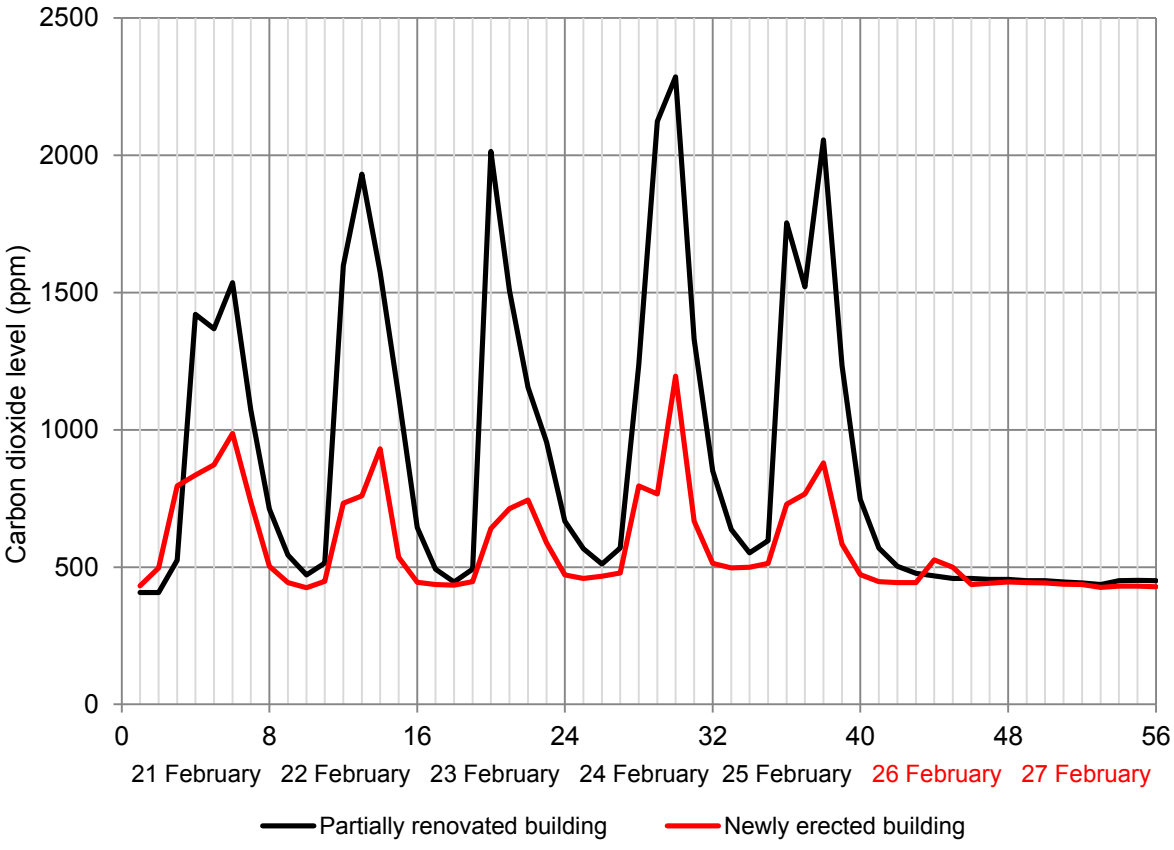

Figure 3. Carbon dioxide level in the indoor environment in partially renovated and newly erected kindergarten buildings

4. Discussion

Heat energy consumption to one square metre per annum in unrenovated kindergarten building is less than in the other conditions of buildings. The thermal comfort zone is defined between 19.0–25.0ºC. As shown in Figure 1, the partially renovated kindergarten building has an indoor air temperature that is lower than defined in many cases. In all cases, indoor air temperature has the property of mimicking changes in outdoor air temperature. This has been indicated on an unbalanced heating control unit. Indoor relative air humidity, as reflected in Figure 2, is for the most part lower than the set standards. Ventilation systems without air humidifiers are responsible for the cause and effect. Figure 3 also reflects the inadequate supply of fresh air in a partially renovated building.

“The outdoor concentration of carbon dioxide can vary from 3500-400 ppm or higher in areas with high traffic or industrial activity” (MDH, 2010). Our fixed outdoor concentration of CO_2 level varied from 410 to 440 ppm in February and March 2011 in Riga city. Table 1 reflects conditions that have an influence on the IAQ.

Table 2. Conditions of kindergarten buildings

Building	Year	Total floor area (m^2)	Heat consumption in the year 2008 (kWh)	Children/ Personnel	Achieved data rooms floor area (m^2)	Remarks
Newly erected	2007	1901	645 000	21 February – 16/2 22 February – 12/2 23 February – 11/2 24 February – 13/2 25 February – 13/2 26 February – 0/0 27 February – 0/0	88	With mechanical ventilation system
Partially renovated	2004	2054	486 000	21 February – 12/2 22 February – 14/2 23 February – 13/2 24 February – 12/2 25 February – 11/2 26 February – 0/0 27 February – 0/0	60	1.New heating system 2. New PVC windows 3. Without mechanical ventilation system

The investigations revealed the presence of various polluting substances in indoor air. The optimal concentration of aldehydes does not exceed the WHO-recommended limit for formaldehyde, which is the more toxic of aldehydes. In turn, indoor air pollution with VOC is higher than the recommended limit.

5. Conclusions

The personnel of kindergartens and children have complaints of smells and stuffy air. There is the possibility of poor IAQ in the case of plastic windows and rooms without ventilation, as well as kindergarten rooms with synthetic indoor materials. The project also aims to establish a common protocol for the evaluation of the IAQ.

Increased heat energy consumption in kindergarten buildings indicates that partial renovation was done with inadequate project solutions.

The main solution to these problems is to take an integrated approach to the IEQ and to establish energy-saving, quality ventilation and air condition systems.

Poor and unconformable IAQ indicate the necessity to make ventilation systems according to current building legislation.

Partial renovation of buildings has not decelerated heat energy consumption and has not enhanced the IAQ to the required level.

6. Acknowledgement

Current research has been done with a support of ESF grant.

SB13 Graz - Re-Commissioning Services: Immediate Savings and Triggering Building Refurbishment Measures in Non-Residential Buildings

DI (FH) Reinhard Ungerböck
Project manager
Grazer Energieagentur
ungerboeck@grazer-ea.at

Short Summary

In many cases the question arises, how and where to start with the energetic optimisation and high quality rehabilitation of complex, large-volume non-residential buildings like hospitals, universities etc. Usually, an energy audit is carried out, measures are defined by an expert and a decision making paper for the management is worked out.

A completely different approach offers Re-Commissioning: a systematic approach to examine existing building equipment systems, their operation and maintenance procedures and – highly important – communication and interactions with facility building management staff and occupants. Through Re-Commissioning the first 10% of the energy bill can be saved without immediate investments. Staff is trained in energy efficiency and the users are motivated to change their behaviour and contribute with own ideas to smart energy savings. The process and the first successes lead to a higher energy consciousness and the desire for greater savings. Investments into comprehensive refurbishment measures as a result of an internal evaluation process are more likely to follow.

The process follows a standard Plan-Do-Check-Act management cycle; it is compatible with energy management systems as described in ISO 50001 and builds on 5 key components:

1. Establishing an energy information system
2. Data analysis and selected measurements
3. Optimisation of existing building technologies
4. Information and motivation of building occupants
5. Monitoring and quality assurance instruments of the project results

In the "Re-Co.eu" project[1], energy efficiency engineers, economists and marketing experts from 10 partners are joining forces to develop Re-Commissioning services and markets in 8 European countries and test the feasibility of the concept.

[1] Supported by the Intelligent Energy Europe program of the EU

In our speech we will summarise Re-Commissioning services, components and tools (e.g. process flow, pilot project log, data base for measures implemented and the measurement and verification approach). We will report on preliminary results of selected pilot projects implemented in hospitals and universities, show examples of successful measures and strategies and how these results are communicated to stakeholders.

We will conclude with the lesson learned that for the achievement of sustainability in large-volume, non-residential buildings a comprehensive approach is necessary. Besides high-performing building technologies the continuous adaption and optimisation of the technology, the communication with the staff and the integration of energy efficiency in management routines are important elements.

Keywords: Re-Commissioning; www.Re-Co.eu; large-volume buildings; energy management system; energy efficiency

1. Why Re-Commissioning?

In many cases the question arises, how and where to start with the energetic optimisation and high quality rehabilitation of complex, large-volume non-residential buildings like hospitals, universities etc. Usually, an energy audit is carried out, measures are defined by an expert and a decision making paper for the management is worked out. Evaluations of this procedure show that only a few of the proposed measures are carried out due to different reasons:

- the audits often concentrate on high investment measures with long payback periods
- managements tend to implement measures with short payback first before considering longer payback periods
- the proposed measures are often not embedded into a holistic concept including energy monitoring, information of users and quality assurance

A completely different approach offers Re-Commissioning: a systematic approach to examine existing building equipment systems, their operation and maintenance procedures and – highly important – communication and interactions with facility building management staff and occupants. Through Re-Commissioning the first 10% of the energy bill can be saved without immediate investments. Staff is trained in energy efficiency and the users are motivated to change their behaviour and contribute with own ideas to smart energy savings. The process and the first successes lead to a higher energy consciousness and the desire for greater savings. Investments into comprehensive refurbishment measures as a result of an internal evaluation process are more likely to follow.

2. Approach of Re-Commissioning

The process follows a standard Plan-Do-Check-Act management cycle; it is compatible with energy management systems as described in ISO 50001 and builds on 5 key components:

1. **Design:** The Re-Co Services Consultant (Re-Co SC) creates an overview of the owners building stock and works out the individual strategic objectives for the building owner and corresponding success indicators. E.g. improving energy efficiency, reducing operating cost or improving user comfort.

2. **Investigation:** The Re-Co SC investigates the building stock, identifies high potentials and defines specific measures of improvement and a plan for their implementation. The owner recieves a clear calculation of costs and benefits of each measure to decide about the implementation. A concept for evaluation – usually a suitable technical metering system – is defined and installed.

3. **Implementation:** The measures are being implemented. All cost and timelines are documented.Operations are actually starting to improve.

4. **Evaluation:** All measures are evaluated using individual approach according to success indicators. The evaluation shows the individual cost effectiveness of each measure and the amortization of the whole Re-Co Service.

5. **Continuity:** Re-Co Services are intended to come and stay. The metering concept and the success indicators are great tools to continuously monitor the performance of your buildings, to maintain the savings and to even indentify further measures of improvement.

The similarity of the process to energy management systems (as shown in the graph X) entitles the scheme of re-commissioning to be used as a preparation for the implementation of an energy management system: Depending on the individual design of the project a high number of the elements to be necessary for an energy management is already been implemented during the re-commissioning-process.

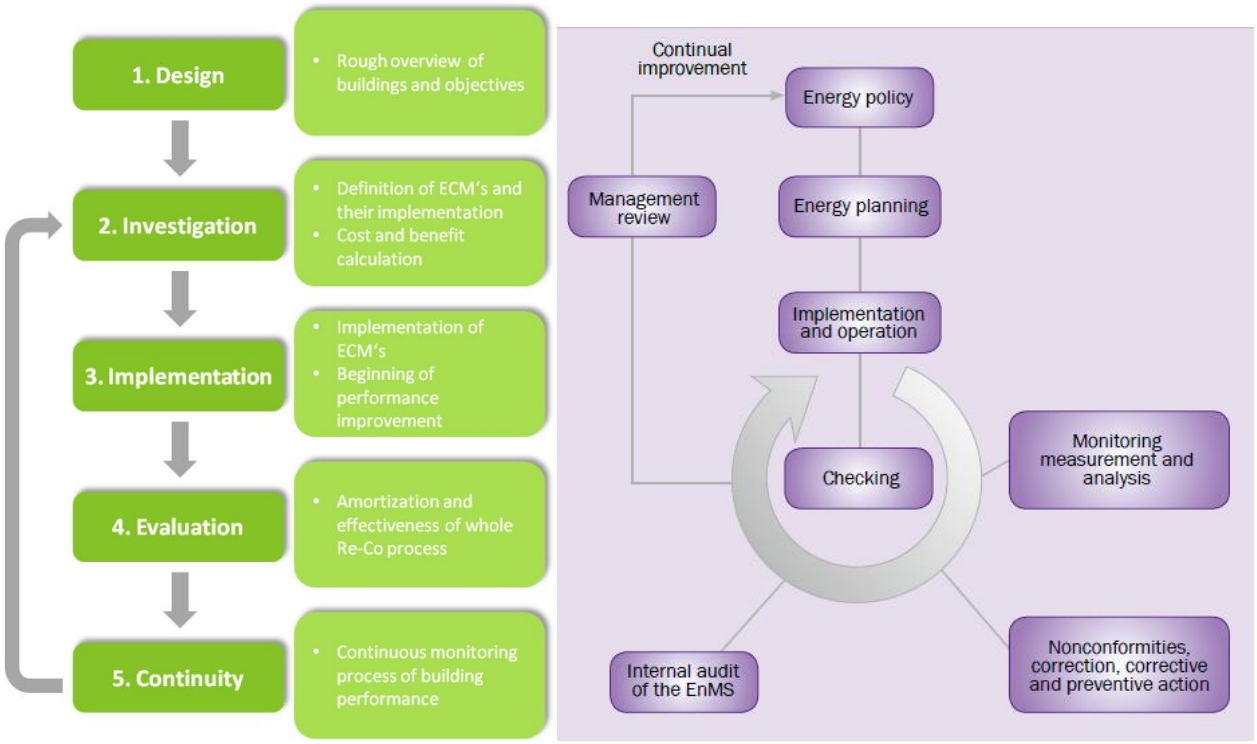

figure 1: similarity between the process of re-commissioning and ISO 50001

3. IEE-project Re-Co

In Re-Co 10 partners from 8 countries join their forces and experience to develop a common understanding of re-commissioning in Europe. As the individual approaches of all partners regarding technical appliances, tools and communication strategies are quite different, the common structure has been identified and experiences – whether strategies or tools work out or not – are exchanged between experts.

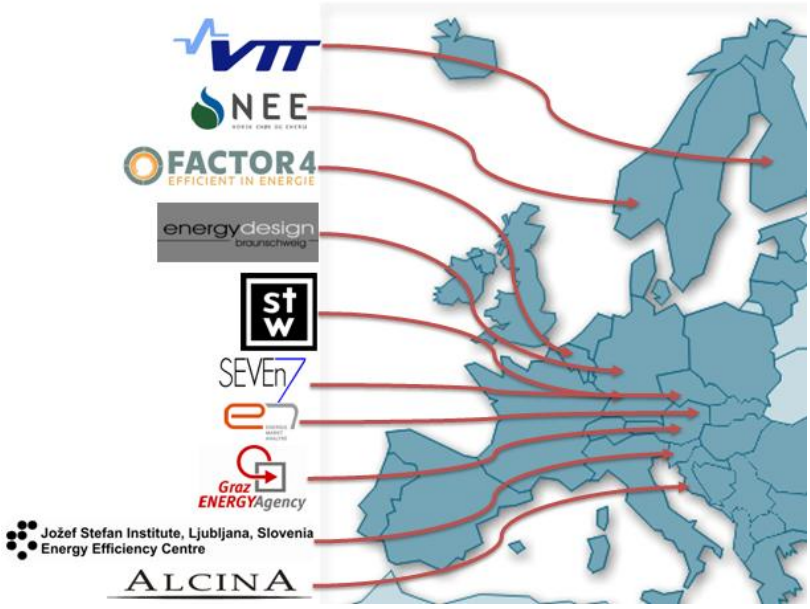

figure 2: partners of the IEE-project Re-Co

4. Two best practice examples to demonstrate that different technical approaches can be successful

4.1 BGU Ludwigshafen, hospital in Germany

In this pilot project the experts concentrated on the optimization of the ventilation system after the analysis of the energy consumption showed that 45% of the overall energy consumption is used by these systems.

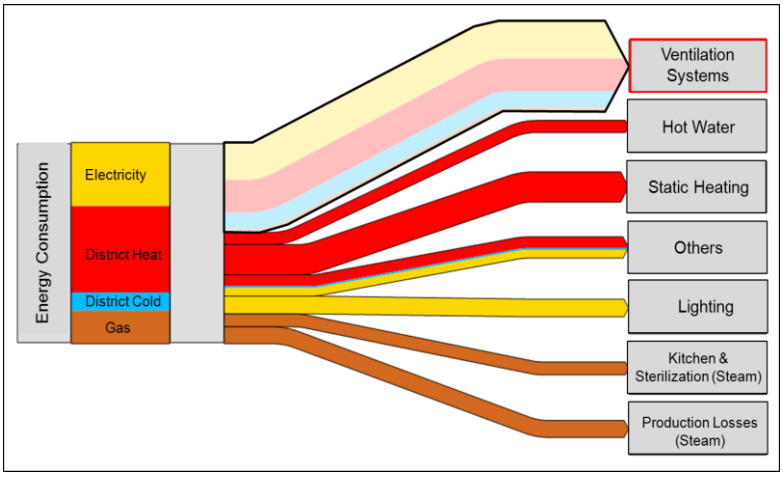

figure 3: sankey diagram BGU Ludwigshafen

Consequently a simulation of the 5 ventilation system has been performed, showing saving potential in the systems in respect of usage and time on the one side and pressure and volume on the other side. The optimization avoided a loss of comfort and a violating of hygienic standards, so the implementation of the proposed measures – pressure reduction, air volume reduction and runtime reduction – was only a technical issue and not an organisational. An unexpected saving benefit has been that one of the ventilation systems could be turned off completely as it turned out that the respective building has been out of use as a whole, a situation which is not a one-time-occurrence but can be found quite often.

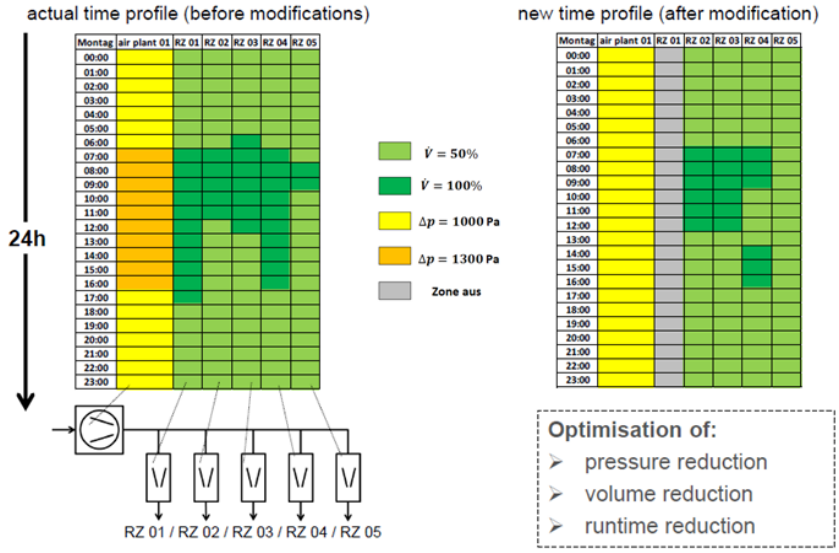

figure 4: BGU Ludwigshafen: optimization of ventilation system

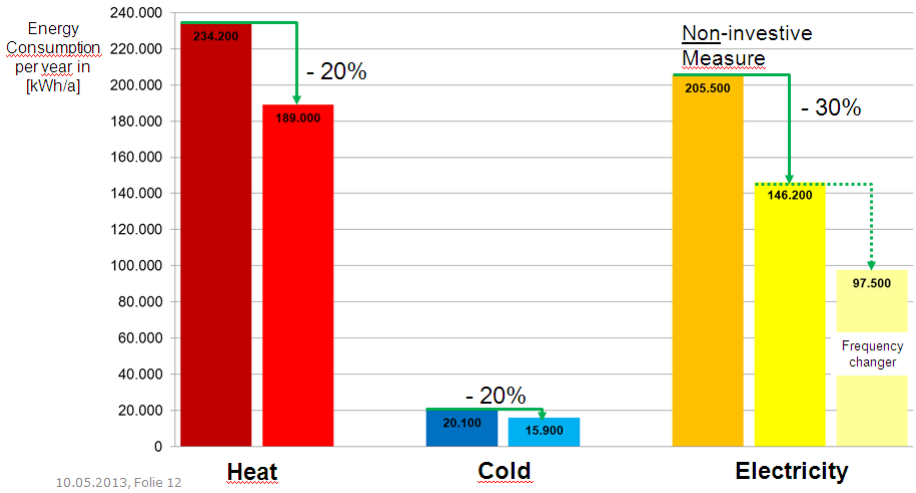

figure 5:BGU Ludwigshafen:saving potentials of ventilation system

The gained savings through pure optimization without investment are 20% for heat and cold and 30% for electricity, whereas in the process an investment measure – the implementation of frequency converters – has been developed, which should reduce the electricity consumption by another 30%.

4.2 KH Güssing, hospital in Austria

the focus in this pilot project has been on technical optimization, user motivation and training of technical staff. To enable an optimized output of ideas for measures a special communication structure has been set up: The group of users chose a team of energy coaches, who were determined to develop measures in their range of influence, i.e. the hospital units, administrational offices, surgery rooms. On the other side the technical staff has been invited to perform the same in their range. Both groups created these measures but also created measures to be enabled by the respective other group. These measures have been reported by the experts to the other groups, so a interactive dialog developed, which not only created innovative and individual measures but also a better understanding for the needs and way of thinking of the counterpart.

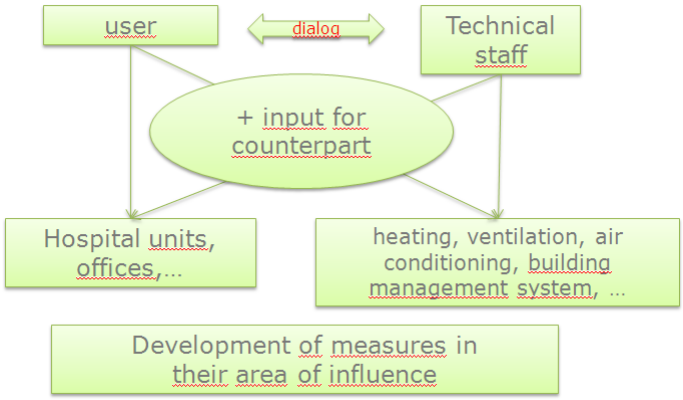

figure 6: a.ö. KH Güssing: communication structure

In this scheme a number of 26 technical and 30 user behavior measures have been developed, the staff has been empowered by the management to enable measures themselves, while the

experts acted more like mediators, giving advice and technical background to the members of the discussion groups and preparing communication means for the client, i.e. posters, stickers and manuals for technical issues and communication. A selection of measures of these 56 measures:

1. optimisation of ventilation system
2. reduction of room temperatures (25°C → 22°C)
3. training of technical staff in control system
4. information and motivation campaign for users regarding cooling, lights, elevators, stand-by,…

5. Conclusions

The evaluation of the pilot projects shows that the targeted 10% of end-energy savings are realistic to achieve – even in modern buildings and organizations with professional and well-educated building-staff.
Re-commissioning is especially suitable for clients with a high level of internal technical know-how and with need for high operating safety (i.e. hospitals) and it can act as a door opener for high investment measures after the implementation of low-cost-measures in the re-commissioning-project.
Re-commissioning can and has to be adjusted to the individual needs of the client depending on the desired access and involvement for the consultant to technical settings in respect of security reasons and depending on the individual know-how-level of the internal staff.
In the end the similarity of the re-commissioning-process to energy management systems suggests to use re-commissioning as a preparation for the implementation of an energy management system, i.e. ISO 50001.

The advantages for the client are that

1. through re-commissioning he reduces his energy consumption and related energy costs,
2. he can but doesn't have to use internal resources for the planning phase,
3. the implemented measures show sustainable effect due to the conversion into an PDCA-cycle
4. the implementation of the measures happens in ongoing operational business
5. the part of user-motivation can also be seen as team-building
6. as "side-effects" reasonable investment measures can be evaluated and prepared for further decisions

Short Summary

The paper deals with the thermal rehabilitation of 19th century townhouses using interior insulation. It presents the latest research results of two ongoing projects of the Research Centre of Building Physics and Sound Protection of Vienna University of Technology. Essential details concerning the renovation – focusing on the thermal rehabilitation of an exterior wall, e.g. interior insulated wooden beam connections – are discussed. It is shown, how the risk of damage of an inside insulated construction can be assessed by hygrothermal simulations and the analysis of certain issues.

A planning example of an internally insulated exterior wall with wooden beam connections is presented. The worst case scenario is described by variation of certain boundary conditions. It is shown how selective tempering of the joist bearing can minimize the risk of damage as well as the energy expenditure. Besides the description of the technology of wooden beams' temperature controlling, a patent is introduced which is currently being further developed in an ongoing project of the Research Centre of Building Physics and Sound Protection of Vienna University of Technology.

Keywords: Interior insulation; building component tests; wooden beam head; risk assessment; life cycle costs

1. Introduction

Increasing energy consumption in buildings was leading to greater awareness of energy conservation and to rising energy efficiency. The highest potential for thermal optimization lies in renovating existing buildings. Due to the fact that many buildings are listed worthy of preservation renovating the historical façade with a thermal insulation system is obsolete. Therefore interior insulation is gaining tremendous importance and many research institutes, planers, executives and consulters are busily engaged with the process.
Hereafter the planning process of interior insulation systems and related questions are discussed. At the beginning the correlation of significant planning parameters are analysed. Subsequently the theoretical planning process is demonstrated by a case study. The approach is based on the specifications of the "Framework for Probabilistic Assessment" according to the IEA Annex 55.

For planning an interior insulation several parameters must be observed. These are referred to as “framework” and represent all relevant parameters that are required for designers and contractors of interior insulation systems.

2. Considerations for the framework

2.1 Definition of the scope

The planning and evidence of internal insulations can be divided into different **levels of complexity**. This ranges from the entire building to individual components and specific connection details.

1. Whole building
2. Nonsteady state calculation of a detail with multidimensional heat and moisture transport including airflows (4D HAM)
3. Nonsteady state calculation of a detail with multidim. heat and moisture transport (4D HM)
4. Building component with 1D layer structure (1D HM)

In section 3, examples are given how the ideal calculation model can be selected. It is shown how a construction with low potential of risk can be created and it is demonstrated by calculations with appropriate planning tools. A proof of a damage-free construction is currently used rarely used in practice. With the help of the framework a comprehensive verification can be implemented.

Fig. 1: Parts of a building on the example of a 19th century building

Depending on the level of complexity, there are different aspects that must be taken into consideration when designing the framework. For instance, considering the entire building the renovation and maintenance costs may constitute a relevant variable. In contrast, if focusing on a ceiling connection detail for example the maintenance costs are negligible. The planning and execution costs must already be compared to the potential of maintenance procedure costs during the planning phase. Considering the risk of damage of a certain construction the retrofitting costs and the consequential costs of damage have to be evaluated.

At the beginning of a project the **targets and the performance criteria** as well as the consequences of these criteria must be considered. The central goal of thermally renovating an existing building using interior insulation is to increase the energy efficiency of the property. This is achieved by minimizing the heat losses. The effectiveness of a thermal retrofitting can be described by the maintenance of a certain U-value of an external wall structure. At the same time it must be ensured that the renovation does not cause any structural damage. This can be done by evaluating specific performance criteria of a certain construction, e.g. the moisture behaviour of the materials and the permeability or the air-tightness of a construction. The goal is to demonstrate the functionality of the interior insulated wall section. Moreover, it has to be proved that the construction shows a long-term damage-free condition. This verification is based on defining various influencing parameters.
These parameters are based on the **existing conditions and the general information** about the building to be retrofitted. As shown in [1], the detailed planning process starts with a building survey. For this purpose a detailed assessment of certain issues concerning the renovation project is necessary. The questions must include all relevant influence parameters in order to make an object-specific statement. The following checklist shall help to identify the dangers and the relevant parameters within the given object.
The first part of the checklist deals with outside influences on the structure. Here the effects of weather and other constructive material-related features are revealed that – combined with internal insulation – may cause a problem.

		Testing Option			Limit	
Influences	Basic Questions	Y	N	T	L	Detailed Parameters
Outside Boundary Conditions	Are there any climate data of the location?					Which minimum temperature is to be expected in winter? In which climate region is the restoration object situated?
	Is there a driving rain?					Which driving rain group does exist? Which side is stressed the most? Is a functioning rain protection available?
	Is there a risk that the façade dries very slowly?					Can the facade dry fast enough after a driving rain event? Does the facade have parameters that facilitate the drying process? • coloring • surface roughness etc.
	Was the façade hydrophobized?					Are there any defects in the hydrophobing?
	Is there rising moisture?					Is it • constant humidity or • temporary humidity?
	Can the facade absorb moisture at a driving rain event?					How much moisture is absorbed? What happens to it? Can the consequences be estimated, or even seen?
	Is there solar irradiation to the facade?					May it come to reverse diffusion? Is the location of the building • freely and exposed or • in a built-in area?
	Is there existing damage on the facade due to effects of moisture?					Do the effects of moisture come • from the soil? • by driving rain? • by water damage?
	Are there areas on the facade where rainwater can easily penetrate into the construction?					Are • joints, • cracks

Fig. 2: Questions for the survey based on the outside boundary conditions (Part 1 of the checklist)

The second part of the checklist deals with the boundary conditions on the inside of the wall construction and the user-specific conditions. Here the focus lies on existing damage due to moisture and constructive defects on the wall's surface.
Further sections of the questionnaire are dealing with constructive and component-dependent influences on an interior insulation. The whole questionnaire is described in [1]. By using the questionnaire the retrofitting object can be analyzed in detail. In this way problems which could be potentially overlooked in a rough planning process can be detected. The checklist gives further information on the objectives and design possibilities and provides clear knock-out criteria for certain variants.
From the results of the building survey **retrofitting strategies** can be assumed. If the possibilities of renovating a building thermally are already limited to applying an interior insulation the selection of alternatives is very small. It is, however, possible to raise the comfort with the help of special building services like under-floor- and wall-heating-systems.
A basic calculation of an interior insulation can be performed using different **limitations and assumptions**. Especially material properties have to be estimated partially, because historical materials can have wide differences in their key parameters. External climatic conditions can be received by weather stations, thus providing very realistic input parameters for the calculation method. The internal climate conditions must be selected depending on the usage. The indoor climate is described in ÖNORM B 8110-2 or in the WTA data sheet 6-2-01.

2.2 Identification of benefits and hazards

The execution of an interior insulation system requires an intensive and detailed planning process. A lot of object-specific parameters must be investigated. These influential parameters and their uncertainties must be considered when choosing the right insulation system. The following figure shows the essential boundary conditions and divides them into four main groups, each with two sub-groups as shown in Fig. 3.
The uncertainties of the individual parameters can be determined in several ways:

- approximation of parameters (climate data of the location, moisture load of the interior

climate etc.)
- measurements of parameters in the laboratory (material data, flow resistance etc.)
- measurements of parameters of existing properties or demonstration buildings (moisture content of the existing structure, climate conditions etc.)

In ongoing projects calculations of the construction are mainly based on assumptions about material parameters whereas measurements of individual parameters are only made in some

Fig. 3: Influencing parameters

specific cases.

2.3 Importance of parameters

The efficiency of the internal insulation can be evaluated and limited by different variations of the parameters. Thereby one can determine the importance of the individual variables. It is shown that many parameters are object-specific. Thus, the boundary conditions can be sorted by importance for a particular rehabilitation project.

2.4 Implementation of risk assessment

Once the systematic building survey has been completed and the different influencing parameters have been weighted by importance the risk assessment can be carried out. Thus the risk of damage of a construction is recognized. On the basis of life-cycle costs different alternatives of renovations and interior insulation systems can be compared. For constructions with a high risk potential higher restoration costs have to be assumed. These higher costs will negatively affect the life-cycle costs.

In order to determine the risk of damage of an internally insulated construction the combination of

different boundary conditions and influencing parameters has to be taken into account. In addition to the uncertainty of climatic boundary conditions especially material parameters vary significantly, as shown in [2]. These uncertainties can be visualized in probabilistic functions. The calculation of the risk of failure is based on probabilistic calculations incorporating individual parameters. This approach corresponds to a probabilistic safety concept. The research activities in IEA Annex 55 are focussed on implementing a probabilistic verification method in building physics – similar to the verification concept in the statics.

3. Choice of simulation geometries and boundary conditions

Considering the hygrothermal assessment of construction parts, the Glaser-method was the standard of knowledge up until the 1990s. As described in [3], this method, however, works solely with stationary constraints und does not take into account all thermo- and moisture technical storage phenomena and moisture transport through capillary conduct. Since the 1990s methods for a non-steady-state calculation of heat and moisture transport in construction parts are being developed in various research institutes.
As mentioned in 2.1, various calculation models can be used. Thereby the results differ significantly. The simplest way to calculate an interior insulation is a **1D simulation**. Hereby a homogeneous layer structure and a one-dimensional heat flow are assumed. This model corresponds to a flat wall cutout.

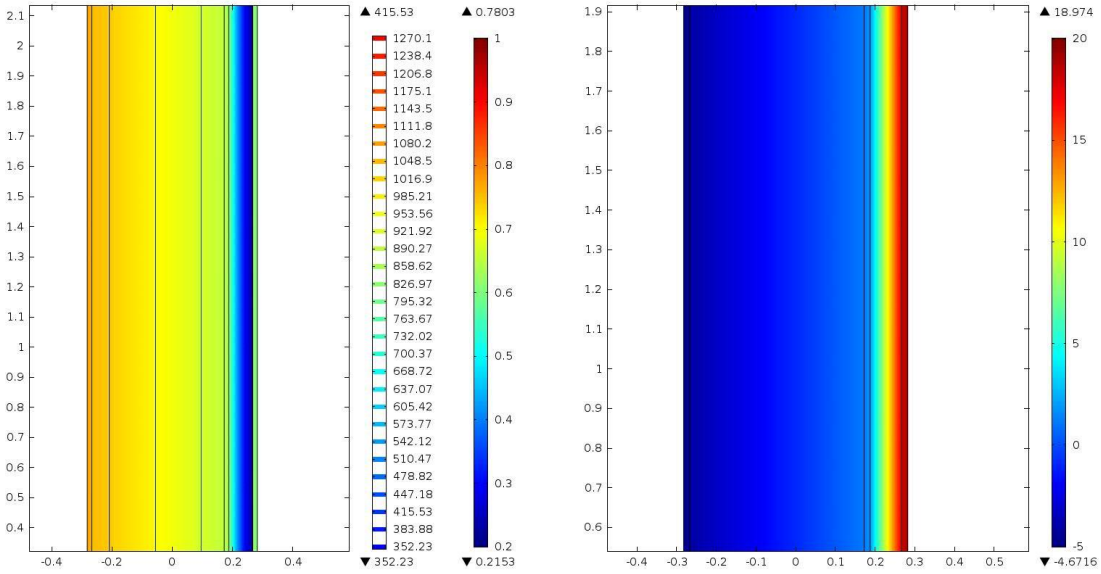

Fig. 4: 1D-Simulation of an inside insulated construction
left: partial pressure and relative humidity; right: temperature

The next complicated model includes a **2D geometry** for calculating two-dimensional heat fluxes. By using these models thermal bridges can be easily displayed. Thus surface condensate or the risk of mould growth can be proved.
For calculating some specific details a **3D simulation** is absolutely essential. Critical thermal bridges are usually three-dimensional and must be calculated accordingly. When planning an interior insulation especially ceiling and interior wall connections as well as window reveals are important three-dimensional details which have to be proved for their proper functioning.
Furthermore, it is essential that liquid water transport and air flows are taken into consideration when hygrothermal simulations are carried out. As shown in [4] and [5] air flows have a significant influence on the functioning of an interior insulation system. This fact is demonstrated in section 4 on the basis of a wooden beam connection. Water entering is relevant especially in the case of facades which are subject to driving rain.
The planning process of an interior insulation should always start with the simplest way of simulations. After clarification of all essential parameters simulations must be continued with the verification of three-dimensional thermal bridges.

4. Influence of calculation methods – Case study of a wooden beam head

The following case study of a wooden beam head shows the impact of different 3D-simulation methods. The beam is situated in a brick wall. At the bearing the wood is surrounded by air. The interior insulation system consists of mineral wool with an air-tight layer on the inside. The simulations were carried out with COMSOL Multiphysics. Temperature, relative humidity, partial pressure and the air flow were evaluated. In three different calculations the same model was simulated using different boundary conditions.
Fig. 5 shows the easiest way to calculate the 3D model. Only vapor diffusion and heat transfer are taken into account.

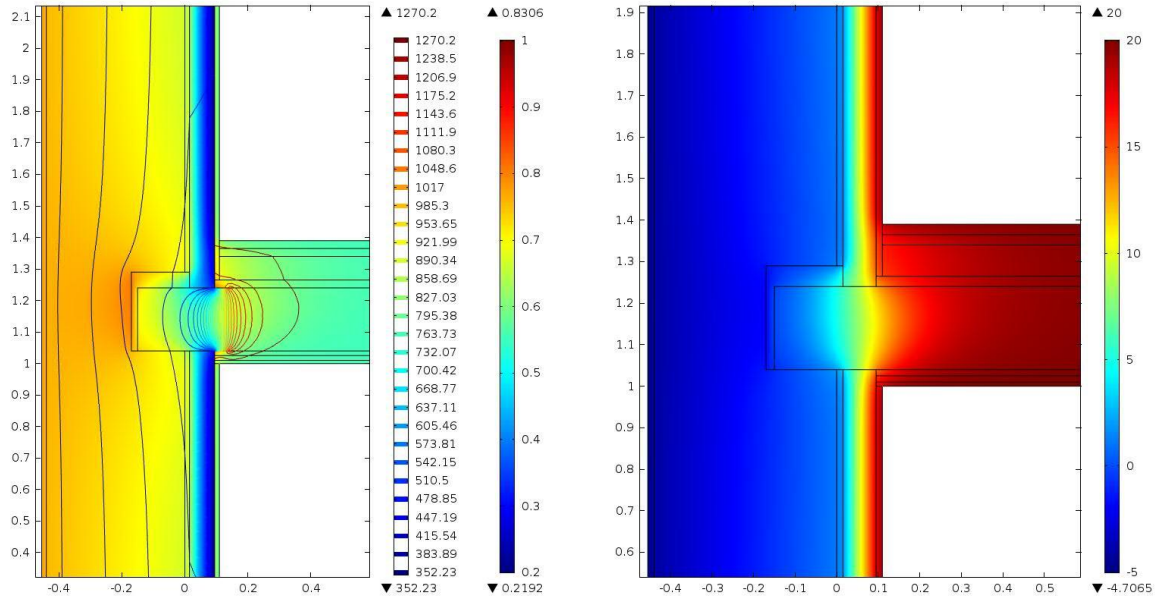

Fig. 5: 3D-simulation of a wooden beam head without airflow;
left: partial pressure and relative humidity; right: temperature

In Fig. 6 vapor diffusion, heat transfer and airflow are taken into account.

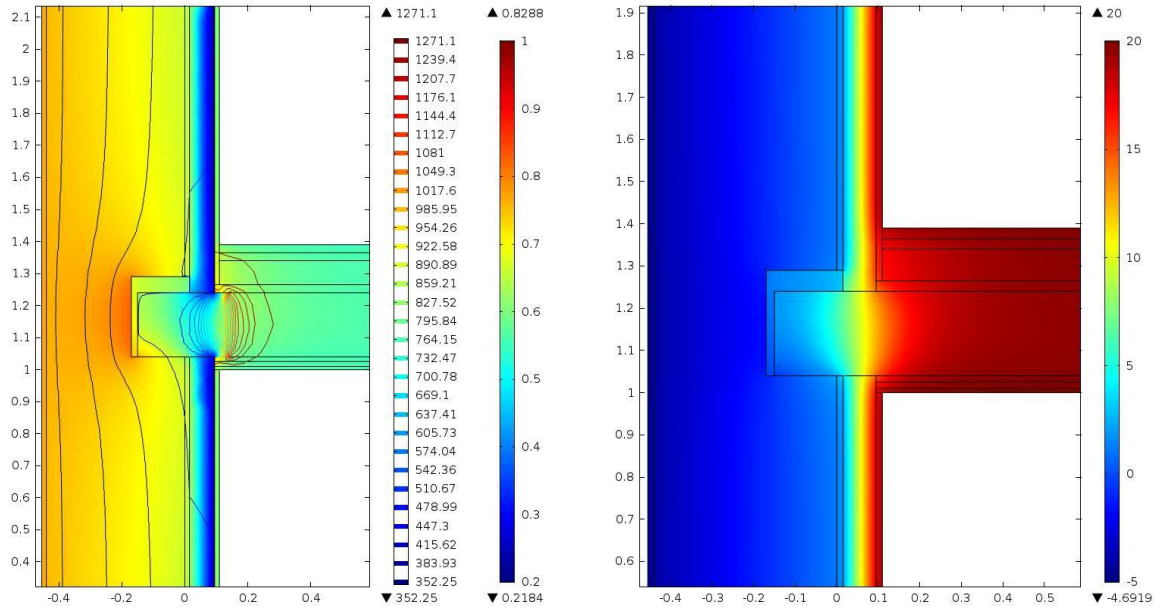

Fig. 6: 3D-simulation of a wooden beam head with airflow;
left: partial pressure and relative humidity; right: temperature

In Fig. 7 vapor diffusion, heat transfer, airflow and a leakage in the construction with a pressure difference of 0,5 Pascal are taken into account.

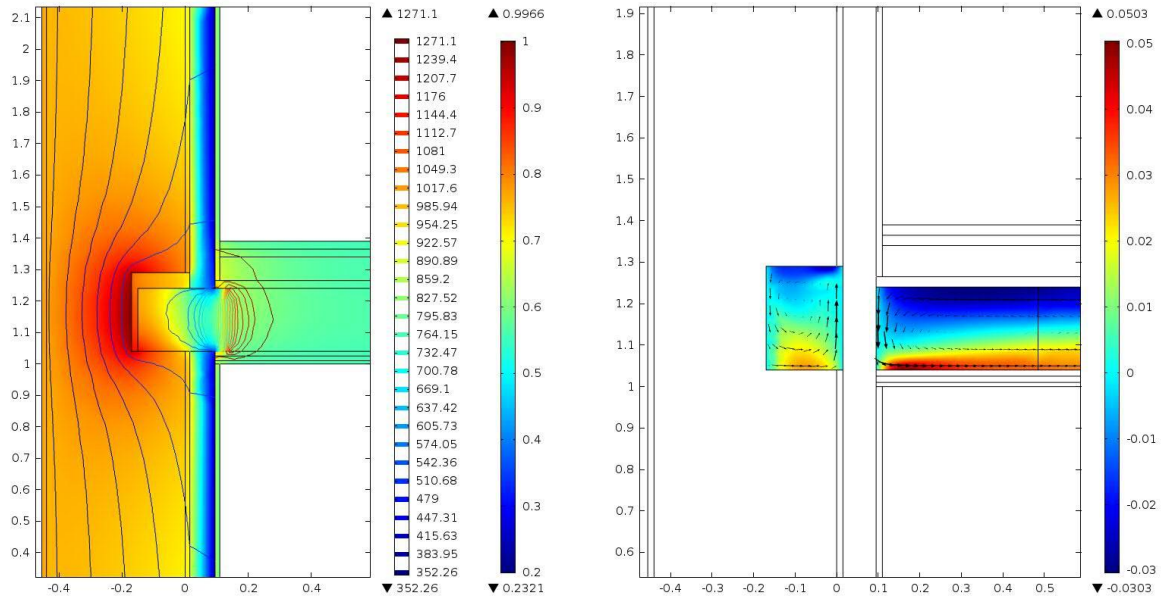

Fig. 7: 3D-simulation of a wooden beam head with airflow, leakage and pressure difference;
left: partial pressure and relative humidity; right: temperature

Comparing the three models one can see the impact of air-flows through constructions and the wide range of simulations' results. It shows that considering or neglecting a single parameter in a simulation can cause completely different results. Therefore it is very important to evaluate all parameters.

5. Conclusions and look-out

The risk of damage of inside insulated wooden beams can be described by the temperature and the relative humidity at the beam head. As shown, these parameters depend on the considered boundary conditions.

The risk for rotting and mould growth can be minimized by selective temperature control in the joist's bearing. A mechanism for temperature control of the wooden beam's end is described in [6]. Fig. 8 shows the effect of the temperature control. The temperature level is raised at the joist's bearing. So the relative humidity can be kept low in order to avoid rotting. Zelger described in [7] a simplified estimation of the additional energy costs.

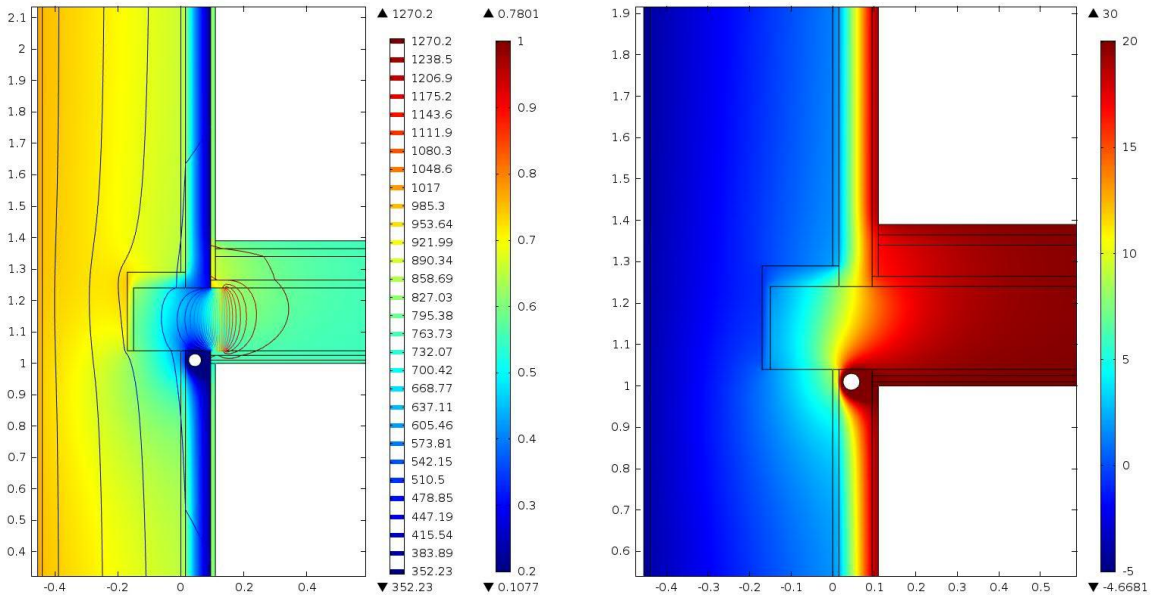

Fig. 8: 3D-simulation of a wooden beam head with airflow and local temperature control; left: partial pressure and relative humidity; right: temperature

It has been demonstrated that using hygrothermal simulations in which worst-case scenarios are assumed can provide results on the safe side. As shown in [7], the estimated costs for planning and quality assurance for specific constructions (with / without leakage) and outdoor climate conditions can be calculated. The evaluation is performed by comparison with limits such as for example, the Isopleth's model to assess the mold growth [8].

In the future, the evidence of the durability and the functionality of interior insulation systems should be based on a probabilistic safety concept. The basics such as the formation of probability distributions of material parameters and climatic boundary conditions are currently being processed. By using probabilities the retrofitting costs and life-cycle costs can be estimated in a better way.

Short Summary

The box type window (BTW) is a typical craftsmanship's construction for European buildings until the mid of the 20th century, so that there still is a high amount of such windows. While their design is quite complex (as a double window), their assembly is rather simple for a skilled joiner. Therefore they can easily be reconstructed or renovated which – instead of replacing them with new windows – saves embodied energy. Improving their thermal performance is nevertheless crucial nowadays and a deeper understanding of their thermal behavior as well as their flow characteristic is required. This paper sets out to show the outcome of a comprehensive study of the thermal behavior of BTWs´ inner cavity and close surrounding regarding some of the most promising renovation concepts.
Climatic preconditions as well as window geometry had to be considered. Results of in situ measurements of two identically designed and differently refurbished historic box type windows had been used for validating the outcome of Computational Fluid Dynamics (CFD) simulations. The simulations demonstrate effects of heat transfer, buoyancy driven air flow and radiation for the window cavity, interior room and immediate external environment and are consistent to the measurements to a great extent.

Keywords: Computational Fluid Dynamics, Historical Box Type Windows, Renovation Concepts, Thermal Performance, Flow Behavior

1. Introduction

Today Europe´s cities still consist to a notable extent of buildings established from the early 19th century to the mid of 20th century. Several of them are heritage buildings. The box type window was a typical construction at that time for a temperate climate. In Germany and Austria more than 100 million BTWs can be found on buildings´ facades [1], [2].
Because of their simple assembly BTW can be reconstructed or renovated easily and thus fulfill current requirements of heritage protection. Renovation of BTW, especially improvement of their thermal performance reduces heating demand and energy consumption as well as embodied energy otherwise spent on new windows. The huge amount of BTWs requires a detailed understanding of thermal behavior and flow characteristic inside BTWs. Beside briefly touching on convective flow this paper concentrates on simulation of the most promising renovation concepts for traditional BTWs.

BTWs consist of an interior and an exterior casement with an air filled cavity of 150 to 200 [mm] thickness in between. These casements are mounted on a wooden frame so that a box is formed by the frame and the inner and outer casements covering the cavity. Sometimes BTWs also include a shutter box on the top (Fig. 1 and Fig. 2). Normally they have air permeable joints between casement and frame with a gap-width of 1 to 2 [mm] for the inner and 3 to 4 [mm] to the outer layer. The air permeability of the joints allows vapor from the interior to flow to the exterior thus preventing condensation in the cavity which might damage the wooden parts. Furthermore it provides natural air change.

Weathering causes an increase of the air permeable joints' width. As a result convective flow inside the window increases and leads to higher heat loss from the interior to the exterior. Consequently a higher risk of condensation in the cavity and uncomfortable air-speed near the window arise. Several concepts of improvement have been developed to avoid these situations, most of them in agreement with guidelines of Austrian organizations for monument protection. The renovation concepts (Fig. 1) based on the standard BTW (A) which were analyzed in this study are: (B) a gasket frame for the inner casement, (C) insulated glass for the inner casement and thermal insulation for the shutter box, (D) an additional interior casement and (E) a vertical airproof divider within the cavity.

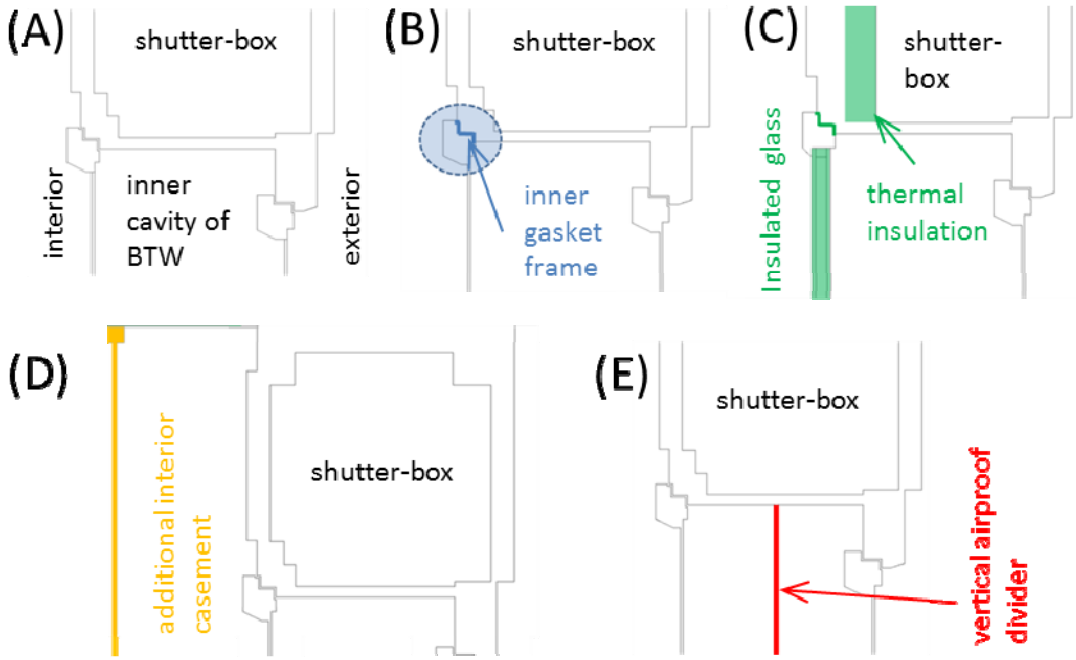

Fig. 1: Schematic of considered renovation concepts for BTWs: (A) refurbished (traditional), (B) gasket for the inner casement, (C) insulated glass for the inner casement and thermal insulation for the shutter-box, (D) additional interior casement, (E) vertical airproof divider.

To improve the level of knowledge on thermal behavior and flow characteristics of BTW the Institute of Building Construction conducted in situ measurements of two similar designed BTWs in combination with hygrothermic simulations. One window (A) was renovated and painted, the other one was additionally improved by adding a gasket frame to the inner casement and changing the inner single glass panes with low-e-coated glass panes (B). The attained data from standard BTW (A) were used for validating the results of Computational Fluid Dynamics (CFD) simulations which are the main focus of this research.

2. Literature research

Current literature shows several studies regarding natural convection in a closed cavity of double windows as well as double-skin façades [4], [5], [8] and [10]. The aspect ratio (Eq. 1) of height and length of the inner cavity is at more than 20 in all these studies.

$$A = \frac{H}{L} \tag{1}$$

The aspect ratio for a typical BTW´s inner cavity is approximately 8. Moreover Wright et al. [3] published results from an analysis of natural convection in a tall cavity between a hot and a cold wall at different Rayleigh numbers (Eq. 2). The aspect ratio was around 40 and the distance between hot and cold side was much smaller than it is in BTWs.

$$Ra_x = \frac{g \cdot \beta}{\nu \cdot a} \cdot \left(T - T_\infty\right) \cdot x^3 \tag{2}$$

A related study was conducted by Alawadhi [5] to determine the effects of window integrated phase change materials (PCM) on thermal and flow behavior of the window and the PCM. The PCM was implemented as a shading device in between the window panes.
A number of studies cover the thermal behavior of open joint façade systems as laboratory experiments in combination with numeric simulations [9] and [10]. Different measurement methods for flow characterization were used as well as several CFD simulations for validating the experimentally achieved data.
Coussirat et al. [11] investigated different numerical models for natural and forced convection in a double-glazed rear ventilated façade. The results by using different turbulence and radiation models were compared with conclusions from Manz et al. [21], resulting in SKE and RNG turbulence models being most suitable. The P1 model showed best agreements for compared radiation models.
Further more accurate flow characteristics could be achieved by using velocimetry measurements. Mortensen et al. [7] analyzed the microclimate inside a box with Particle Image Velocimetry (PIV) technique. A chiller attached at the top wall provided enough cooling power to enable natural convection inside the box.
Bhamjee et al. [12] experimentally monitored natural and forced convection within an air-supply window with the Laser Doppler Velocimetry (LDV) measurement method.
Natural convection has been covered by many studies coping heat transfer in double-glazed facades with integrated shading devices having a notable influence on convection [15] - [17], [19] and [21]. All of these studies used either two or three dimensional geometry for the CFD simulations. An alternative for investigating thermal behavior inside double-glazed facades and windows is a full scale experimental set-up, as in the studies of Pappas et al.[20], Kuznik et al. [22] and Peeters et al.[23].
Almost all of these studies concentrated an overheating on hot summer days in warmer climate. In colder climate the effort on heating for providing comfortable climate indoors in winter is significant higher than the cooling effort in summer. As no literature was found on this subject, this research at first copes with measurements for a typical BTW and the validation of simulations by measurement data followed by a theoretical reflection of four different renovation concepts.

3. In situ measurement

3.1 Measurement build up

Multiple measuring approaches are known to investigate the thermal quality of windows.

One of the most important laboratory test-sets for rating the thermal behavior of windows under controlled boundary conditions [12] is the hot box method [13], where two boxes at different temperature levels are positioned on either side of the façade or window.
In huge outdoor test facilities full scaled façade elements can be integrated and their thermal behavior under the influence of the external climate can be observed [19].
Integrating all sensors in a window in a building is called “in situ” measurement. This method was used for monitoring the thermal behavior of the renovated BTW (A) and improved BTW (B) mentioned in this paper. The windows are installed in one of the reference objects of the research project “denkmalaktiv I”: Schönbrunngasse 30, 8034 Mariatrost in Graz, Austria, a former mental home built in 1885, now a public kindergarten.

The right BTW (A) on picture (1) in Fig. 2 was used for validating the simulation results. The main dimensions of the window are 1.63 x 1.76 x 0.28 [m] (W x H x L). Each of the two BTW´s casements consists of three window parts, two of which can only be opened simultaneously. A shutter box is the upper enclosure of the inner cavity. The dimensions of the inner cavity are 1.36 x 1.49 x 0.21 [m] (W x H x L), adjacent masonry is about 0.55 [m] thick. The joints between casement and frame are varying about 0.5 and 5.0 [mm]. Several sensors were installed to measure temperature, humidity, air flow and global radiation. For the validation of the simulation results the following four temperature sensors were needed:
Sensor T-top (picture (3), Fig. 2, highlighted by a red circle) was mounted 0.2 [m] below the wooden plate forming the upper cavity enclosure and in the horizontally canter.
Sensor T-bot was also fixed in the center of the BTW´s cavity about 0.2 [m] above the base plate (highlighted by a magenta circle, picture (2), Fig. 2).
Two more sensors were attached to the window 0.34 [m] above he base, one sensor on the inner surface of the exterior (T-ext) and the other on the outer surface of the interior (T-int) glazing (picture (2),Fig. 2).

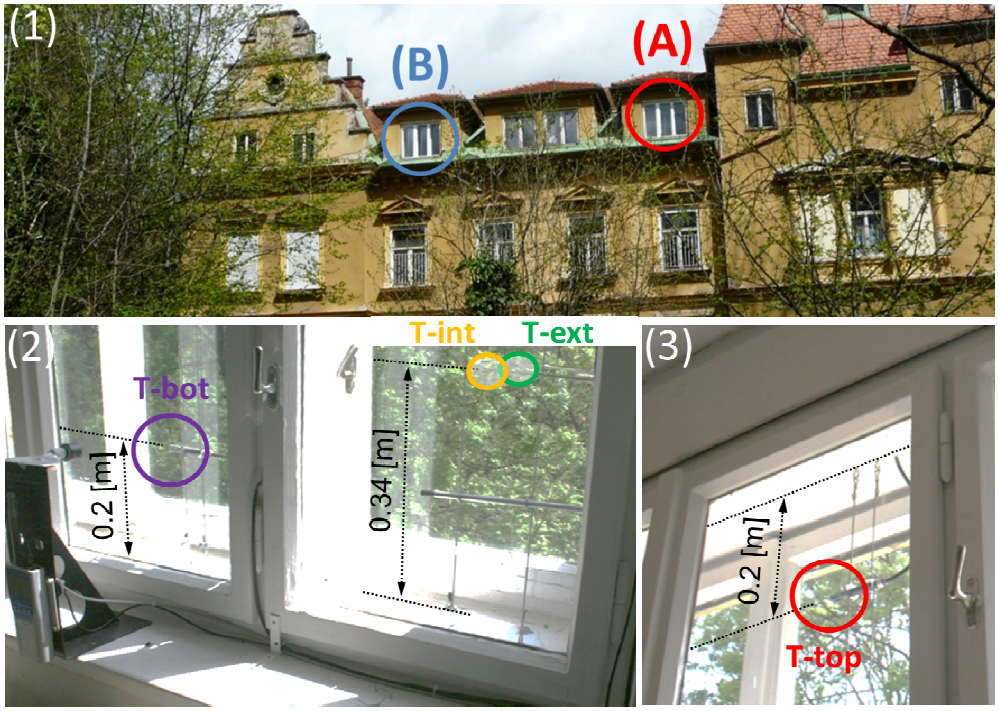

Fig. 2: (1) the south façade of the historical building Schönbrunngasse 30, Graz, including a refurbished (A) and an improved (B) BTW, (2) and (3) pictures of the BTW and details about temperature measurement build up.

3.2 Measurement results

Fig. 3 gives a sectional view on the temperature, monitored in 2012 for the refurbished BTW (A) from February 2nd to 22th. The figure also shows room temperature (T-room) as well as the external temperature (T-out) close to the window. The external temperature was ranging between -15.0 and 10.0 [°C] while room temperature was approximately between 20.0 and 30.0 [°C]. Temperature peaks in the inner cavity were resulting from the influence of solar radiation.

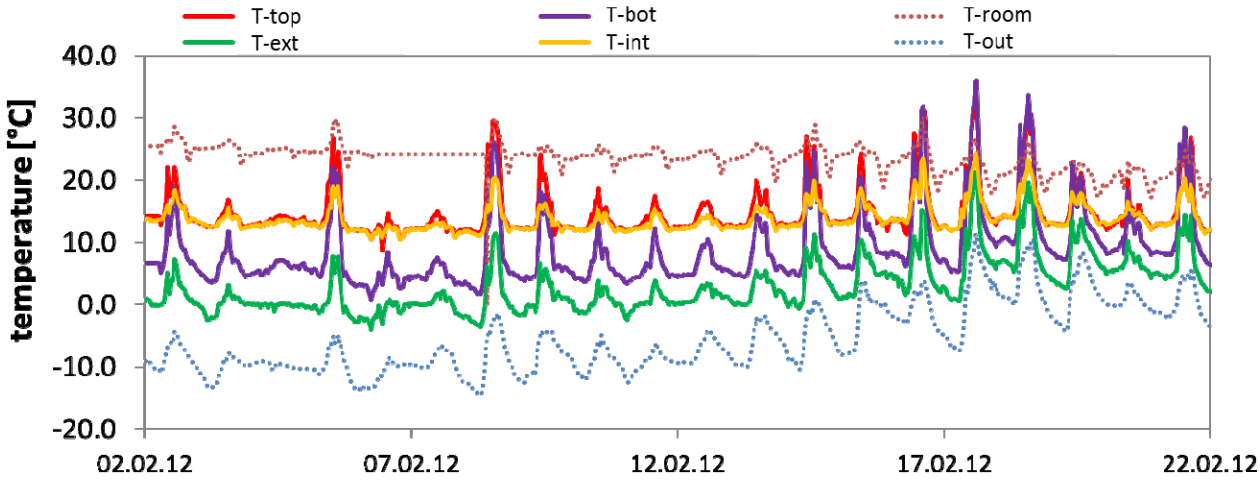

Fig. 3: Temperature measurement from February 2nd to 22th, 2012 for refurbished BTW (A).

4. Computational Fluid Dynamics (CFD)

4.1 Numeric approach and required parameter

While in-situ measurements provide only sample values for validation, Computational Fluid Dynamics can give a deeper view inside the thermal behavior of BTWs. Main goal was to reproduce the physical behavior for the inner cavity of the BTW. All simulations of this study were accomplished by the use of special CFD software called ANSYS Fluent [25]. This software provides a broad range of model-equations for description of fluid flow, thermal considerations, radiation, chemical processes etc. which are described very detailed by the theory- and user-guide [25]. Good quality in simulation results required numerical reproduction of air flow, buoyancy effects, energy consumption, thermal conductivity as well as consideration of long wave radiation. For CFD-Software available turbulence models, which have significant influence on the behavior of air flow, were derived from Reynolds Average Navier-Stokes (RANS) equations (Eq. 3).

$$\rho \cdot \overline{u}_j \cdot \frac{\partial \overline{u}_i}{\partial x_j} = \rho \cdot \overline{f}_i + \frac{\partial}{\partial x_j}\left[-\overline{p} \cdot \delta_{ij} + \mu \cdot \left(\frac{\partial \overline{u}_i}{\partial x_j} + \frac{\partial \overline{u}_j}{\partial x_i} \right) - \overline{\rho u_i' u_j'} \right] \tag{3}$$

For all simulations in this study the realizable k-ε (RKE) turbulence model was used. This simulation model was very suitable for complex flow which occurs in the BTW cavities, interior room and external environment. The extension of the enhanced wall treatment was necessary for better solution of thermal effects close to the solid surfaces. Further required was to enable gravity force and to implement full buoyancy effects in order to generate natural convection in the simulations. The air permeable joints could be defined as laminar zones, because the calculated Reynold numbers (Eq. 4) did not exceed the critical value that indicates turbulence.

$$\mathrm{Re}_x = \frac{\rho \cdot u \cdot x}{\eta} = \frac{u \cdot x}{\nu} \tag{4}$$

The discrete ordinate (DO) model was applied to involve the effects of radiation between air space adjacent walls. The input value for the Theta and Phi Divisions as well as for the Theta and Phi Pixels was 5. During the simulation radiation was calculated every 25th time step. Moreover in simulations air was treated as an ideal incompressible gas because of low Mach number (Eq. 5) with values far below 0.2.

$$Ma = \frac{u}{c} = \frac{u}{\kappa(T) \cdot R_S \cdot T} \tag{5}$$

The thermal conductivity λ for wooden components was 0.13 [W m^{-1} K^{-1}], 1.0 [W m^{-1} K^{-1}] for the window glass and approximately 0.38 [W m^{-1} K^{-1}] for the masonry wall. All simulations were performed for steady state condition by using an implicit pressure based solver. The solution method SIMPLE was used for the pressure-velocity coupling. Further the body forced weighted pressure method was used for discretization of pressure. Method for discretization of the gradients was the least squares cell based. Method of second order upwind scheme was used for convective, radiation and energy term discretization.

4.2 Geometry and boundaries

A two dimensional CFD-model geometry was developed (Fig. 4) for simulations, according to the dimensions of the BTW and the room from in-situ measurement in the building Schönbrunngasse 30 (Fig. 2). For the air permeable joints a simplified assumption with a width of 2 [mm] was made. One study from recent literature research [17] showed how important it was to consider the external environment in simulations of natural convection and ventilation effects for double-skin facades.

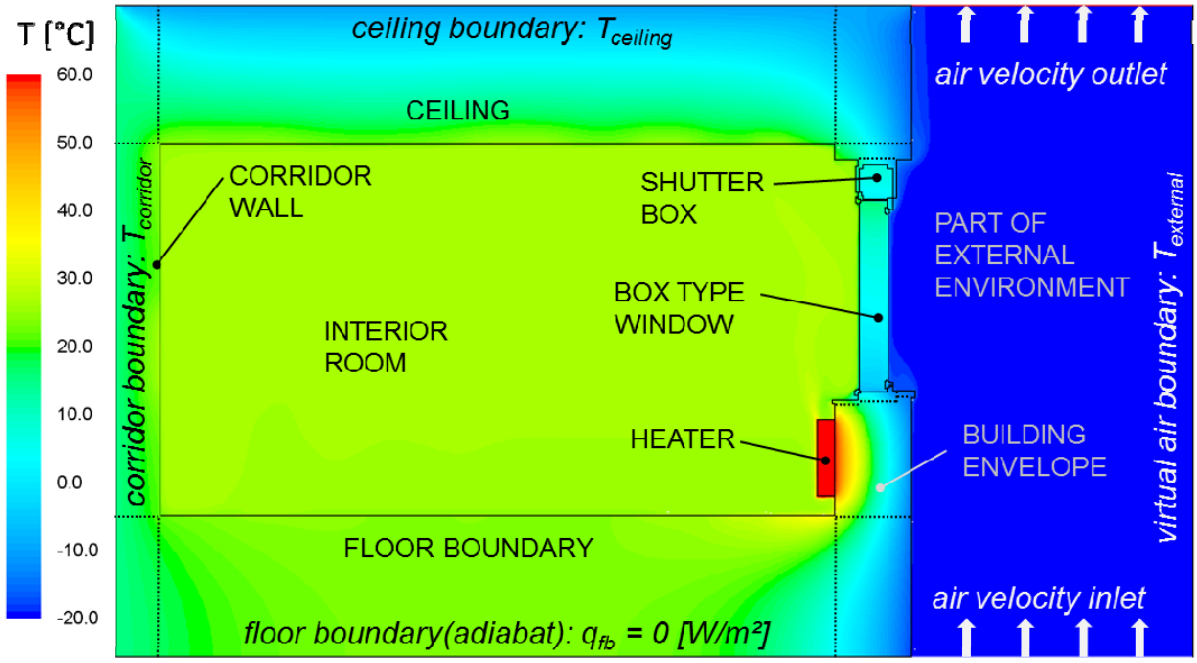

Fig. 4: Simulation model including zones and boundaries.

Main dimension of the interior room was a height of 2.67 and a length of 4.8 [m]. The room was enclosed by the ceiling, the floor and the corridor boundary as well as the building´s envelope. For the floor boundary no heat exchange to the room below was defined. The influence of external wind was included in simulation by definition of a velocity outlet at the top and a velocity inlet at the bottom of the external environment zone. Below the BTW bench a radiator was attached that supplied heating energy to the room by predefinition of the heater´s surface temperature.

4.3 Grid for CFD simulations

For the grid generation of the BTW simulation geometry the “pave” method was used. The grid nucleation was initialized at the air permeable joints at a starting cell size of about 0.5 [mm]. The grid generation was accomplished with the help of the software Gambit [25]. Afterwards the grid had to be adapted by considering the wall function. For the adaption process the generated grid was imported to the CFD Software Fluent ANSYS. The boundary conditions in adaptation process were the same as in the CFD-analysis of the thermal behavior for a cold winter day (5.1). The adaptation process was completed when turbulence rating y^+ had reached a value smaller than 1.0 [25]. After adaptation process the grid consisted of approximately 600.000 linked cells. Fig. 5 gives a sectional view of the grid structure by showing the region of the bottom located inner air joint. The grid´s cell size varied between 0.05 x 0.05 and 64 x 32 [mm].

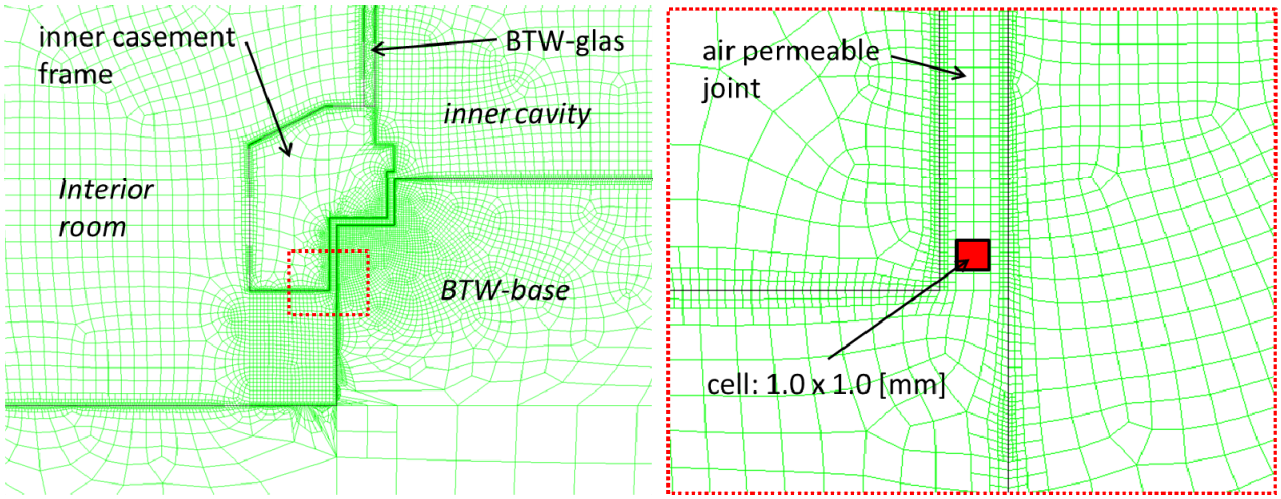

Fig. 5: Sectional view of the grid structure for the BTW simulation geometry at the region of bottom located inner air joint.

5. Results and Discussion

5.1 Thermal and flow behavior for a cold winter day

The first analysis was the examination of convective flow during a winter day in the region of Graz in Austria. The external temperature was -20 [°C] at a wind speed of 0.1 [m/s] along the façade of the building. This wind speed input was resulting from the most prevalent horizontal wind loads occurring at this location of the building. The ceiling boundary temperature was -10 [°C] for consideration of heat loss through the roof of the building. The corridor boundary temperature was 15 [°C], assuming that the buildings´ corridors were held at moderate temperature. The effect of heating was defined by a heater´s surface temperature of 60 [°C].
Fig. 6 and Fig. 7 give a sectional view of the temperature distribution and convective flow inside and close to the BTW. The red arrows highlight the main flow characteristic for the inner cavity. At the bottom located exterior joint infiltration of air from outside was detected. In the region close to the exterior casement frame at the bottom of the BTW cavity several air vortices were obtained. The air streamed from exterior to the interior casement at the bottom of BTW cavity. A jet of cold air flowed inside to the room through the bottom located interior joint. This cold air was mixed up with the upwards streaming, by the radiator heated air and caused a reduction of the room temperature. Additionally the air streamed upwards due to buoyancy effects. Along the whole interior window glass a thin natural convective flow could be observed. At the top temperate air from the interior room streamed into the BTW´s cavity and got mixed up with the upwards streaming air along the interior window glass. This mixed air streamed from interior to exterior casement along the upper edge of the cavity. Through the upper exterior joint temperate air flowed to the external environment. A rest of air was streaming around the upper exterior casement frame. Close to the

exterior window glass the air was cooled down and flowed downwards. Furthermore occurred a small partition of air that was recirculated at the top of the BTW cavity.

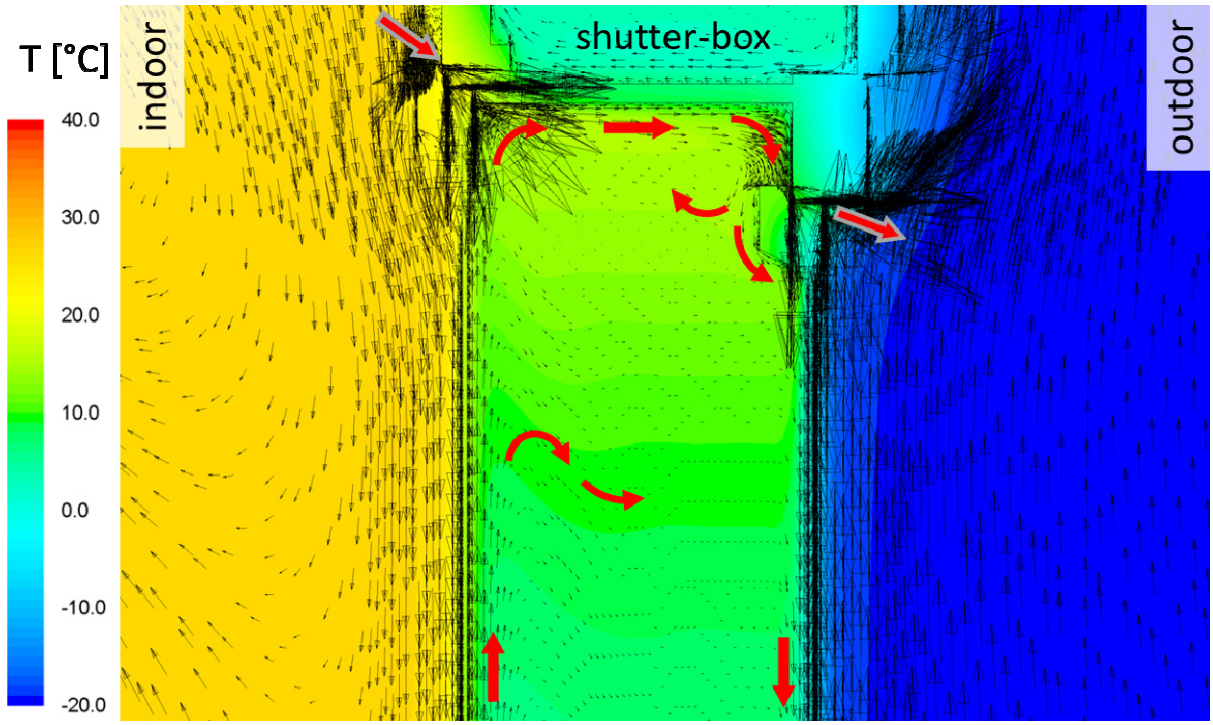

Fig. 6: Illustration of temperatures and air vectors for the upper region of the inner cavity of the refurbished BTW (A).

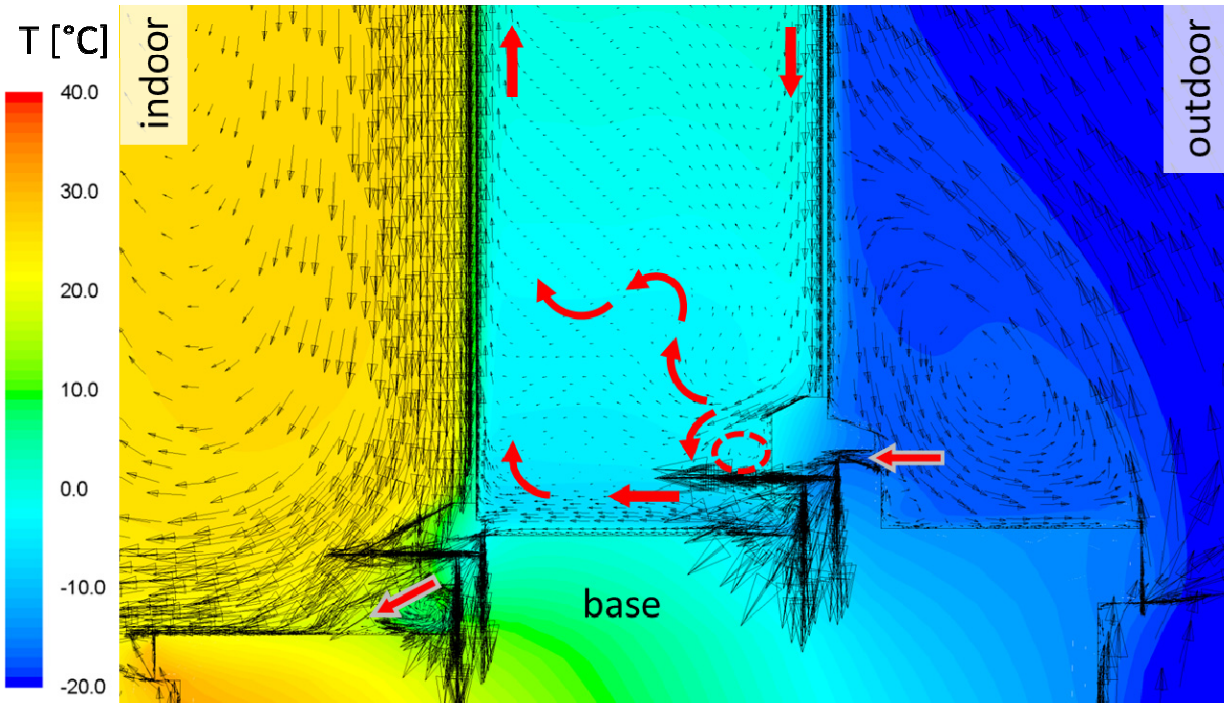

Fig. 7: Illustration of temperatures and air vectors for the lower region of the inner cavity of the refurbished BTW (A).

More details about the temperature and buoyancy velocity for inner cavity are shown in Fig. 8 and Fig. 9. Fig. 8 includes temperature and velocity profiles along the length of the BTW cavity at the middle of the BTW´s height (A-center), 20 [mm] distanced below the upper cavity edge (A-0.2-top)

as well as 20 [mm] in distance above the bottom edge of the cavity (A-0.2-bot). Fig. 9 contains three sections of temperature and buoyancy velocity profiles along the BTW height (at the middle position (A-middle) of BTW-length and in 10 [mm] distance to exterior (A-0.1-ext) and interior (A-0.1-int) window glass).
The temperature profiles showed a stratification of temperature along the height of window´s cavity where temperature was increasing upwards. The profiles indicated fluctuations of temperature near the air permeable joints. The buoyancy velocities of convective flow along the window glasses reached a maximum in the middle of the BTWs´ height. The thickness of these flows varied between 3 and 12 [mm]. In the middle of the BTW´s length a zone was obtained, that showed almost no buoyancy velocity.

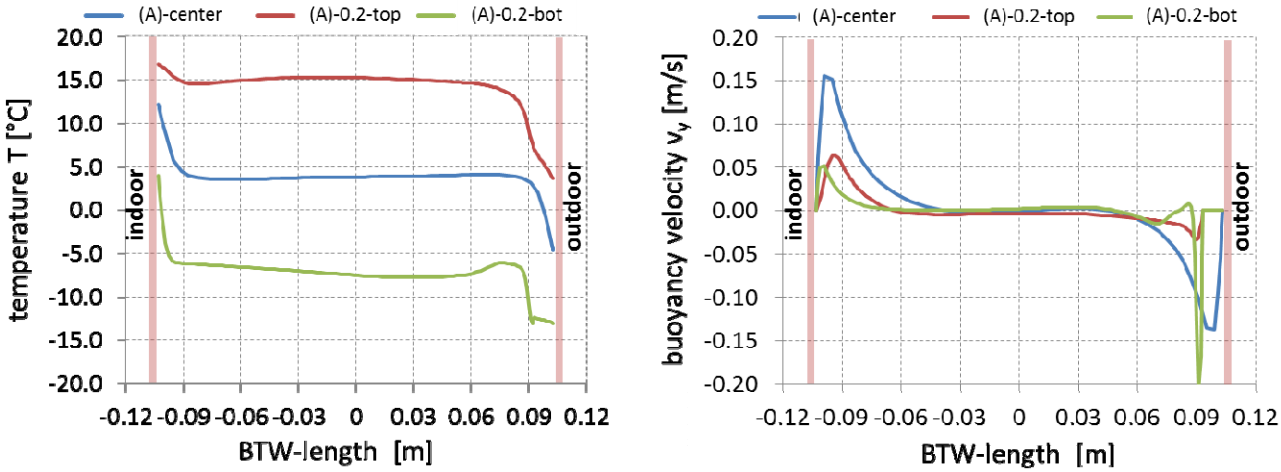

Fig. 8: Profiles of temperature and buoyancy velocity along the inner cavity´s length for the refurbished BTW (A) at different BTW heights.

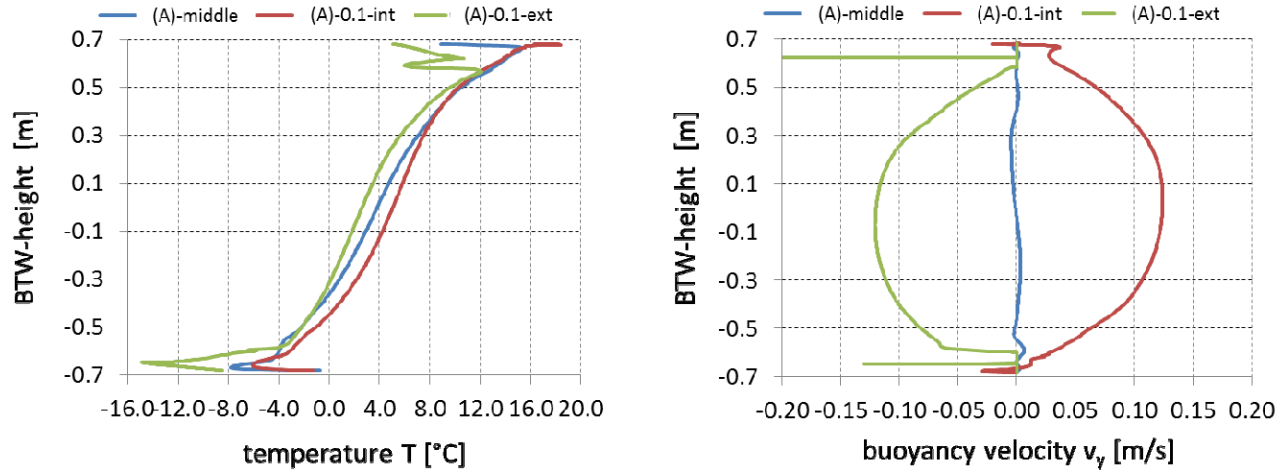

Fig. 9: Temperature and buoyancy velocity along the inner cavity´s height for the refurbished BTW (A) at different BTW length.

5.2 Comparison between measurement and simulation

This chapter shows a comparison of the computed temperature profile with the data from measurements for the refurbished BTW (A). On 6th February between 9 and 12 p.m. almost constant temperature was indicated which was perfectly qualified for the validation of the steady state simulation´s results. At this point of time external measured temperature was -9.96 [°C]. The corresponding measured room temperature was 24.2 [°C].
In the CFD simulation the measured external temperature was used as input for the virtual air boundary. During simulation process the surface temperature of the heater had been changed until

the room temperature had reached the measured value. The results of the computed temperature profiles from this simulation compared with measurement data are shown in Fig. 10. This diagram contains the computed temperature profile along the BTW-height (A-middle) at the cavity measurement sensor´s position (T-top, T-bot, also shown in Fig. 1) as well as the temperature profiles along the cavity-oriented surface of the external (A-ext-pane) and the internal (A-int-pane) pane. Measured (T-int, T-ext) and simulated temperatures at the window glasses showed good agreement. The computed values underestimate the measured temperatures inside the BTW. The difference at the upper sensor position was 1.54 [°C], the measured temperature at the lower sensor position was 2.57 [°C] higher than computed. These deviations could be explained because of the two dimensional simulation geometry and simplifications in form of the assumption of a uniform width for the air permeable joints.

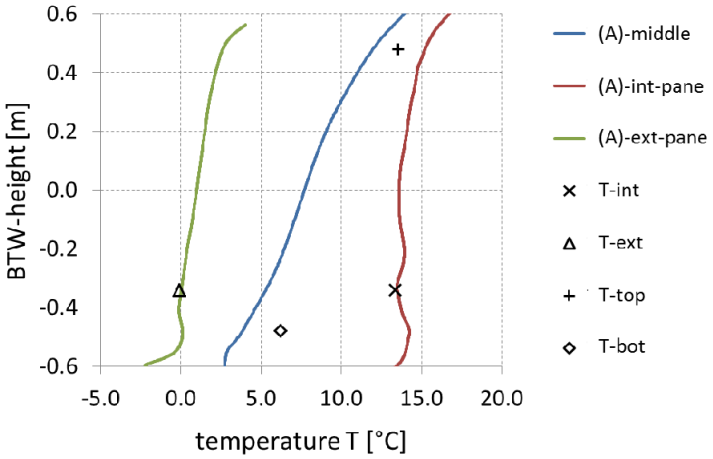

Fig. 10: Comparison between in situ measurement and the computed temperature profiles at corresponding positions in the cavity of the refurbished BTW (A).

5.3 Comparison of renovation concepts

After determination of air flow and validation of simulation data for the refurbished BTW (A), the comparison of the before mentioned renovation concepts (Fig. 1) follows. By the reason, that for renovation concept´s simulations the boundary conditions were inherited from the refurbished BTW simulation of a cold winter day (chapter 5.1) a cross-comparison was possible. Resulting temperature profiles of the renovation concepts are shown in Fig. 11. This figure also includes the comparison of the average room temperature for all renovation concepts. A higher averaged room temperature indicates better quality for the corresponding renovation concept. Therefore a specially expression of the BTW rating (Eq. 6) was developed:

$$rating_{BTW(i)} = \frac{T_{average,BTW(i)} - T_{average,BTW(A)}}{T_{average,BTW(A)}} \cdot 100\% \qquad (6)$$

Concerning to this evaluation method the application of an insulated glass as inner pane and thermal insulation for the shutter-box (C) effected highest average room temperature and thus received the best BTW rating (21.6 %). The renovation concept with the integrated vertical airproof divider (E) showed an improvement of 6.9 %. The concept with the additional casement at the interior room side (D) followed with 4.4 % in improvement ranking. The implementation of the interior gasket frame (B) also showed a slight improvement (1.24%).

The influence of each renovation concept on the air temperature of the inner cavity as well as on the temperature profile close to the interior casement is shown in Fig. 12. Temperature profiles for the interior room close to the window confirmed the results of average room temperatures. The temperature profiles inside the cavity showed inverse behavior to the room temperature with the exception of the renovation concept (E) with the vertical inner divider.

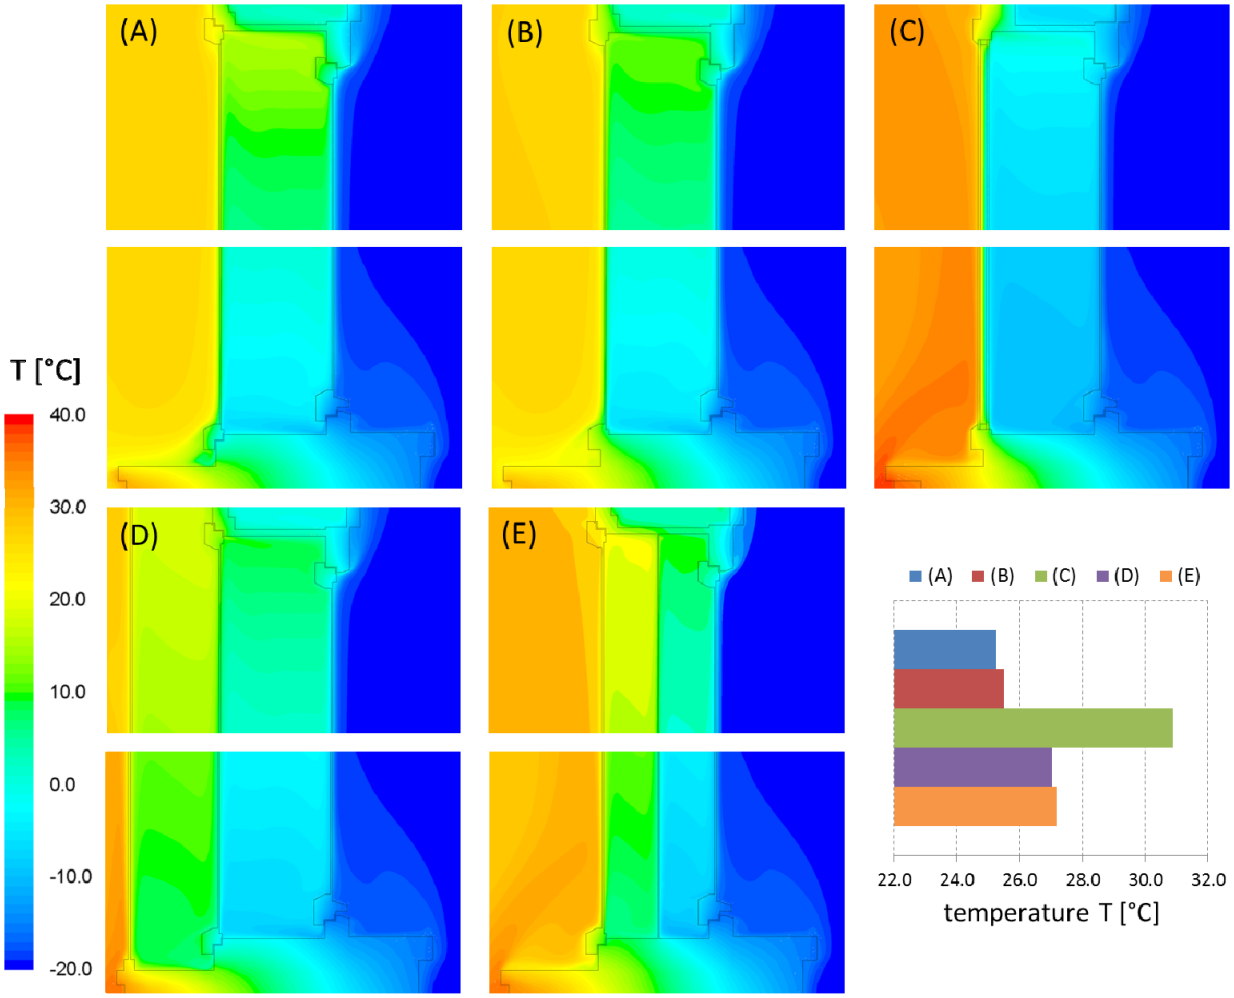

Fig. 11: Temperature distribution at the bottom and top region of the inner cavity for (A) the refurbished BTW, (B) the BTW with implemented interior gasket frame, (C) BTW containing an insulated glass and insulation for the shutter-box, (D) BTW with additional interior casement and (E) BTW with an vertical airproof divider. The diagram shows a comparison of average room temperature of the five BTW types.

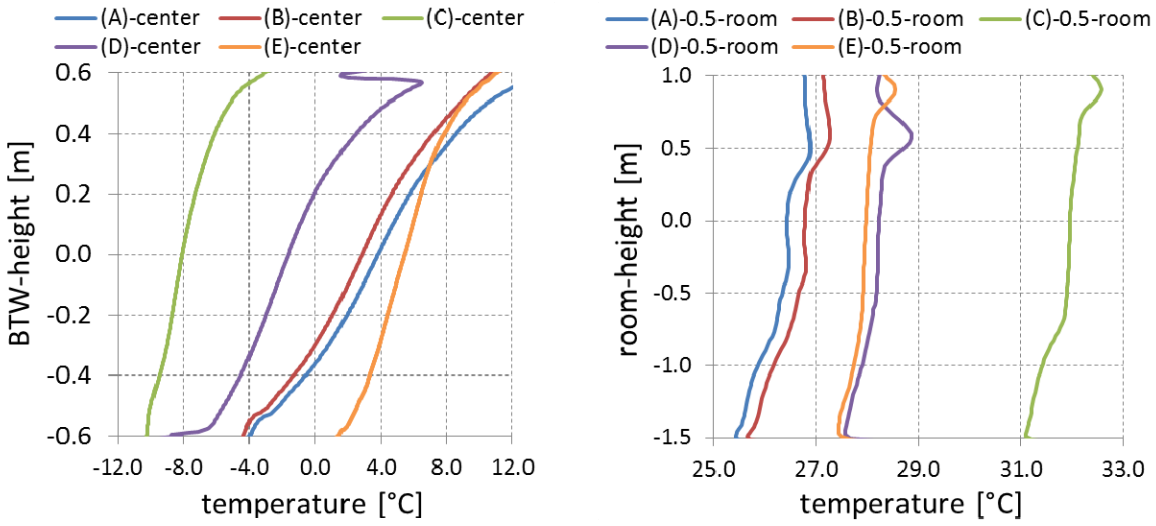

Fig. 12: Left diagram shows the comparison of temperature profiles along the BTW cavity height, right diagram shows the temperature profile along the room height at a distance of 0.5 [m] to the interior window glass.

6. Conclusions and Outlook

This paper covers a detailed prediction of the thermal behavior of a traditional BTW´s (A) inner cavity and close environment by use of Computational Fluid Dynamics. Boundary conditions were those of a cold winter day in a temperate climatic zone. Flow characteristic of the inner cavity as well as effects of infiltration and natural ventilation have been discussed.
Sectional profiles of temperatures and buoyancy velocity described shape, stratification and magnitude of the convective flow along the windows casements at the inner cavity. Maximum buoyancy effect occurred in the middle of the BTW´s height.
The validation with results from in situ measurements showed good accordance between simulation and measurement data at the window glasses while the computed temperature inside the BTW cavity was too low. The influence of solar radiation on convective flow for the inner cavity was indicated by high temperature peaks.
Differences in thermal behavior between four different theoretical renovation concepts were simulated by CFD and compared with the results from the refurbished BTW. The BTW (C) containing an insulated glass and insulated shutter-box achieved the best rating concerning thermal performance. All other renovation concepts also showed improvement.
Further experiments and measurement set-ups with controlled boundary conditions would produce a higher level of data and validation quality.
As a summery it can be assessed that investigations of the transient behavior of BTWs as well as consideration of three dimensional simulation models improve the quality of the simulation results.

7. Acknowledgement

The CFD simulations and the measurements were accomplished within the “denkmalaktiv I[1]” research project. So the authors wish to thank the “FFG” as well as the “klima + energie fond” for the financial support and sponsoring.

Summary

Building rehabilitation is essential to achieve the targets defined by the EPBD recast regarding energy efficiency, reduction of carbon emissions and use of on-site renewable energy sources. Besides the energy efficiency the Indoor Environmental Quality of Buildings (IEQ) and environmental impact must also be considered when planning a refurbishment project. Thus to propose an effective building rehabilitation is necessary select the adequate construction solutions taking into account their impact on the energy performance, thermal and acoustic comfort, indoor air quality and environmental impact of the building. In this work a multi-criteria decision analysis method, ELECTRE III, is applied to balance all these aspect, during the design phase of a refurbishment project, in order to assist the design team on the selection of construction solutions. Throughout the multi-criteria analysis performed, it was possible to verify that the rehabilitation solutions with lower embodied energy were the best refurbishment options.

Keywords: Refurbishment; Thermal behaviour; Acoustic performance; Energy efficiency; Multi-criteria decision analysis

1. Introduction

Energy efficiency and indoor environmental quality of buildings are nowadays major concerns as European Union (EU) buildings account for 40% of the total energy consumption and the population spend about 90% of their time inside closed spaces [1]. Thus, it is mandatory to control the energy consumption in the building sector, while maintaining, or even improving, the indoor environmental quality (IEQ), to reduce these needs and, consequently, reduce the EU energy dependency as well as the greenhouse gas emissions, in accordance with what is pre-scribed in the Energy Efficiency in Buildings Directive (EPBD) and reinforced with the "EPBD recast" [1, 2].

The rehabilitation of the building stock is an opportunity to achieve these goals. In Portugal, 80% of the building stock was built before 1990, year of the publication of the first Portuguese thermal regulation, leading to high levels of thermal discomfort and excessive energy consumption, as the majority of the existing buildings was built without any thermal concerns and shows very high energy consumptions even when minimal comfort conditions are required [3].

To correctly select the rehabilitation construction solutions it is necessary to consider their contribution to the energy efficiency, thermal and acoustic comfort, daylight conditions and the indoor air quality, its environmental impact (considering the embodied energy, for example), but also their contribution to the thermal inertia of the building, the weight of the solution and its effect on the structural project of the building and the thickness as the useful area might be reduced.

However, these goals are often in conflict and there is not a unique criterion that describes the consequences of each alternative solution adequately and there is not a single solution that optimizes all criteria. In many cases, the best solutions to accomplish different comfort requirements are not compatible, especially in what concerns natural ventilation and daylighting strategies and the acoustic and thermal performance. For instance, the type of window used can have a strong and opposite influence on the thermal and acoustic performance of the building, just not to mention its interference with the indoor air quality (IAQ). It is, then, necessary to have an integrated approach to ensure the best overall behaviour taking into account all of the, sometimes incompatible, comfort and energy efficiency requirements.

Thus to propose an effective building refurbishment is necessary to select the adequate construction solutions and materials taking into account their impact on the energy performance, thermal and acoustic comfort, indoor air quality and environmental impact of the building.

Therefore, thermal quality, acoustic behaviour and energy reduction strategies, that are mandatory, should be meshed at an early stage of the rehabilitation process with the other requirements to ensure the buildings overall comfort conditions and energy efficiency. To do so, it is necessary to select the correct materials, and construction solutions, among a large number of options to improve the occupants overall comfort and, at the same time, reduce the energy costs. Furthermore, to make a conscious selection of the possible alternatives, it is necessary to balance the positive and negative aspects of each solution into the global behaviour of the building trough a multi-objective optimization. The correct comparison of the solutions is difficult as the behaviour of some are affected by imprecision (design phase) and it is also necessary to take into account the constraints of the project and the decision maker point of view.

Multi-criteria decision analysis (MCDA) is, in this way, an important tool in such problems, since it can be used in any location and employs mathematical models that evaluate alternative scenarios, taking into account both their objective characteristics (acoustic insulation, U-Value, etc.) and the preferences of the decision makers regarding the objectives and constraints of each project.

The aim of this study was to select the materials and construction solutions to refurbish the façade walls of a building, based on criteria that are mandatory (U-value and acoustic insulation) and the designer must conciliate. The embodied energy, superficial mass and thickness of the construction solutions were also considered as they are a designer concern, affecting the environmental impact, the thermal inertia and the useful area of the building. The MCDA method ELECTRE III was chosen to assist the design team in the selection of the most adequate refurbishment solutions [4].

2. Methodology

To achieve an adequate behaviour of the buildings it is necessary to consider the indoor environmental quality, the environmental impact as well as energy efficiency. It is then essential to optimize the building envelope, by improving construction solutions and insulation levels, glazing type, optimizing the thermal and acoustic behaviour, the natural ventilation and daylighting techniques through an appropriate refurbishment. In this study several construction solutions for the façade walls were studied.

2.1 Retrofit Building Characteristics

The case-study building to be refurbished is a detached single family house (Figure 1), from the 1980s. The building is a single residential unit with two bedrooms, north oriented, with 54.42 m^2 and 2.44 m of floor to ceiling height. The construction system is a low cost construction system based on a steel reinforced concrete pillars and beams structure, single pane hollow concrete block walls (CMU) and clear single glass with aluminium frame windows with PVC (Polyvinyl chloride) roller shutters. The window to wall ratio is approximately 20%. Table 1 lists the main characteristics of the building envelope.

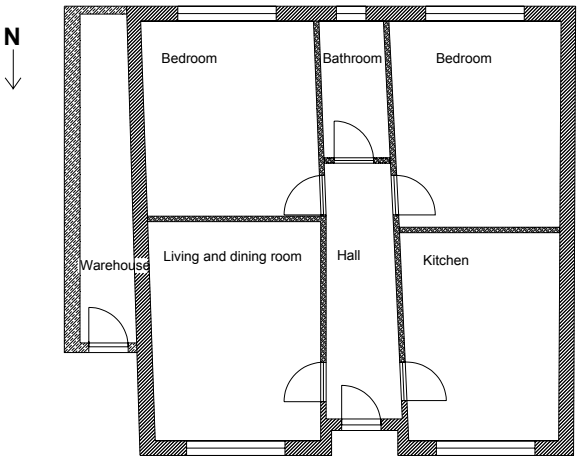

Fig. 1: Floor plan of the building

Table 1: Characteristics of the building

Building element	Construction solution	U-value [W/(m^{2}ºC)]
Structure	Concrete pillars and beams	-
Floors	concrete	-
Roof	Pitched roof	2.35
Ceiling	Beam and pot slab	3.08
Façade walls	Single pane hollow concrete block	1.90
Roller shutter boxes	concrete	2.85
Windows (window to wall area of 20%)	Single clear glass with aluminium frame	5.14
Partition walls	Hollow brick	-

2.2 Multi-criteria analysis

The multi-criteria decision analysis (MCDA) defines flexible approach models to help the decision maker, and/or the design team, perform a multi-objective optimization to select the most adequate solutions to optimize the building IEQ and energy efficiency among a large number of options and possibilities. The MCDA methods can be applied when there are several decision agents, each one with different objectives and criteria, sometimes with opposite visions. The problem of the decision makers is a multi-objective optimization problem characterized by the existence of multiple, and in several cases competitive, objectives that should be optimized, taking into account a set of parameters (criteria) and constraints [5].

This kind of analysis is able to reflect the objectives and limitations of each one of the alternatives to be studied, but it is necessary to be thorough on selecting the criteria that should be exhaustive but not redundant (it is recommended to use no more than 12, which represents an acceptable compromise between feasibility and detailed description) and must be coherent (which are the criteria to be maximized and to be minimized) [6, 7].

The multi-criteria methodology selected in this work to help the decision maker selecting the most adequate solutions to optimize the building indoor environmental quality, was the ELECTRE III (ELimination Et Choix Traduisant la REalité - ELimination and Choice Expressing the REality) model as it may be considered as a decision-aid technique suited to the appraisal of complex civil engineering projects [4, 8].

2.2.1 The ELECTRE III method

ELECTRE III is a multi-criteria decision analysis method that takes into account the uncertainty and imprecision, which are usually inherent in data produced by predictions and estimations [4]. The construction of an outranking relation amounts at validating or invalidating, for any pair of

alternatives (a, b), the assertion "a is at least as good as b". This comparison is grounded on the evaluation vectors of both alternatives and on additional information concerning the decision maker's preferences, accounting for two conditions: concordance and non-discordance.

The ELECTRE III method is based on the axiom of partial comparability according to which preferences are simulated with the use of four binary relations: I, indifference; P, heavy preference; Q, light preference and R, non-comparability. Furthermore, the thresholds of preference (p), indifference (q) and veto (v) have been introduced, so that relations are not expressed mistakenly due to differences that are less important [4].

The indifference threshold (q) defines the value beneath which the decision maker is indifferent to two option valuations, the preference threshold (p) defines the value above which the decision maker shows a clear strict preference of one option over the other, and the veto threshold (v) where a ‘discordant’ difference in favour of one option greater than this value will require the decision maker to negate any possible outranking relationship indicated by the other criteria. The indifference (q) and preference (p) thresholds of any criterion can also be interpreted as the minimum imprecision and the maximum margin of error respectively [9].

The ELECTRE III method does not allow for compensation, which may occur when using methodologies based on performance indexes, due to the use of the veto threshold. Using this method, an option which shows too poor results in one criterion cannot be ranked in a higher position [10]. The model permits a general ordering of alternatives, even when individual pairs of options remain incomparable or when there is insufficient information to distinguish between them [11]. Also, the technique is capable of dealing with the use of different units, the mix of both quantitative and qualitative information and when some aspects must be maximized and others minimized.

This method allows, in an easy and quick way, to outrank construction solutions options according to a set of criteria pre-established and based on criteria weights and thresholds assigned to each one. The criteria, criteria weights and thresholds are selected by the design team according to the objectives and constraints of each project which enable the use of this methodology to a vast set of possibilities (selection of materials, construction solutions, design alternatives, rehabilitation scenarios, etc.), based on different criteria (U-value, acoustic insulation, embodied energy, weight, heating and cooling needs, etc.). This methodology is not specific to a country and can be used in an early stage of the design phase of a new building or of a refurbishment project, when not all the characteristics are defined.

2.3 Prediction Tools

The prediction of the building thermal behaviour, related to thermal comfort and energy efficiency, was done using the U-value, determined using the publication ITE50 – U-Values of Building Envelope Elements [12]. All the solutions selected respect the minimum requirements defined in the Portuguese Thermal Regulation [13].

The acoustic performance of the building elements the weighted standardized level difference of the façade ($D_{2m,\,nT,\,W}$) was estimated using the Acoubat Sound Program [14, 15]. All the solutions selected respect the requirements defined in the Portuguese Acoustic Regulation [14].

The embodied energy was assessed using the Cumulative Energy Demand 1.04 method from the Life Cycle Assessment (LCA) software, SimaPro 7.1.8 [16, 17, 18].

3. Results

3.1 Criteria, Criteria Weights and Thresholds

In the study performed, the ELECTRE III method was applied to the evaluation of several alternative solutions for the façade walls on the basis of five criteria: thermal and acoustic

insulation, superficial mass, weight and thickness. Table 2 lists the different criteria, thresholds and criteria weights that were selected, by the design team, for this case-study.

Table 2. Criteria, criteria weighting and thresholds (criteria to: ↓ - minimize; ↑ - maximize).

Criteria	Units		Criteria Weight	Threshold		
				Preference	Indifference	Veto
Thermal Insulation (U-Value)	W/(m^{2}ºC)	↓	25	0.25	0.10	0.50
Acoustic Insulation ($D_{2m, nT, W}$)	dB	↑	25	5	2	10
Embodied Energy (EE)	MJ/m^2	↓	20	200	50	400
Superficial Mass (Msi)	kg/m^2	↑	20	50	10	100
Thickness	cm	↓	15	10	2	30

The criteria selected to outrank the construction solutions options are related to the most important characteristics of the IEQ, the thermal and acoustic comfort and influence the energy efficiency of the building. These criteria were also selected because it is possible to define them in a non subjective way, it is possible to predict them in an early stage of the design phase, they are under the designer scope and they are the issues that are also the most valued by the users of the buildings. The minimum thermal and acoustic insulation values are also defined in the Portuguese thermal and acoustic regulations and are mandatory [13, 14].

The embodied energy, the superficial mass and the thickness of the construction solution were also selected. The embodied energy is considered to account the environmental impact of the construction solution, as this is nowadays a concern of the building sector. The superficial mass is considered to account the impact of the construction solution in the thermal inertia of the building, as this is essential to the correct behaviour of the building. The thickness of the solutions was selected as it influences the useful area and is an important factor, valued by the designer.

The U-Value, the embodied energy and the thickness of the construction solution are criteria to be minimized to improve the thermal comfort conditions, energy efficiency and environmental impact and to increase the useful area available. The Façade acoustic insulation, $D_{2m, nT, W}$, and the superficial mass are criteria that should be maximized, to improve the acoustic comfort and the thermal inertia of the building.

As the definition of criteria weights and thresholds must take into account the objectives and constraints of the project and capture the points of view of the decision makers, to select them, a sensitivity analysis was performed and the visualization of the outcome impacts was assessed.

The criteria weights were defined taking into account the relative importance of each one of the criteria. The criteria weighting established for the thermal and acoustic insulation criteria, associated to the thermal and acoustic comfort, were defined according to the relative importance of each one to the occupants based on studies performed in Portugal and according to literature [19, 20, 21]. These studies showed that the thermal and acoustic comfort are the most valued criteria. The embodied energy, superficial mass and thickness of the solutions are essentially a concern of the designer.

The thresholds were defined according to the criteria characteristics, for example a 2 dB difference is the threshold at which human beings can perceive differences in noise levels and 5 dB is the noise difference at which clear preference can be expressed for one option over another [22].

3.2 Construction Solutions

The first step of the refurbishment process was the replacement of the existing single glass windows and PVC roller shutters by windows with double pane glass with air inlets in the aluminium frame with thermal break (U_w = 2.50 W/(m^{2}ºC)) and insulated roller shutters (considering the thermal resistance of the window, during daytime and the thermal resistance of the window and of the roller shutter during the night-time, U_{wdn} = 2.00 W/(m^{2}ºC)). The air inlets were introduced to improve the air change rate and the indoor air quality. Additionally 20 cm of mineral wool were

placed in the roof (0.21 W/(m^{2}ºC)) to improve its thermal performance.

The rehabilitation construction solutions selected (shown in Figure 1 and listed in Table 3) cover the solutions most used in Portugal (External Thermal Insulation Composite Systems, ETICS, ventilated wall, insulation and plasterboard or hollow brick panes). The study was done considering four insulation materials (expanded polystyrene, EPS, expanded extruded polystyrene, XPS, mineral wool, MW and cork, ICB).

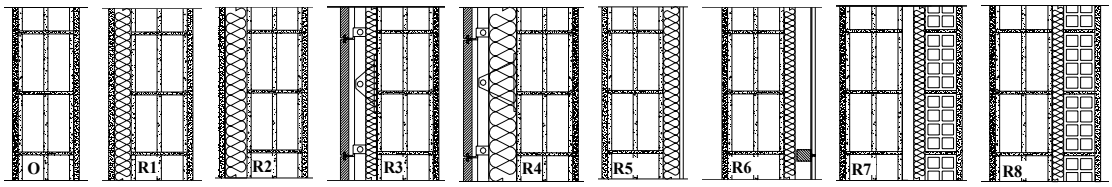

Fig. 2: Vertical cross-section of the existing and rehabilitation construction solutions of the façade walls

Table 3. Construction solutions studied for the façade (as represented in Figure 1).

Option	Wall	U-Value [W/(m^{2}ºC)]
O	Hollow concrete block with 20 cm	1.90
R1	Hollow concrete block wall, 20 cm and ETICS system with 4 cm of EPS	0.65
R2	Hollow concrete block wall, 20 cm and ETICS system with 8 cm of EPS	0.40
R3	Hollow concrete block wall, 20 cm and ventilated wall with stone with 5 cm with 4 cm of XPS	0.67
R4	Hollow concrete block wall, 20 cm and ventilated wall with stone with 5 cm with 10 cm of XPS	0.34
R5	Hollow concrete block wall, 20 cm and plasterboard wall (1.3 cm) with 4 cm of MW	0.57
R6	Hollow concrete block wall, 20 cm and plasterboard wall (1.3 cm) with 6 cm of MW	0.48
R7	Hollow concrete block wall, 20 cm, air gap and hollow brick (11 cm) with 4 cm of MW	0.48
R8	Hollow concrete block wall, 20 cm and hollow brick (11 cm) with 6 cm of ICB	0.42

* EPS – expanded polystyrene; XPS – expanded extruded polystyrene; MW – mineral wool; ICB – Insulation corkboard.

Table 4 lists the results of the prediction of the façade walls behaviour according to the five criteria selected to outrank the design alternatives. The U-Values are weighted averaged values taking into account the opaque, the glazing part of the façade and the roller shutter box.

Table 4. Criteria for the different design alternatives studied for the façade.

Options	U-Value (weighted averaged values) [W/(m^{2}ºC)]	$D_{2m, nT, W}$ [dB]	EE [Mj/m^2]	Msi [kg/m^2]	Thickness [cm]
O	2.23	30	0	150	24.0
R1	1.09	35	61	150	30.0
R2	0.90	35	145	150	34.0
R3	1.10	37	2018	150	35.0
R4	0.86	38	2184	150	41.0
R5	1.04	35	161	75	29.3
R6	0.97	37	205	75	32.2
R7	0.97	38	261	150	41.5
R8	0.93	39	262	150	39.4

The credibility degree matrix and the results of the outranking using ELECTRE III method are presented in Table 5. The credibility degree matrix gives a quantitative measure to the force of the statement “a outranks b” or “a is at least as good as b”. Number 1 indicates the full truthfulness of the assertion and 0 indicates that the assertion is false.

The ranking of the alternatives can then be determined based on the credibility degree matrix through a distillation procedure, where the alternatives are located firstly following their qualification going from the best to the worse one and then inversely, from the worse to the best one, defining two pre-ranks. Finally, the final ranking is achieved by using the results of these two pre-ranks.

Table 5. Credibility degrees matrix for the alternative solutions selected for the façade walls.

Options	O	R1	R2	R3	R4	R5	R6	R7	R8	Non-Dom		Ranking
										A	m(A)	Options
O	-	0.00	0.00	0.00	0.00	0.00	0.00	0.00	0.00	O	0.09	R2
R1	0.91	-	0.85	1.00	0.70	1.00	0.97	0.88	0.73	R1	0.93	R1
R2	0.72	0.92	-	1.00	0.92	0.95	1.00	0.92	0.83	R2	0.99	R8
R3	0.00	0.00	0.00	-	0.77	0.00	0.00	0.00	0.00	R3	0.00	R5
R4	0.00	0.00	0.00	0.77	-	0.00	0.00	0.00	0.00	R4	0.00	R7
R5	0.64	0.78	0.78	0.85	0.63	-	1.00	0.77	0.67	R5	0.78	R6
R6	0.53	0.72	0.84	0.85	0.83	0.98	-	0.85	0.85	R6	0.75	O
R7	0.65	0.65	0.81	0.92	0.98	0.78	0.86	-	1.00	R7	0.77	R3, R4
R8	0.65	0.66	0.85	0.95	1.00	0.78	0.89	1.00	-	R8	0.93	

Table 5 shows that option R2 (refurbishment with the ETICS system with 8 cm of EPS) is ranked as the best action and is “at least as good as” options R3 and R5 in all criteria, as the number 1 in columns 4 and 7 indicates. This refurbishment solution has one of the lower U-Value, the second lower embodied energy and is one of the solutions with the higher superficial mass and is also one of the thinner solutions.

Solutions R1 (4 cm of EPS ETICS), with the lower embodied energy, acoustic insulation and thickness and one of the higher U-values and superficial mass, was ranked second. Option R8 (6 cm of ICB and hollow brick pane with 11cm) was ranked third. This option has the third best thermal performance and the best acoustic behaviour, has a high superficial mass but is also the third thicker solutions and has the third higher embodied energy.

The existing solution (O) with the worst thermal and acoustic performance and the ventilated walls, option R3 and R4 (with the lowest U-value), with high thermal mass, with the second and third best acoustic insulation, but with the higher embodied energy were ranked last.

4. Conclusion

Throughout the multi-criteria analysis performed, it was possible to verify that the refurbishment solutions with ETICS system, with low U-value and embodied energy and higher superficial mass were ranked the best rehabilitation options.

The solution with ICB and a second hollow brick pane, that presents the second lower U-value, the higher acoustic insulation and a high thermal mass, was ranked third.

The existing solution with the worst thermal and acoustic performance and the ventilated walls, with the lowest U-value, high thermal mass, with the second and third best acoustic insulation, but with the higher embodied energy were ranked last.

The best ranked options were not the ones that had the best performance in the criteria with highest weights. This example shows that applying this methodology, due to the use of weights and thresholds, the best action is not the one associated to the highest weight, even if it is the one that has the best performance in that criterion.

Short Summary

The objective of the paper is to describe a stochastic model that has been developed to obtain load profiles for household electricity. For the study, several profiles have been generated in order to simulate the electrical demand of a residential building block or neighbourhood and evaluate the uncertainty of its energy use. The paper is divided in three different parts: development of the model, validation and determination of the uncertainty demand. In the first parts the basis of the model and how it works is explained. The second one represents the validation of the model, the input data and its results. The last step is focused on a statistical analysis of the electricity demand of a block of dwellings to evaluate minimum number of dwellings needed to estimate the average demand representative of the Mediterranean dwelling with different levels of accuracy.

Keywords: stochastic model; electric load; residential building; Mediterranean regions; cluster of buildings

1. Introduction

In the last years, the increased interest on energy efficiency and on the use of renewable energy technologies in residential buildings has produced the need to improve the knowledge of all the factors that take part in the energy balance. In addition to the technological improvements, an important progress has been the increased availability and use of energy simulation tools. The simulations tools allow realizing building model to test and optimize the energy efficiency measures and energy renewable systems in the design stage. Therefore, detailed load profiles for domestic energy use are important as input to simulations of energy systems such as distributed generation or Net Zero Energy Buildings (NZEB). The heating and cooling load can be calculated by physics models, because these loads are mainly forced by external phenomena. However, the DWH and electric loads of appliances depend on the user behaviour and must be pre-determined, with assumptions, profiles and statistical studies. On the other hand, if the objective is to analyse a cluster of buildings having information of each individual building, it is not realistic to use the same electric load profile for all dwellings. For these reasons are needed to have tools that reproduce real and random electric load.

The objective of the study is to develop a stochastic model to obtain high resolution load profiles for household electricity in Mediterranean climate. Several profiles have been generated in order to simulate the electrical demand of a building block or neighbourhood and evaluate when the

uncertainty demand is low enough. Moreover, this paper wants to share information to the Energy Services COmpanies (ESCOs) about the uncertainty in the energy demand in the residential sector. The rate of energy efficiency refurbishment of the buildings is low, especially in the Mediterranean regions [1]. High investments are needed to carry out the renovations, and the ESCOs are the entities that could afford this investment. However, there are aspects that restrain the ESCOs to carry out this kind of projects, as the uncertainty of the energy demand in residential dwellings.

In the last decade, occupancy and behaviour models have been developed with different motivations, but all of them with the need to obtain realistic profiles of the energy use of buildings. Widen [2] has worked in an occupancy model based on Markov-chain transition probabilities and Time Use Data (TUD) of Sweden. TUD gives the information about the occupancy and their activity, which should be translated to end-uses. Widen uses the Markov-chain method to produce realistic patterns and to produce realistic load profiles for household electricity. The model has been adapted to generate different load profiles: electricity, hot water and lighting. Richardson [3] has developed a model of domestic electricity use based on a combination of patterns of active occupancy and daily activity profiles, using Markov-Chain Monte Carlo techniques. The statistical information used is from the United Kingdom. Dar [4] has used the Richardson's model in the field of the NZEB design for a case study in Norway. All of these aspects are related to the Demand Side Management (DSM), where Paatero [5] has been working on. Paatero has built a model for generating electricity load profiles for a dwelling using representative data sample and statistical averages from Finland. The randomness has been included using stochastic processes and probability distribution functions (starting probability function based on the seasonal, hourly and social factors). Another key element is the high influence of the occupancy activity with the heating and cooling loads and in consequence with the size of the systems. Baetens [6] has simulated in Modelica the user behaviour and the use of lighting and appliances. The use of appliances has been implemented by a semi-Markov-process based on the presence of an occupant and the activity profiles. In the paper the results of the model have been compared with deterministic approach proposed by the ISO 13790 [7], obtaining important differences in the demand peaks.

The models described above are based on statistical data of equipment stock of dwellings and user activities or habits in Northern European countries and UK. Recently, "Instituto para la Diversificación y Ahorro de la Energía" (IDAE) has been carried out the SECH-SPAHOUSEC project [8], where a detailed characterization of the energy use of the residential sector in Spain. This study has been used as basis information for the model presented in this paper.

2. Method

All the study has been carried out using mainly the detailed data from the SECH-SPAHOUSEC project. This project characterizes the energy consumption of the residential sector in Spain. The dwelling description includes detailed information about the equipments stock and different energy uses. The information is divided by regions (Atlantic, Continental and Mediterranean) and building type (detached houses and block of apartments). In this paper, the results are related to Mediterranean region and for block of apartments.

The model is divided in two sub-models: electrical appliances (refrigerator, freezer, washing machine, dish washing, television, tumble dryer, microwave, PC, lighting and others which includes a group of small appliances) and kitchen devices (gas and electrical stove and oven).

The model has been developed as a component of TRNSYS 17.1 and gives the possibility to simulate more than one dwelling at the same time. The time resolution is one hour. Each equipment has to be characterized with the parameters described in the Table 1. In addition, general parameters are needed to carry out the simulation: number of simulated dwellings and seeds for the random number generators.

Table 1 Description of the parameters and inputs of the stochastic model of electrical load profiles of dwellings

Data type	Parameter	Units	Description
Stock characterization	Penetration rate (Pr)	%	Fraction of dwellings with at least one equipment. The input of the model is its complementary (1-Pr).
	Multi-equipment probabilities (Mp)	%	These values represent the probability to have 1, 2, 3 or 4 equipments in a dwelling. The multiequipment is defined with 4 probabilities (probability to have 1 equipment, to have 2...). At the same way of the penetration rate, the input of the model is its complementary (1-Mp).
	Fraction of electric devices (FE)	%	In the case of the kitchen devices, it is necessary to include the fraction of electric devices. The gas devices are calculated as the difference of the electrical ones.
Technical data	Power (P)	kW	This power has reference to the nominal power. This information is available in the technical sheet of the equipment. This power could be different to the used power when the equipment is working.
	Power Fraction (PF)	%	PF is the hourly mean power when the equipment is ON divided by the power (P) of the equipment. This parameter is constant over time.
	Cycle Length Fraction (CF)	%	CF is the relation between the cycle length and the integer hours. For example, the duration of the cycle of a washing machine is 1.5 hours, then the integer hours is 2, and CF is 1.5/2. This parameter represents the fraction of the hour when the equipment is spending energy. This parameter is constant over time.
	Power of Stand-by (Pstb)	kW	Pstb is the power of the stand-by mode. If the equipment does not have stand-by, the value should be 0.
Statistics of use	Hourly profile of probabilities of use (prob(t))	%	The probabilities of use represent the probability to use one equipment at each hour. There are hourly profiles for each season (summer, winter and mid season) and type of day (weekday and weekend). It means that there are six hourly profiles of probabilities of use.

The simulation is divided in two steps: dwelling characterization and simulation process. The dwelling characterization is done only at the beginning and consists in the selection of which equipments are in each dwelling. The selection is done by a random number that is compared with (1-Pr). After that, how many equipment there are has to be defined. To do that, the same random number is compared with the multi-equipment parameters. In the equation (1) is represented the conditions to choose the equipments of each dwelling.

$$\left.\begin{array}{ll} RNE_e^d < (1-\mathrm{Pr}_e) & \rightarrow \text{There is no equipment } e \text{ in dwelling } d \\ RNE_e^d \geq (1-\mathrm{Pr}_e)\begin{cases} (1-Mp_{e1}) > RNE_e^d & \rightarrow \text{There is 1 equipment } e \text{ in dwelling } d \\ (1-Mp_{e1}) \leq RNE_e^d < (1-Mp_{e2}) & \rightarrow \text{There is 2 equipments } e \text{ in dwelling } d \\ (1-Mp_{e2}) \leq RNE_e^d < (1-Mp_{e3}) & \rightarrow \text{There is 3 equipments } e \text{ in dwelling } d \\ (1-Mp_{e3}) \leq RNE_e^d < (1-Mp_{e4}) & \rightarrow \text{There is 4 equipments } e \text{ in dwelling } d \end{cases} \end{array}\right\} \quad (1)$$

Where RNE_e is the random number for each type of equipment e and dwelling d. Pr_e is the

penetration rate for each type of equipment. Mp_{e1}, Mp_{e2}, Mp_{e3} and Mp_{e4} are multi-equipment probabilities for each type of equipment.

The selection of the equipments in the sub-model of the kitchen devices is different. First, it is necessary to define the presence of the kitchen devices in each dwelling. After that, it has to be chosen if the device uses electricity or gas. It can be represented in the following equation:

$$\begin{cases} RNE_e^d < (1-\mathrm{Pr}_e) & \rightarrow \text{There is no equipment } e \text{ in dwelling } d \\ RNE_e^d \geq (1-\mathrm{Pr}_e) \begin{cases} FE_e < RNE_e^d & \rightarrow \text{There is an electrical equipment } e \text{ in dwelling } d \\ FE_e \geq RNE_e^d & \rightarrow \text{There is a gas equipment } e \text{ in dwelling } d \end{cases} \end{cases} \quad (2)$$

The second step starts after setting the equipments of each dwelling: the simulation process. In each time step of the simulation period, in our case an hour, the model has to define which equipments are ON or OFF (or Stand-by) to be able to calculate the energy consumption for each dwelling. Then, in each time step another set of random number has been generated ($RNP(t)_e$) in order to be compared with the probabilities of use of each equipment type. In the following equation the comparison done at each time step is shown:

$$\begin{cases} RNP(t)_e^d \geq prob(t)_e \rightarrow E(t)_e^d = Pstb_e \cdot \Delta t & \rightarrow \text{The equipment is OFF or in Stand-by} \\ RNP(t)_e^d < prob(t)_e \rightarrow E(t)_e^d = P_e \cdot PF_e \cdot CF_e \cdot \Delta t & \rightarrow \text{The equipment is ON} \end{cases} \quad (3)$$

Where $RNP(t)_e$ is the random number generated for the equipment *e* of the dwelling *d* at time *t*. $prob(t)_e$ is the probability of use at the time *t* of the equipment *e* (*t* refers to the season, type of day and hour of day). $Pstb_e$, P_e, PF_e and CF_e are the parameters of the equipment e described in the Table 1. Δt is the time step (1 hour). Finally, the $E(t)_e$ is the energy consumption for the equipment *e* of the dwelling *d* at time *t* (in kWh). The probabilities of use have been obtained after post-processing work using the database of the project SECH-SPAHOUSEC.

As can be seen in the model description, there are two sources of stochasticity: the random selection of the type and the number of equipment in each dwelling and the random selection of which equipment are ON or OFF (or stand-by) in each time step.

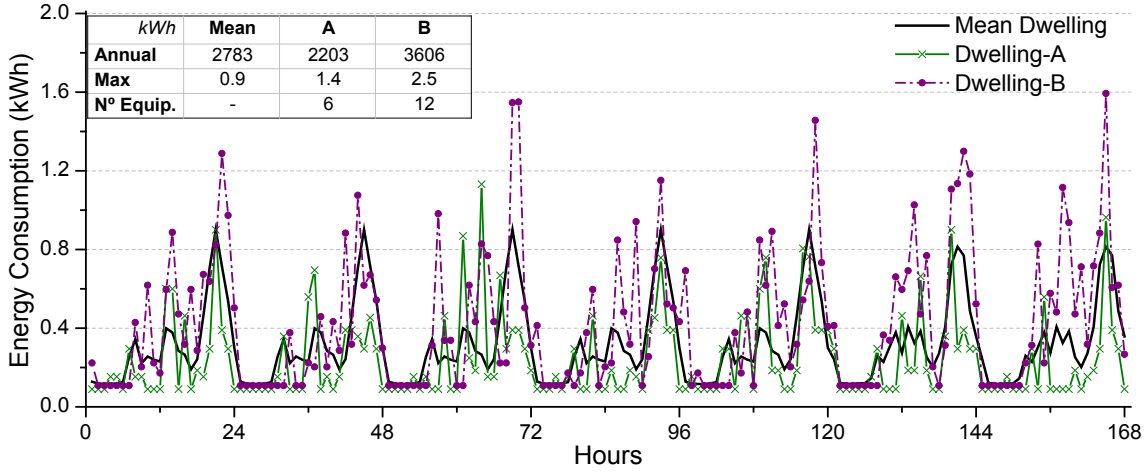

Fig. 1 Hourly electric consumption for a winter week. Example output of the model, two random dwellings and the mean dwelling (reference data).

In the Fig. 1 an example of the output of the model is shown, plotting the hourly electric consumption of two random dwellings during one winter week. In addition, the hourly consumption of a mean dwelling has been included in the graph, in order to view that the simulated dwellings

have random profiles. One of the most important advantages of the outputs is to catch the peak values of the load profiles, which are different between days and dwellings.

3. Model validation

The validation of the model is done in two levels: energy consumption of individual equipment and energy consumption of a dwelling. To validate the model, 1000 dwellings of Mediterranean region have been simulated (multi-dwelling building). In the Table 2, the used technical parameters of the equipment in the simulation are shown. The parameters have been obtained from the database of the project SECH-SPAHOUSEC, where there are measurement data of equipments of 200 dwellings over Mediterranean regions of Spain. These parameters has been compared and adjusted with reference studies. However, the following assumption has been done in the case of gas kitchen and gas oven due to the absence of data: the efficiency of the gas kitchen and gas oven is lower than the electrical ones (60% for gas and 75% for electrical ones).

Table 2 Technical data of the equipments used in the simulation

Equipment	P W	PF %	Cycle Length Min	E_{ON} Wh	E_{STB} Wh

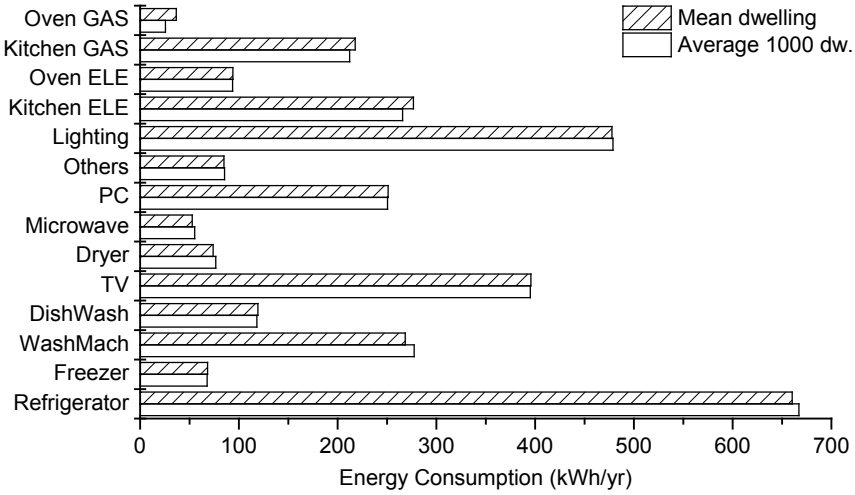
In the Table 3 the average annual energy consumption for equipment is shown. In addition, reference data are included in order to be compared with the model results. Comparing the results, in general terms the model fits to the reference data. There are differences in some equipment



although they are coherent with the SECH-SPAHOUSEC. The input data of the model are based on the equipment stock of Spain, where approximately 40% of the equipments has an energy labelling equal or higher than A-label [8]. Reference data in Table 3 (Smart Appliances [9], Remodece [10] and Richardson [11]) are from other European countries with cultural and climate differences which affect to the energy use. Both aspects could be the cause of differences between the simulation results and the reference data.

Once the equipment parameters have been checked, a validation of the energy consumption of dwellings is presented. In the Fig. 2 the annual energy consumption for a mean dwelling are represented, broken down by energy uses. The bar diagram compares the average of 1000 simulated dwellings with the mean dwelling. The graph shows a good performance of the model, having differences lower than 5%.

Moreover, in the Fig. 2 the normalized root mean square error (NRMSE) has been included (equation 4) in order to evaluate goodness of fit of the model. The great part of the elements has an acceptable value of residual variance, lower than 20%. Particularly, there are four elements, washing machine, dishwasher, electric oven and electric kitchen that are lower than 10% of residual variance, which means that the 90% of the variance observed in the these elements are reproduced by the model. However, there are two equipments, refrigerator and freezer, which NRMSE is considerable high, comparing with the other equipments. The reason is that, despite the nearly constant profile over the year, in the reference data there are small variation between seasons, and the model uses a constant value. This variation does that difference between the maximum and minimum value is very small, and then the normalization is done with a low number (denominator). Comparing the diagram with the NRMSE, it is possible to see that a good annual performance not involve a good hourly behaviour. In the section 5, the sources of error that could influence in the results are discussed.

$$NRMSE = \frac{1}{\left(E_{mean}^{\max} - E_{mean}^{\min}\right)} \cdot \sqrt{\sum_{t}^{n} \frac{\left(E_{sim}(t) - E_{mean}(t)\right)^2}{n}} \tag{4}$$

Where the $E_{sim}(t)$ and $E_{mean}(t)$ is the hourly energy consumption simulated and the reference data, t is the time and n are the 8760 hour of the year. E^{max} and E^{min} are the maximum and the minimum value of the reference data over the year.

	NRMSE
Oven (ele)	8%
Kitchen (ele)	9%
Lighting	10%
Others	15%
PC	17%
Microwave	13%
Dryer	14%
TV	19%
DishWash	9%
WashMach	7%
Freezer	56%
Refrigerator	31%

Fig. 2 Annual energy consumption for equipment type. Comparison of the average consumption of 1000 simulated dwellings with the mean dwelling (reference data).Right: Normalized root mean square error (NRMSE) of hourly energy consumption for each equipment for the year.

4. Sample size analysis

The objective of this section is to analyse the sample size needed to characterize the buildings during the design process of energy efficiency measures. For this scope, the empirical distribution of the annual energy consumption is analysed. The Fig. 3 represents the distribution of the annual energy consumption simulated for different sample sizes. It can be seen that over 100 dwellings, the two main parameters of the distribution converge; the mean is around 2850kWh/yr and the standard deviation around 500kWh/yr. The distribution of the annual energy consumption is slightly left-skewed but it performs quite similar to a Normal distribution.

nº DW	STATISTICS (kWh/yr)			
	Mean	SD	MIN	MAX
10	3028	364	2565	3611
50	2877	513	1822	4606
100	2777	492	1763	4287
250	2861	495	1791	4452
500	2829	484	1683	4354
1000	2834	499	1600	4606

Fig. 3 Distribution of the annual energy consumption for dwelling, increasing the number of dwellings. Description of the box plot parameters: mean by square; median by horizontal line; 25% and 75% percentile by box; 5% and 95% by whiskers; 1% and 99% percentile by cross; minimum and maximum by dash. In the right table, the statistical values of each sample (mean, standard deviation (SD), minimum and maximum).

Based on the data from the SECH-SPAHOUSEC project and the simulations performed the sample size for two different scenarios are calculated. As previously, the decision variable in this analysis is the total annual energy consumption of a dwelling. The first scenario is designed with the objective to characterize of a population; it wants to determinate the number of dwellings that are required to estimate the mean annual energy consumption of the total population, with different levels of accuracy. The following equations define the sample size for this scenario:

$$n = \frac{N \cdot \sigma^2 \cdot Z_{\alpha/2}^2}{(N-1) \cdot e^2 + \sigma^2 \cdot Z_{\alpha/2}^2} \tag{5}$$

$$n = \frac{N \cdot \sigma^2 \cdot Z_{\alpha/2}^2}{e^2} \tag{6}$$

Where (5) is the equation used for a known target population size and (6) for an unknown one. $Z^2_{\alpha/2}$ is the normal distribution value for a confidence level α, σ^2 is the variance of the variable, e^2 represents the error corresponding to the defined level of accuracy, and N is the target population size.

Table 4 shows the value for different levels of accuracy. It can be seen that with a sample size of 48 and 12 the mean annual energy consumption can be estimated for any set of Mediterranean dwellings with an accuracy of 5% and 10% respectively. For lowers values of accuracy, the sample size depends on the target population size.

Table 4 Sample size to estimate the mean annual energy consumption for different targets of population size (α =0.05).

Target population size	Accuracy		
	1%	5%	10%
20	20	14	8
100	92	33	11
500	354	44	12
1000	548	46	12
3000	862	48	12
10000	1079	48	12
Unknown	4839	194	48

Table 5 Sample size to reflect the annual energy saving in the electric consumption after to apply energy efficiency measures (paired test, α = 0.05, β = 0.9).

Energy saving	Sample size
5%	265
10%	66
15%	29

The second scenario wants to define the sample size for an energy efficiency measures in a set of dwellings. Given an expected energy saving, the sample size needed for observing differences between the annual yearly consumption before and after the action is calculated.

$$n = \frac{2 \cdot \sigma^2 \cdot \left(Z_{\alpha/2} + Z_{\beta}\right)^2}{\Delta^2} \tag{7}$$

Where Δ^2 represents the expected energy saving after the energy efficiency improvement. The Table 5 shows the value for different levels of energy saving, applying different energy efficiency measures. It can be seen that for greater values of improvement, smaller sample sizes are required. This is because, when comparing two values (mean energy consumption before and after the measure), the greatest is the difference, the easiest is to find it statically significant.

5. Discussion

Regarding the validation process, the model is able to generate random profiles of electric consumption for a dwelling or several dwellings, with preservation of important qualitative features. The load profiles are realistic and their annual consumption is consistent in comparison to Spanish data and from other European countries. However, analysing the results in detail there are slight differences between the simulation and the reference data. The reasons could be due to the limitation of the model, where the following approximations have been done. 1) The technical parameters of FP and CF for each equipment are constants over time. For a refrigerator and for a freezer, it may be a good approximation because their variations during the year can be lower. However, in the case of the other equipments, such assumption could not be justifiable, as for example that the power of lighting is the same during the whole day or the programme of the washing machine or dryer is always the same. 2) Although the input data (hourly consumption of each equipment) takes into account the length of the cycle, in the model there is no relation with the previous hour and the duration of the cycle is not simulated.

In the section 4 a statistical analysis of the annual energy consumption distribution for the simulation results of Mediterranean dwelling is done. The objective has been to evaluate how to reduce the uncertainty in the energy consumption choosing the adequate sample of dwellings. For the first test, it is observed that in the measure that the target of dwellings increase, the size sample needed is proportionally smaller. The second test shows that the energy efficiency measures with high impact are not necessary to be applied in a high number of dwellings to obtain the expected energy savings.

6. Conclusion

The model developed in this study is able to reproduce the hourly and annual patterns of the electric consumption for a residential building or a block of buildings of the Mediterranean region. A general validation has been done in this paper. However, there are aspects that should be tested and improved. A sensitive analysis has to be done to analyze the influence of the variation of technical parameters of equipments, now constants during the simulation. The validation of the model results is done at annual level. It would be interesting to validate the model at hourly level, in order to verify the hourly peaks. At the moment, the model is not related with the occupancy level neither with the user behaviour. These parameters could be included in the model to increase the range of possibilities to adapt the model to each situation and necessity. The use of this type of models is a good tool that could help to reduce the uncertainty of the energy consumption of the residential sector, improving making decision process in the early stage of refurbishment projects.

7. Acknowledges

The research was supported by the MED Programme of the European Union under the MARIE strategic project (Agreement Nº 1S-MED10-002). The authors also want to thank to IDAE for providing the data base of the SECH-SPAHOUSEC project.

Short Summary

In a contemporary perspective, the building refurbishment is no longer indifferent to technological innovation and energy efficiency goals. The photovoltaic (PV) integration becomes a possible way for design in "sensitive contexts". The research proposes, within a wider strategy of sustainable reconstruction, some experimental projects for urban voids rehabilitation in minor historic villages hit by earthquake. The developed case-studies demonstrate possible and affordable ways for integrating PV within urban/architectural innovative zero-energy concepts in sensitive areas.

Keywords: BIPV, historical centers, refurbishment, reconstruction, photovoltaic.

1. Introduction

The refurbishment of many historical villages abandoned or hit by earthquake, is today an issue of vital relevance in Italy and it is a complex and multidisciplinary field of research, in which the focus on sustainability can be recognized as a potential scenario of common development [1]. Despite the current background often directed to demagogic "in style" interventions, an innovative way of research is aimed to rethink these settlements in relation to a "sustainable" return to life in next years that can't neglect the topic of energetic efficiency, both at building and urban scale. Unfortunately the less physiological "measurability" of some factors involved and the greater disciplinary complexity are an actual barrier and too often the premises are discouraged, determining an inactive and dangerous tearing between sectors. The first objective of the ongoing research path, begun some years ago, has been a definition of the main forms of compatibility among PV systems and the wide range of environmental, landscape, historical and material values of these places [2]. In a contemporary perspective, no longer uncaring of environmental topics, so, PV integration can be recognized as one of the key-aspects for a more responsible design in "sensitive contexts". The goal of the presented research, following other studies already made about methodology of BIPV (Building Integrated Photovoltaic) [3], is to experiment the real PV compatibility (in historic villages hit by earthquake of 06.04.2009 in Italy) through the development of case-studies regarding the urban voids rehabilitation. The study takes into account 3 different areas within a village, considering different historic and landscaping scenarios. The use of PV is conceived not only as an energy goal but also as a part of a wider and more complex refurbishment project that is characterized by architectural distinguishability with ancient, technological reversibility/temporality/lightness and energetic autonomy. Outcomes of these case-studies show as PV may become, within a careful and aware project, a compatible and characterizing factor within an innovative logic of reconstruction, demonstrating a possible and effective co-existence with historical and landscaping values of these places. Furthermore the complex reality typical of these areas requires a "controlled transfor-

mation" variable case by case. Following these experiences, the believed scenery of the research is a real applicability in the reconstruction process, through knowledge transfer, development of guide-lines, tools, criteria and advices to be implemented in urban planning and building rules in next years. PV will require to be considered as an architectural and urban opportunity as well as an innovative challenge to be deepened, introducing the perspective of Nearly-Zero Energy Villages in the contexts concerned. Future prospected works along this path will be other case-studies in margin areas (valley, green areas) and in urban grids (streets) aimed to extend the PV integrability concept from building to a wider scale. This general topic will also match some new international Task related to "Solar Energy and Urban Planning" [6].

2. Perspectives: PV towards new urban and landscape scales

2.1 From Nearly-Zero Energy Building (NZEB) to Nearly-Zero Energy Clusters (NZEC)

The recast of the European Directive 2010/31/EU establishes that starting from 2020 new buildings will have to become Nearly Zero Energy (Nearly ZEBs). According to this Directive, a *Nearly Zero-Energy Building* has a very low energy consumption, which can be achieved by both high energy efficiency as well as by renewable energy produced *on-site* or *nearby* [4]. In the perspective of "Nearly-Zero" Energy Buildings (NZEB), PV has already today a basic role, thanks to its ability to be integrated everywhere within the building envelope, to produce renewable energy and thanks to a rapid prices falling that allow by now to consider PV as an ordinary building material. If incorporating some module, just to respond to the "minimum standard", has so far often relied on a tacit and shared culture of architectural (and constructive) "camouflage" excluding the solar systems by specific design thinking (like a television antenna or a chimney), the raising of energy level and the significant increase in quantity, will put inevitably the need of a more conscious assumption of responsibility by designers and other stakeholders at widespread scale. From this point of view, the design potential of PV could turn from a legal constraint into a new challenge for architects. From a cultural perspective, PV is rarely perceived as a creative challenge, but rather as a necessity that cannot be postponed. From the technical point of view, moreover, the building envelope today might not be sufficient to produce all the energy required [5]. In the near future, therefore, the design of Nearly-ZEB will have to evaluate, in addition to the space considered so far (the "footprint" of the building), the need to extend the available area for solar power generation systems "beyond the envelope" that is at the scale of the site, neighborhood, city and landscape. Even at the international level, after several experiences on Building Integrated Photovoltaic (BIPV), this awareness is leading to startup of specific research aimed to develop processes, tools and case studies on the integration of solar systems on an urban and landscaping scale, both for new complexes as well as for the refurbishment of existing settlements [6]. With the objective of quickly converting new and existing housing stock within a stronger energy efficiency logic, in addition to the standard Nearly-ZEB that today is already an accessible and feasible reality, the main challenge of the coming years will be a broader perspective (eg. Nearly-Zero Energy Clusters/Cities). The building is no longer seen as a closed an self-referential unit, but as an integral part of a more complex system (clusters, grids, city) in turn piece of a smart eco-sustainable city on a wide scale, where energy efficiency is not given just by the sum of many efficient buildings but, contrariwise, by an innovative interaction among urban areas, mobility, transport, industry, agriculture, waste ... etc..

2.2 Landscape Integrated Photovoltaics (LIPV): from solar fields to land art

The enlargement of perspectives from building to sustainable urban areas for the coming years, certainly opens up the research towards new fields putting in relationship PV and landscape. For some time, with the progressive spread of the "solar fields", this investigation path has become increasingly paradigmatic and has not yet saved the photovoltaic by several criticalities, even tough. There is no doubt that large installations are a real mark on the territory, characterizing the

perception of the landscape on a wide scale: in variuos cases, often forced by the logic of the economic investment, PV has caused damages to agriculture, soil, vegetation and wildlife as well as to the landscape. Beyond instrumental positions, it is clear that in the planning of such interventions becomes necessary to develop specific investigations of "environmental compatibility" for the evaluation of the different and complex environmental systems interacting. In response to a recognized need of environment protection, however, it is unquestionable that a new and controversial search for a balance between the natural values to be preserved and the energy issue emerges by the contemporary debate, creating a major complexity than in the past and putting in conflict aspects linked for the first time, in some way, to the same goal of rational use of resources and environmental protection. The acceptability and compatibility of photovoltaic implementation respect to the context, of course, are sent on a case by case investigations aimed to analyze the contextual characters (geomorphological data, microclimate, settlements, characters of vulnerability ...), the legislative, natural and anthropic constraints, and the landscaping impact analysis (eg. with an environmental impact assessment). Therefore in areas with particular worth, as the minor historical centers, the solar implementation requires to carefully investigate the compatibility issue that, , through a deep and sensitive design phase aimed to find the ways of a high acceptability, in alternative to the zero hypothesis. Even in such contexts, the research has shown the possibilities to overcome aprioristic positions, also thanks to a new "craft technology" able to meet, in a flexible way, the project demand in every specific context, respecting environmental and historical values [7]. Despite legislative instruments of territorial planning not yet diffusely updated to these topics, the best practices of international projects offer innovative visions as reference. A new way of thinking about renewable energy in our landscaping environment is shown, for instance, by movements and initiatives of Land Art which have demonstrate a creative and artistic way to use renewable sources and technologies in harmony with nature [8].

2.3 PV and historical heritage: a new possible way

The presence of several research sectors that, under various titles, are linked to the heterogeneous field of the “historical built”, can be considered a consequence of the complex character of this matter. In a contemporary perspective of “sustainability” in architecture and in urban planning, even the field of PV integration has recently entered this sector showing, both on a research level and with some real interventions, the possibility to implement renewable energy. Some first BiPV guiding-cases of refurbishing historical neighbourhoods in Europe mark this new season [9], where PV implementation within historical consolidated environments becomes a reality. Even some interventions on historical protected heritage (medieval churches, towers, etc.) show a possible shift from the research field to the real one [3]. Despite the “ordinary” heritage opens the project to the opportunity of re-shaping the pre-existing bringing a new character and a higher quality, in historical contexts many values need to be preserved (historical, landscaping, environmental), requesting a more "conservative" and “compatible” way of intervention. In particular, in the "minor" historical centres hit by earthquake, new methodological challenges related to the control of energetic demand are required, at different scales. After the earthquake of 2009, the need to rebuild and rehabilitate the wide urban area in the crater of L'Aquila, with its several historical centers, poses relevant questions for these topics and defines an innovative objective for the reconstruction process in following years that will have to be faced in a challenging way.

3. New goals: PV in urban systems of minor historical centres

Minor historical centres appear as a whole crossed by roads, streets and squares, which together form the unitary image of the historic built, closely linked with topography, morphology and surrounding natural environment. The PV implementation within these contexts, as opposed to the ordinary heritage, moves in a complex and peculiar relationship with *"the overall environmental value"* charachterizing these areas. The study of PV integration strategies, so, before to refer to individual building envelopes, requires to investigate new ways of thought on a *"urban"* scale which includes open-relation spaces and landscape areas as following explained. The building-scale, futhermore, must be expanded towards the size of the *building "aggregate"* defined by a homogeneous built unit, "autonomous" from the rest of the historic settlement [3]. The research, after introducing the whole discussion, is addressed to the topic of urban voids refurbishment.

3.1 Built tissues: roads and urban networks

A possibility in the refurbishment of minor centers, especially in the post-earthquake reconstruction, could be a different use of streets and roads of urban settlements: though, on one hand, this theme converges on the planning of underground services (technological tunnels, service networks ...), to a broader and ambitious view it could be declined in an innovative concept of "sustainability" networks. The streets could be re-thought as passive urban bioclimatic tunnels/spaces between the houses (a kind of buffer zone), able to interact with the local weather conditions for controlling of microclimate and lighting, and to be inhabited during different seasons, carrying a new functional, urban and social role. In an active way, moreover, they could be used as energetic grids both offering a location to solar (or wind) systems, where this appears compatible, and integrating technological underground tunnels (water, electricity, optical fibers, pressure waste systems, etc.) with a network of other services linked to an energy-efficiency policy at urban scale (e.g. pipes of district heating linked among houses and power stations, smart grids coming from energy fields, etc.).

3.2 Relation areas: squares and open spaces

Relation and open areas of historic villages are generally the centrality and the representative places of the entire settlement, as the “square”. Around these urban areas are typically collected the most symbolic monuments such as the church (with any convents, cloisters ...), the town hall, stately palaces and other important buildings, often examples of high historical value of premodern architecture or art. Within these historic cores, even in cases where the earthquake has caused serious damages, there is a low degree of transformability and consequently the introduction of "energy systems" is linked to specific compatibility analysis and evaluations. However important possibilities of "micro-intervention" aimed at energy efficiency of these spaces has not to be excluded, such as the upgrading of lighting scenarios and urban furnishing, in which a careful and "customized" use of the PV can establish a new possibility for the rehabilitation of these spaces as well as a demonstrative important symbol [1] [7]. Some examples of Anglo-Saxon and European integration of solar systems on medieval churches or on historical buildings show us even wider opportunities [3]. We have not to forget then, especially in contexts of reconstruction, the chance to reintegrate or rebuild historical artifacts completely collapsed with contemporary distinguishable interventions, could offer another way to re-think at renewable sources as a vital means of design.

3.3 External areas: energy towards the landscape

The historical centers concerned are usually connoted, as already said, by a special relationship with the surrounding nature of which they form an integral part. Many centers of Abruzzo, built on rocky ridges, appear as huge blocks of stone crossed by streets and squares, immersed in a landscape system in which the natural and the artificial become one. Defensive strategies of the time are still readable in the walls around the built boundary. Beyond this perimeter, in cases still intact

by the wild post-war building, the nature marks the contour with a mountainous landscape punctuated by valleys, orchards, fields, and ancient paths. In this border areas, now abandoned and disused, is frequently hidden a great potential for restoration and enhancement of these places, if we think about the possibility to open new routes (pedestrian, cycling, horse trails, sustainable mobility ...), natural parks and waterways or other scenarios of sustainable re-use, which should become the distinguishing values of their return in life. In a perspective of organic re-planning of the territory after the earthquake, this network between the villages could become an important occasion for introducing parks and energy fields (biomass, solar, wind, hydro), as well as power plants for the built centers or a new sustainable mobility system (bikes and electric cars).

3.4 Refurbishment of urban voids as a new challenge: method and case-studies

Refurbishment design and accordingly PV integration in reconstruction contexts, will have to face with the voids of the urban system. Just visiting any of the historical villages around L'Aquila there is the perception of a "negative of the original" with the overthrow of full and empty due to the "voids" created by collapse and the rubbles within the original open spaces (streets, squares ...) [9]. From this state of art, the presented research experiments possible ways for recovering these urban spaces through an approach aimed to environmental and material lightness, energy self-sufficiency and a controlled distinguishability from existing historical matter. Although the main topic was PV integration in sensitive areas, the presented case-studies cannot give up a wider design sensibility as well as the need to realize more general goals for the life return of these villages, for providing services during the reconstruction process or for introducing memory signs of the tragic event. Projects has been developed with Building-Engineering/Architecture students within a specific lecturing module at University of L'Aquila, and concerns one of the most hit centres due to the 2009 earthquake that is Sant'Eusanio Forconese nearby L'Aquila in Italy. The small village, born between XII and XIII centuries, has about 400 inhabitants and is located in a very meaningful natural environment: after the earthquake it was completely abandoned. Hoping in a quick re-born, despite the hard and complicated reconstruction process waited for the following years, the presented study has been directed to experiment a new coexistence between memory and hope, through the proposal of urban elements designed either for nowadays than for next years. The chosen areas are located either within the historical centre than at the edge with landscape, representing different design possibilities in dissimilar kinds of urban voids.

Fig. 3: Pictures of the 3 different urban voids in the post-earthquake status

3.4.1 A sensible media box in the central square

This first project is located in the central historic square of the village, and its goal is to replace a building collapse happened between the church and the stately building beside to the main entrance of the historical village. The site conserves some traces of the old walls and is bordered by a building just on one side while the other ones overlook the square. Considering the high sensitiveness of the place, historical hearth of the town, the main goal was offering a memory of the event: the concept is, so, an insertion of an interactive box thought as a broken cube whose pieces becomes parts of the square. The external vertical envelope of this urban element is completely made by a media shell, made with a special PV thin-film glazed module. PV glazed panel is frontally printed with a local stone pattern that, partially reducing the energy yield of about a 20%, allows an aesthetic integrability during the day. At night the envelope becomes a kind of lighted lantern thanks to rear LED hot spots that form a grid of pixels onto the facades. The inner space, separated by a double skin, is characterized by electrochromic glazed walls on which are electronically shown movies, pictures and stories. The roof is also conceived as a semi-transparent PV glazed double-skin. Piezoelectric internal and external floors allow both producing energy as well as to self-light, internally, as a smart touchscreen sensible to people feet steps. A transparent opening obtained in a corner of the cube, looking towards the square allows in each moment to view from interior towards outside and to compare the story internally told with the external reality. The energy concept allows to entirely provide the energy demand with BiPV and piezoelectric systems also offering public services as a media screen, urban lighting, wi-fi zone, etc.

Fig. 4: The "memory" box in the central square. Conceived as a media urban system, it is characterized by a PV media skin patterned as a stone wall and self-lighted by led (Bucci, Santoro, Troia).

3.4.2 An autonomous temporary laboratory for the reconstruction

This project is aimed to redevelop an urban void located between the square and the east boundary of the historic village within the urban tissue. This area, at the edge with historical walls, is essentially enclosed by built volumes (or ruins), though overlooks towards the landscape on the east side. Due to this strategic location the project proposes an immediate recovery through a temporary structure useful as a laboratory for the reconstruction process. This solution could allow a fast life return thanks to the location of a strategic research centre to be lived by actors of reconstruction in the current years within the abandoned village. Due to its temporary character and to the absence of energetic grids it's conceived as a self-sufficient system with the use of recycled materials (coming from nearby construction areas, rubbles and building ruins), the rain water storage and with completely electric devices powered by an integrated stand-alone photovoltaic systems. The structure is conceived by a 4 storeys scaffolding frame with the insertion of completely reused containers. At the top, a semi-transparent customized PV surface provides a peak power of nearly 10 kW and the sun protection of the laboratories below. Internal services are just conceived for lighting, pc work stations and electrical heating in winter to be provided by solar energy storage system. The specific study of containers location, the lightness of the scaffolding frames and the glazed roof allow preserving a sight towards the landscape without entirely refilling the void. On the east façade some vertical flexible PV tents provides further 2 kW peak energetic power besides to protect from sun the container glazed openings avoiding overheating in summer.

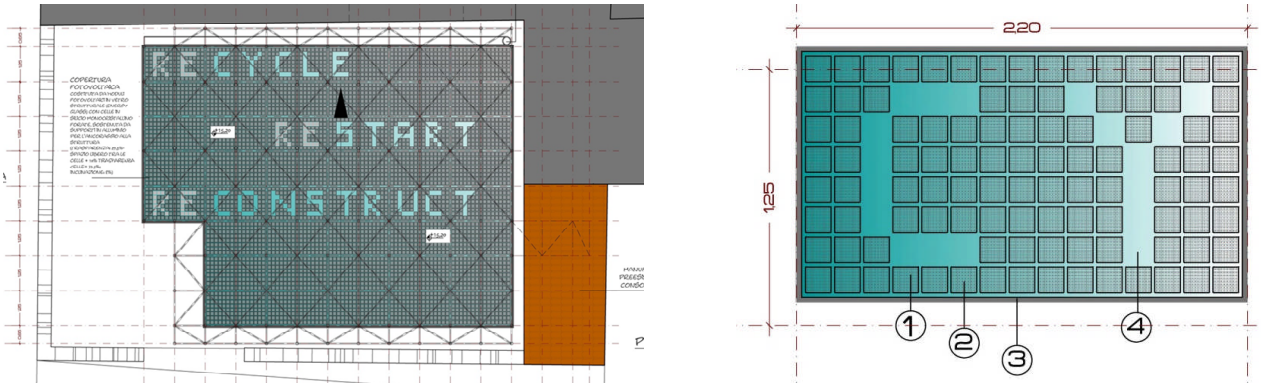

Fig. 5: The PV glazed roof is partially made by customized module (De Michelis, Cortellini, Pacini).

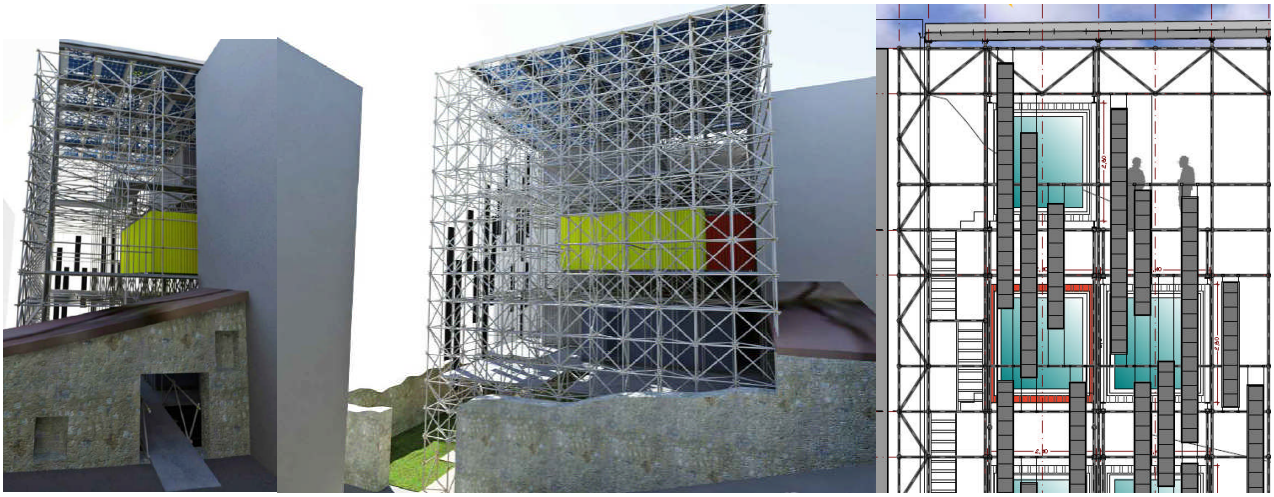

Fig. 5: The temporary laboratory is built with recycled components and is energetic autonomous

3.4.3 A sight towards the landscape: a sustainable urban library

This third chosen area is the most external, being located just at the boundary of the ancient perimeter in south position overlooking the valley and the landscape. The project, in this case, is aimed to imagine a new public function for the residents, in the perspective of the post-reconstruction status, thinking to a new urban life of the village. The void is partially replaced with a built volume that seems embedded to the earth and appears as a photovoltaic black object really distinguishable from the nearby stone walls. It is a public library room with a small park below where are placed, on the ground, some other PV modules characterized by green cells, introducing a landscape solar challenge able to be replaced in wider areas outside the centre. The building, inserted within a crater generated by a collapse, is conceived like a spyglass with the sight directed from the centre towards the landscape. It is designed with a wood skeleton cantilevered by the foundation, and it's entirely made with dry envelope technologies above a concrete basement. The envelope is externally cladded by PV thin film glazed modules on each side, including roof, east and west ones, apart from the surface below the volume or some edge elements which are similar black glazed panels. Plants, lightings and internal services are supplied by PV skin defining a plus-energy building that could be grid-connected. The estimated yearly energy surplus is more than 20.000 kWh, allowing to satisfy the electric demand of about 5 houses.

Fig. 6: The building is inserted within a crater as a spyglass opened towards the landscape. The skin entirely use a PV thin film cladding (Dell'Orso, Poliandri).

4. Conclusions

In a contemporary perspective, the building and urban refurbishment cannot longer be indifferent to technological innovation and energy efficiency goals. Despite some current background and barriers often directed to demagogic “in style” interventions especially in historical areas, an innovative way of research and practice is beginning to rethink these settlements in relation to a “sustainable” return to life that can’t neglect the topic of energetic efficiency and renewable energies, both at building and urban/landscape scale. The photovoltaic (PV) integration is by now a possible way only if PV is conceived, not simply as an energy device, but also as a part of a wider and more complex refurbishment project linked to an aware contemporary approach. Outcomes of above mentioned case-stories show as PV may become, within a careful design method, a compatible and characterizing factor useful for an innovative logic of reconstruction, demonstrating a possible co-existence with the many historical and landscaping values of sensible areas. Also it emerges as the complex reality typical of minor historical centers requires a controlled transformation variable case by case due to the several and dissimilar values involved. From these first studies the footprint of urban voids, thanks to the small scale of the old surrounding buildings (generally of 2 or 3 storeys), seems to be able to satisfy the own energetic demand and to offer energetic surplus to several nearby houses. It means that the implementation of solar systems just in strategic open areas, controlling the urban density and the balance between buildings and voids in the reconstruction urban planning, could be a way to supply the energetic demand (or anyway a significant part) of the entire historical centre, enhancing the urban liveability with more open areas and avoiding the challenging solar integration on historic building roofs. Also the refurbishment of old buildings, futhermore, will have to follow energy efficiency principles dramatically reducing the energetic demand. Therefore, considering the lower energetic demand, the small scale of these settlements and the presence of several voids able to be strategically re-used, these first research findings show that a premeditated re-planning of urban settlements could allow a significant solar implementation, satisfying a main part of the energy request, also improving the urban quality and, not least, offering a medium term economical payback. Following these experiences, the believed scenery of the research is a real applicability in the reconstruction process, through a transfer of skills, guide-lines and criteria to be implemented in urban planning and in building rules in next years, considering PV as an architectural and urban opportunity, an important design resource and an innovation challenge for the energy efficiency. Future prospected works are, also matching broader international goals on this topic, other case-studies in margin landscape areas and in urban networks with the goal to experiment and extend PV integrability from building to a wider scale and with the hope to introduce, in the contexts concerned, the future challenge of Nearly-Zero Energy Villages.

Energy efficient roofs retrofit for communist prefab concrete blocks

Catalina M. Bocan .
Assistant professor,
Head of Architecture Department,
Faculty of Architecture,
”Politehnica” University of Timisoara, Romania
catalina.bocan@arh.upt.ro

Short Summary

An elaborate survey over one of the most used type of standardized collective housing units erected during the socialist regime, called 770, revealed a great opportunity for roof retrofitting as a sustainable action in order to revive the “grey” dormitory districts. The use of existing infrastructure to create new and contemporary “penthouse” apartments is basically the starting point for larger actions, including thermal rehabilitation with refurbished facades, introducing elevator as comfort upgrade and last, but not least, innovative structural solution and energy efficient construction materials. The project called 770 [1], was created and improved during the passing years by the Centralized Institute for Standardized Building. It’s wide spread implementation all around Romania makes him a perfect candidate for a sustainable study regarding improving comfort measures together with a new and better exterior look of the whole (old building plus new “attic”). The real estate market shows a great demand for better housing units with good position in the city almost central areas. But the existing similar works are dealing only with maximum saleable area and, in most cases, doesn’t care about construction aesthetics or urban image. The psychological idea of having a “penthouse apartment” is neglected in these new houses without any exterior private spaces – balconies or terraces. The mixture between thermal rehabilitation and a complete new level (an attic, according the national legislation) led in the last ten years to several alterations (not always good) and unaesthetic buildings. The solution proposes a switch from nowadays works, on all layers: structure, enclosing materials, roof type, functional improvements (elevators, terraces and open space apartments), respect to existing inhabitants and private property (access to the upper level through the existing staircases, extended). The structure is represented by multiple light prefabricated concrete frames, placed exactly over the old structural grid, with exterior columns that offer a rhythmic exterior design. The enclosing elements, along with the flat roof are energy efficient lightweight materials [2] of composite type with rigid foam polyurethane as thermal insulation. For the existing three layers exterior concrete panels, mineral wool was the insulation chosen for the bonded thermal system (BTS). In order to show the good energetic performance of the whole proposal, an energy certificate was made for the existing construction and the refurbished one.

Keywords: flat roof retrofit; concrete prefabricated blocks; energy efficient composite materials

1. Introduction

During the communist regime, Romania had a similar evolution in construction field with the other soviet influenced European countries. All projects were designed by the National Institute of Standardized Buildings, then erected all over the country. There were few types with many subtypes. Because Romania has serious seismic movements, the great openings used by other states in prefabricated housing construction were not available. Norms, regularly updated, together with maximum usable areas and price limitations lead to constant improvements of same type of

concrete blocks. As general features, 30 cm modulation and maximum weight of panels limited to 5.5 tons were used everywhere. Some local details enriched the usually “grey” and monotonous facades, but the use of prefabricated elements (from large scale to small pieces) and construction details are all the same (Fig. 1).

Fig. 1: Romanian communist prefabricated housing blocks

Most of these buildings are used at their full capacity even today, when big cities are (still) magnets for a consuming society [3]. But the infrastructure and facilities are inadequate to such big number of cars (each family has at least one vehicle) with not enough socializing or playground areas nearby.

2. Project type 770

2.1 Communist existing buildings

One of the most extensively used projects, called 770, with its twelve subtypes (Pa1, Pa2, Pa3, Pa4, Pb1, Pb2, Pb3, Pb4, Pc1, Pc2, Pc3 and Pc4), can be found all around the country (Fig.2).

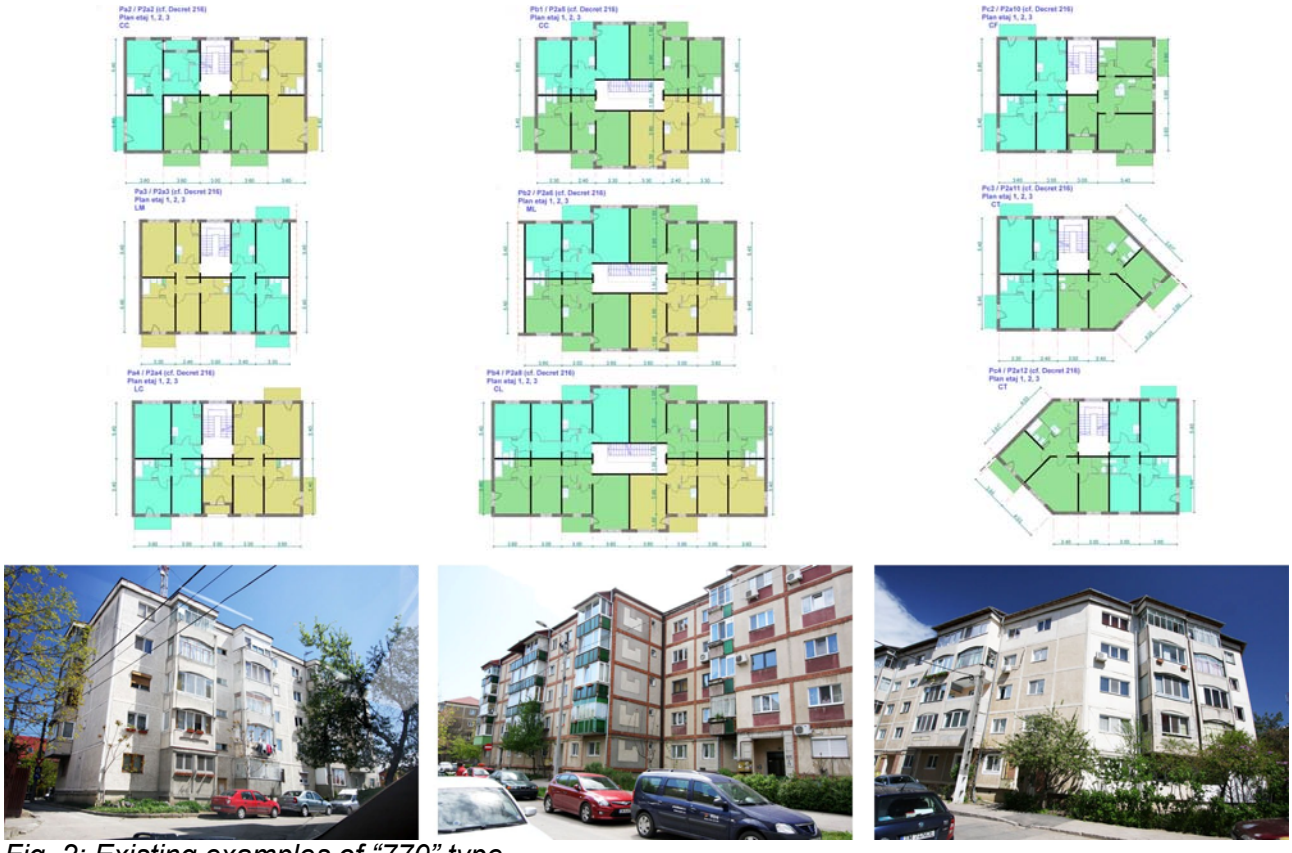

Fig. 2: Existing examples of “770” type

The last improved variant was designed in 1983 (the year of its application) developing rectangular “matchboxes” with 6 types of apartments (with 2, 3 or 4 rooms), small structural cells (2.4 m, 3.0 m,

3.3 m, 3.6 m or 5.4 m) and a standard coupling width of 11.2 m. All the five levels with apartments have the same height (2.7 m) while the technical basement has just 1.7 m. The different ending block panels (opening on long / short side) offer 88 sections of buildings and 72 types of concrete panels, with 1 to 4 staircases.

Most of construction elements were prefabricated. The structure is made out of concrete, with exterior panels made out of three layers and 30 cm thickness, the interior walls and slabs also from reinforced concrete. The flat roof has a thick thermal insulation (expanded clay or autoclaved aerated concrete), usually deteriorated by the poorly executed waterproofing works and many uncontrolled leaking. The plumbing features were also prefabricated as well as the carpentry elements (apartment windows and doors), the common spaces having metal doors.

2.2 Post revolutionary small scale interventions

Once the capitalism started (after 1989's Revolution), the new owners of formers exclusive State's ownerships started to improve their own comfort and develop small scale interventions, interior and also exterior. The diversity of construction works – replacement of wood fenestration with white PVC double glazing, closing balconies, exterior units of HVAC, outside enlarging ground floor apartments, single apartment exterior insulation – show that the great liberty offered by the switch of political regime was, in most cases, badly understood (Fig.3). The financial power and knowledge of each occupant was reflected in these small scale interventions, especially those regarding exterior aspect of the entire building. The change of thermal system, from district heating to individual unit was randomly done.

Fig. 3: Small scale interventions

Some more general alterations were developed for each staircase's apartments or Owner's Associations by changing the roof. The main idea was a traditional aspect with small price and no concern for the whole building image, together with a general rejection for flat roofs. Due to a bad original execution or the materials' aging, the architectural appearance was completely changed and sometimes, the result was worse than the primary conformation. Because one building has usually 2/3/4 staircases and each of it could receive a local and different "hat" (form, material, colour, etc.), the results were very peculiar.

2.3 National Rehabilitation Program

Started in 2002, the National Program for Thermal Rehabilitation of collective dwellings reached its peak in 2009. The whole program included for 2004-2014 25.000 multi-storey buildings and 0.8 million apartments. Later it comprised 3 million apartments and the necessity of 11 billion euro [3]. Some of the selection criteria were: older buildings, greater number of apartments, construction envelope type (preference for concrete prefabricated panels), technical conditions, mildew or dampness, climatic area [4]. No urban reasons and other exterior / social / public works were considered. The rehabilitation measures (only for housing) included: thermal insulation, pitched roof (but no attics), the replacement of exterior doors and windows and the replacement of common mechanical features. Financially, the costs were shared between the state, the local authorities and the owners' association [3]. Due to the global economical crisis, stating from 2010, the State switched to bank credit with governmental guarantee.

From an architectural point of view, the final "product" doesn't show a contemporary aesthetic

attitude, just vivid colours on facades, white PVC windows and improved comfort inside - less money for energy costs with individual heating system. The use of cheap materials, together with the lack of specialists' involvement (the constraints were always financial), different difficulties encountered during the process and the small interest for a unitary district aspect led to an erratic and colourful ensembles (Fig. 4).

Fig. 4: Thermal rehabilitated blocks through the National Program

2.4 Attics and real estate market

A combination between thermal exterior insulation and pitched roof was developed by real estate agencies or contractors in exchange of new attic apartments with maximum saleable area. In fact, a whole new level, even if not completely legal because of a missing elevator (according to nowadays legislation) offered the opportunity of having extra housing units in the same urban area, already too crowded and suffocated by cars. Because of the city position of original blocks (sometimes quite central), some of these new apartments were highly appreciated on real estate market. More problems occurred: legal aspects concerning private and collective property (the flat roof is by law common property and every owner has to sell its share to a third party), fire and structural resistance maintained, inevitable long time disturbance of existing people, insufficient mechanical features and even more parking spaces needed. Other important architectural aspect concerns the different solutions applied on the same building, each staircase (sometimes equivalent with the owners' association) is having a distinct look.

Fig. 5: Attics with maximum saleable areas

3. Proposed roof retrofit

3.1 Description of selected building

A sustainable solution applied on this prefabricated "commieblocks" should consider, first of all, the great opportunity of applicability all over Romania. This is why the choice of a widespread building type and uniform intervention treating problems like comfort, social all ages areas and even parking, together with the use of energy efficient composite materials and a complete approach of exterior design to provide contemporary comfortable new plus old apartments could be a possible retrofit.

Leaving from the 12th basic sorts of 770 type, the study case considers a building with three staircases, apartments with single or double orientation, no settlement joint and three different subtypes (Pa1, Pb3 and Pc1). Because the coupling possibilities of different construction where

related with site conditions, the hypothetical building allows another (similar) block to be urban related with the studied one (Fig. 6).

Fig. 6: Current level and section of analyzed building

3.2 Self imposed constraints

As a reaction to other contemporary similar designs, this study was developed considering that an example should be done, as a reaction to the actual interventions. This means: less interference with the residents during construction works through a quick execution, respect for actual legal constraints, a new and aesthetical image for old blocks.

The legal constraint of an elevator (starting from more than 4 stories) combined with the small cellular structure doesn't give too many possible solutions: an exterior position, detached from the façade, in order not to disturb the private windows or balconies. Another legal problem regards fire resistance. The actual buildings, made out of reinforced concrete, have a very good fire behavior. Any addition to it should maintain the same degree of fire resistance – most of the existing interventions don't comply with this rule. Another major constraint was the weight of new attic construction that has to be similar with the removed components of the former flat roof.

3.3 Architectural innovative solution

The old apartments, with different owners, cannot be treated as a whole and the respect of private property was a key target. If someone wanted to do some interior and personal arrangement, some variants with very small structural but controlled damages have been proposed. The minimum things possible to do were exterior thermal insulation with mineral wool, changing of wood windows with efficient double glazing together with controlled ventilation, all representing improvement of inside existing conditions along with outside picture. Extra measures – insulations of basement ceiling and flat roof insulation (thermal and hydro) plus new plumbing features – can accomplish the basic needs with less to 0 mixing in private property. Different treatment of balconies (open, partially or completely closed) allows diversity, but still unanimous treatment of exterior architectural elements (Fig.7).

Fig. 7: Architectural solution for extended and rehabilitated building

The new level uses an existing infrastructure, so there is no need for foundations, utilities and accesses. The same staircase space, together with an exterior detached elevator provides the vertical connection between new and old. The elevator, connected with the common staircase, can be also used by the actual occupants from the last floors (3rd and 4th). Its detachment from the main building gives privacy to the rooms with exterior openings oriented to this vertical element. At the corner of two buildings with two staircases, a single elevator can serve the both accesses. The interior design is open space and has no structural barriers, due to the chosen system, with identical and repeated light concrete frames consisting of 3 columns (2 exterior and one interior – in the middle) and 2 beams. The recessed closing vertical elements, completely separated from the structural frames, offer a continuous terrace to the new apartments (fig. 8).

Fig. 8: Architectural solution for extended and rehabilitated building

The facades are usually an urban image that relates a building with its public space nearby, being very important in rehabilitation process. Along with square proposal, regarding parking places and playing / socializing spaces, all together in the middle of the plot, surrounded by the “back” facades and new erected elevators – the image of urban vicinity is completely changed. A demi-basement parking with social areas above can replace the nowadays boring and concrete panels garages randomly erected. The pedestrian area, surrounded on all sides by rehabilitated blocks, is a combination between parking alleys with sitting areas and playground equipments

3.4 Energy efficient measures and EPC

The whole solution of roofing retrofit was developed using only energy efficient composite materials, light, good fire behaviour and quickly erected. The use of only prefabricated elements reduces execution time and the interference with occupants beneath is minimized. The nowadays construction materials have different characteristics and the smart combination between them can help to achieve every goal (Fig. 9).

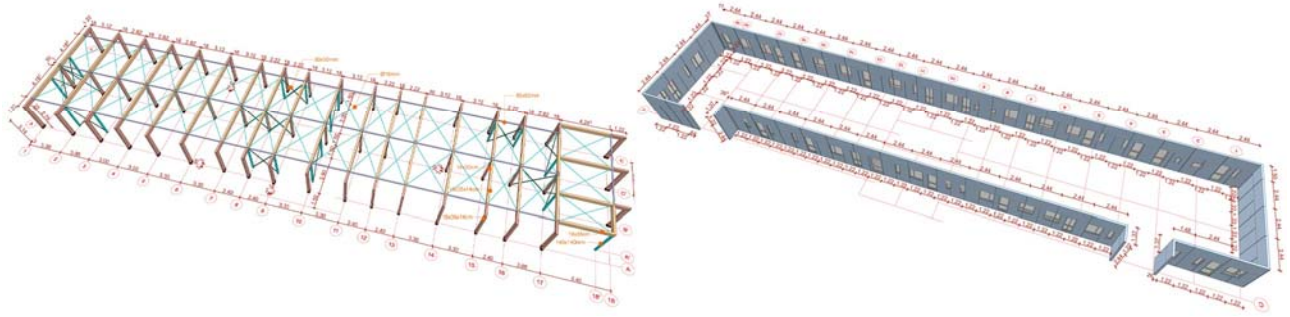

Fig. 9: Structural grid with light concrete frames and modelled exterior closing panels

The reinforced concrete as a structural solution was used for light prefabricated frames – 3 to / frame (with trapeze section, overlapped exactly above the existing structural grid. It was proven that concrete reabsorbs during its lifetime the CO_2 produced during its fabrication process [5]. Light triple layer walls called Glupan 125 (Glulam producer [6]) with Vidiwal fibre reinforced interior gypsum board, rigid polyurethane foam (PUR) in the middle and OSB board outside has 125 mm width, U=0.022 W/mK, 27.55 kg/sqm and the vertical elements (including openings) were modelled after its dimensions. The outside protection for these elements was made with Baumit Thermoputz plaster. The flat roof uses Kingspan KS1000x-dek steel panels also with 100 mm PUR insulation and PVC Sikaplan as waterproof material, U=0.19 W/mK and 24.6 kg/sqm [7]. The whole building received new PVC doors and windows from Internorm type Kunstoff Passion 4-16-4. The same PUR insulation, in situ applied was a choice made even for existing terrace new insulation, and instead of polystyrene or rock wool (because it's U value is almost twice smaller) [2]. 10 cm of Rockwool insulation was used for existing exterior prefab concrete panels and basement ceiling.

For the existing analyzed block and the extended one, a thermal and energetic expertise was done, concluded with an Energy Performance Certificate (EPC) (Fig. 10). The old block, erected in 1983, the minimum thermal resistance corrected (R'M) with thermal bridges of envelopes' each element is lower than the admissible values (sanitary – R'nec and energy efficiency conditions – R'min) and condense appears inside exterior panels and flat roof (table 1). The extended and rehabilitated block, with all new materials enumerated above, exceed the admissible values and there is no mildew (table 2).

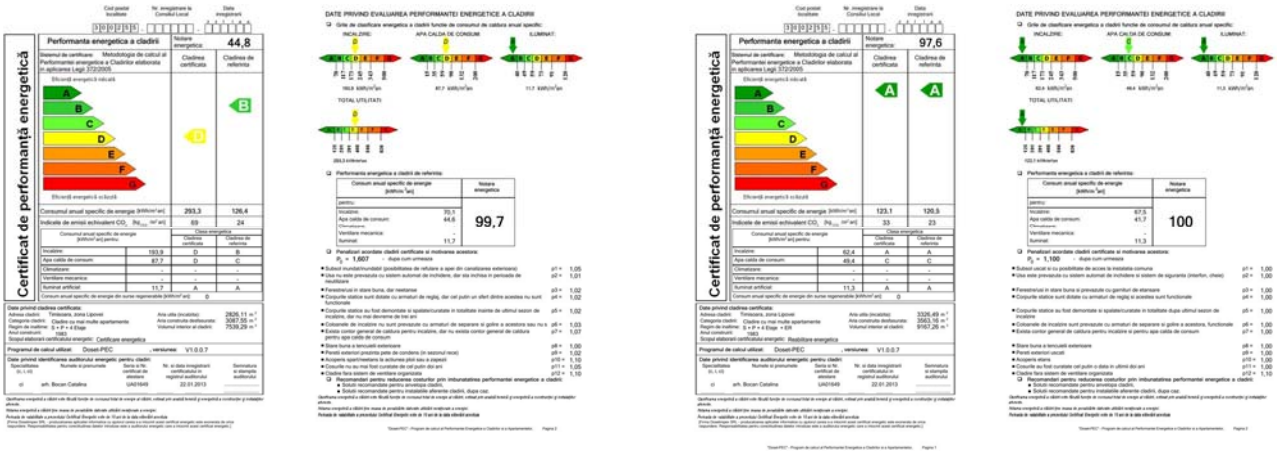

Fig. 10: EPC for existing and extended + rehabilitated building

Table 1 Thermal resistance for each envelope element on existing building

Construction element	**Area**	**R'M**	**R'nec**	**R'min**
	[m²]	**[m²K/W]**	**[m²K/W]**	**[m²K/W]**
Exterior wall	1465.87	0.606	1.188	1.4
Flat roof terrace	570.06	1.132	1.583	3
Slab over basement	560.36	0.244	1.416	1.65
Exterior fenestration	352.31	0.369	0.39	0.4

Table 2 Thermal resistance for each envelope element on rehabilitated building

Construction element	**A**	**R'M**	**R'nec**	**R'min**
	[m²]	[m²K/W]	[m²K/W]	[m²K/W]
Exterior wall	1732.39	2.619	1.188	1.8
Flat roof terrace	577.54	5.146	1.583	5.0
Slab over basement	560.36	3.045	1.416	2.9
Exterior fenestration	448.48	0.833	0.39	0.77

The nowadays rehabilitations are using only cheap materials, like polystyrene for thermal insulation. The use of mineral wool instead is recommended even for fire safety reasons, not just sustainability. Again, the use of PUR insulation allows minimal width when is needed (existing terrace – new attic floor). The use on concrete as ain structural material has never been used in this manner because of a psychological rejection for prefabrication and flat roofs. The structural details (the connection between old and new) is also a novelty for our country.

4. Conclusions

The innovation of this attic solution is given by a mixture of: new attic / penthouse design adverse to general adopted solution with pitch roof; new prefabricated materials used for structural and enclosing part, opposite to wood / masonry/metal/small tiles; different joint type between the original concrete walls and the new reinforced concrete frames instead of monolith solutions; little structural elements inside the new apartments; large covered terraces for the penthouse apartments; the new elevator used as a dynamic element for the back/inner court facade (with less balconies). As a reaction to other interventions (made out of materials enumerated above) I consider it normal to have a large scale operation due to a great interest of real estate market for 3 million apartments. The relocation is not a viable solution and construction works with residents in the building can be very difficult.

All enumerated above contribute to a daring roof retrofit by creating an attic, combined with a thermal retrofit, and may represent a challenge for Romanian people, running away from flat roof, prefab concrete structures and small spaces. Some arguments from a sustainable point of view are: the reuse of existing infrastructure, good energy quality prefabricated materials, quickly erected design solution and smaller disturbance, opportunity for large scale applicability. By using the existing terrace to create new living spaces, the actual apartments' inhabitants pay less money for building rehabilitation and the energetic performance of the whole construction is much better than without the new attic (Fig. 11).

Fig. 11: 3D images of the improved building

Other former communist countries have experienced similar measures, with attics on one, two or even three levels [8], but one of the main characteristic that allows such "liberty" is the lack of seismic constraints or movements - **SuRE-FIT European Program** (Sustainable Roof Extension Retrofit for High Rise Social Housing in Europe.

Short Summary

This paper presents a synthesis of some results obtained from an on-going national research program carried out at the University of Bologna, Department of Architecture, focusing on sustainable renovation processes and effective solutions for increasing the energy efficiency of the existing housing stock. The proposed methodological approach is based on a step by step retrofit strategy, tested by a simulation model, aiming to reduce the energy demand from the current significant present value to at least 15 kWh/m^{2}y. This performance level was assumed as the target of the retrofit action that has been developed by assessing the effectiveness of the different technological solutions adopted. This methodology and simulation set are going to be used for a further development of the retrofitting solution that foresees the use of pre-fab wood panels.

Keywords: retrofitting; volumetric additions; energy savings; quality; housing renovation

1. Starting position and objectives of the research

With the Directives 2010/31/EU and 2012/27/EU, the European Parliament and the EU Council promoted a wide range of improvements in the energy performance of buildings within the EU, proposing a methodology that takes into account outdoor climatic and local conditions, as well as indoor climate requirements and cost-effectiveness. Specific targets are provided for new constructions and existing buildings. In order to meet these targets and exploit the construction sector growth and employment opportunities (including the production of construction components, services rendered by professional studios of architecture and engineering), the Member States are required to establish a long-term beyond 2020 strategy for pushing investment in the renovation of residential and commercial buildings. This intervention strategy should address significant cost-effective renovations leading to refurbishments that can reduce both the supplied and final energy consumption of a building by a significant percentage when compared with the pre-renovation levels, therefore resulting in a very high level of energy performance. Such renovations could also

be carried out in different stages. Since the existing residential building stock represents the single biggest potential sector for energy savings, not only for its dimension and widespread presence on the territory, but also for its related behavioural implications, the expectation of the EU is that the rate of renovation interventions are going to increase in the very near future.
The housing sector plays a key role in this field and several research programs [1] dealt with the sustainable renovation and energy efficiency improvement of the existing stock erected between the '60s and '90s, covering over 65% of the urban fabric of several European cities. This stock is affected by relevant technological obsolescence (both physiological and functional), furthermore, at EU level, the annual consumption per m^2 for residential buildings is around 200 kWh/m^2. Additionally, a large number of these buildings has resulted not suitable for meeting the ever changing needs of todays families and their lifestyle.
This paper presents a synthesis of some results of an on-going national research program, carried out at the University of Bologna, Department of Architecture, focusing on sustainable renovation processes and effective solutions to increase the energy efficiency of the existing housing stock [2]. Based on the significant demand, on a national scale, for high quality residential units – which, following the financial crisis of 2008, is very hard to meet – the research program investigated the impact of volumetric additions to existing buildings in terms of densification.
Starting from a theoretical matrix of strategies for volumetric additions [3;4], this research studied specific topics concerning the re-dimensioning of the units, and increase in energy efficiency and the installation of equipment applying them on some case studies involving Italian residential buildings.
In order to make effective and sustainable the process of retrofitting (not only in financial terms), some topics of strategic importance are pointed out:

- A reduction in operating energy demand;
- Meeting the need for new space arrangement and level of quality;
- An introduction of passive or active solutions to exploit renewable sources;
- The optimization of the energy balance.

All of the above are considered strategic factors in the definition of the design approach for interventions and in addressing the methodology.

2. Research methodology

The research mainly considered multi-family housing (as they represent the greatest part of the residential stock in modern city) and selected several case studies, located in the main Italian and European cities, built from 60's to 90's, in order to obtain an index of the construction techniques originally adopted and a diagnostic analysis of the main pathologies and damages. Following the collection and analysis of the data, a synthesis of the most recurring obsolescence phenomena were associated to the distinctive construction characteristics of each typology [5]. Subsequently, the research focused on the Italian situation with the aim to offer effective design solutions capable of supporting renovation initiatives which – in the current economic climate – seem to be the only viable strategy to meet the housing demand and the increasing request for energy savings measures.
The methodological approach, proposed by the Research Unit of UNIBO, focuses on a step by step retrofitting strategy, to be tested on several case studies, with the aim to reduce the current very high energy demand to a value of at least 15 kWh/m^2y. This performance level is assumed as the target of the retrofitting action that was developed by assessing the effectiveness of the different technological solutions adopted. The methodology foresees the following steps:

- A definition of the simulation models;
- A definition of boundaries conditions;
- A definition of pathologies;
- A definition of renovation targets;
- An intervention scenario;
- An evaluation of the technological choices;
- An assessment of performances.

2.1 Definition of simulation models and boundaries conditions

The main typology adopted in Italian cities for multi-family housing is the one based on a concrete

skeleton with brick blocks closures, narrowly followed by concrete pre-fab panel systems or ones made on site. In order to test the performance of several technological solutions, aiming at drastically reducing energy consumption through a retrofitting action, some simulation models – one for each recurring typology – were set up for the definition of the specific deficit and lack of performance to create the foundation for the further steps of the analysis. In this way, different solutions can be compared (starting from the same basic conditions and targeting the same level of performance) and specific topics can be evaluated. In this paper the model referring to the most recurring typology is described.
Starting conditions were set as follows: the bearing structure is a reinforced concrete skeleton made of 25 x 25 cm pillars with a distance of 4 meters (which can be considered the facade module) and of lightweight concrete slabs with a thickness of 20 cm with reinforced concrete edge and internal beams. The building is assumed to be seven floors, including the ground floor; each floor is 9 Mt in depth and 2.70 Mt in height. Part of the floor slabs extends outside the edge beam in order to obtain the structural support for the terraces. Railings are made of pre-fab concrete panels.
The vertical closure (between the concrete pillars) is assumed to be for the first 1/2 in a double wall of brick blocks with different thickness plastered on both sides. The thermal insulation is provided by a polystyrene panel 3 cm thick between the two bricklayers. The remaining 1/2 of the module is a ceiling to floor clear wall. The windows are assumed to be of wood and single glass. The overall estimated thermal transmittance coefficient of 5.25 W/m^{2}K is well above the values established by law. Doors and windows, even when dealing with very large surfaces, have no protection against solar radiation. The roof slab is insulated (12 cm), protected by a waterproof membrane and covered by a metal sheet coat.
The heating system is assumed to be replaced with a new one in order to provide a more efficient behaviour and avoid heat losses deriving from a non insulated distribution system.
Even though many differences may be present, most of the typological, technological and construction experiments characterizing the recent history of the Italian building sector can be recognized in this model. The model allows to test different layouts for residential units of 45-70-90 m^2 considered the typical measurements of that period. The presented case is one of 70 m^2, with two units on each floor accessed through a staircase. The building is north south oriented and the layout foresees the living room and kitchen facing south side and the bedrooms facing north. The building is located in Bologna and the climate conditions assumed as boundaries for simulations are summarized in table 1.

Table 1: Conditions assumed as boundaries for simulations.

Geographical data			
place	altitude	latitude	longitude
Bologna (BO)	54 m	44°29'	11°20'
Thermal data			
Reference outside temperature: -5,0 °C			
Degree day: 2259		Climatic area: E	
Average heating period temperature: 7,3 °C		Average solar radiation on an horizontal plane during the heating period: 7,92 MJ/m^2	
Summer data			
Mounth of max solar radiation: July		Average monthly summer max temperature: 25,4 °C	
Summer max temperature: 33,0 °C		Difference in temperature during the hottest day: 12,0 °C	
Solar radiation on an horizontal plane during the month of max daylight exposure: 296,19 W/m²			

2.2 Deficits detected and retrofitting targets

The model reflects the high energy losses affecting most part of the existing building stock due to the construction system originally adopted: several thermal bridges are detected between the bearing structure and the building closures especially in correspondence of the terraces. Furthermore most part of these losses are due to a poor quality of glazing and frames. According to the starting conditions set, the primary energy demand is calculated in 160 kWh/m^{2}y (134 kWh/m^{2}y for heating and 26 kWh/m^{2}y for hot water production).
The quality of the units finishing, doors and windows and systems is quite poor. The poor indoor

conditions are related to the low quality of insulation and to a lack of any suitable climate control device. In addition to the above the related operating costs are very high. The current economical crisis does not favour a replacement of the existing buildings with new ones; consequently the only feasible solution seems to be a renovation intervention, also in terms of volume densification, to upgrade the building and limit costs. This solution seems to be the one more readily accessible to small and medium households.
Initial costs and running costs of the different strategies should be taken into consideration during the design activity, since the energy and financial aspects are strictly connected: a high energy performance solution usually needs higher investments, but savings generated during the life cycle are enough to repay the amount invested.
Consequently, the possible solutions analyzed take into consideration the savings generated in the long term, highlighting the economical sustainability of the intervention, in reference to an expected period of time. The main goals of the proposed renovation strategy can be summarized as follows:

- a reduction of operating energy demand by implementing the building envelope;
- an upgrade of the size and the dimensions of the units;
- a densification of the building as a whole;
- an introduction of passive solutions to improve indoor comfort;
- an integration of active solutions to exploit renewable sources;
- an introduction of a lift for each stair case;
- an optimization of technological choices to reduce energy investments
- a construction within budget.

Some supporting initiatives have been promoted in Italy at local and regional level with the aim to encouraging private investments for renovation and refurbishment actions. Unfortunately, the results are far from the expected ones since no planning activities have been put in place.

3. Renovation scenario

A renovation intervention should have an impact on two main aspects: first of all a reduction in the current energy demand in order to obtain a more sustainable behaviour of the building and a drastic decrease in operating costs, and then an upgrading of the units layout and dimensions to meet the new needs. Both of these could be achieved without having to move the residents out by reducing the impact of the intervention inside the unit and the building as a whole.
The analyses performed on the model showed that most of the heat loss occurs through the building envelope. Therefore, during the first stage of this research, a new insulation layer on the façades and a replacement of the windows were considered.
However, this conventional approach doesn't represent an effective answer to all the needs and doesn't offer any economic advantage since a relevant part of the costs are still due to the construction phase. Consequently a different approach was adopted [6; 7].

3.1 Intervention concept

In order to increase the performance of the building envelope and obtain additional surface for the units, two additions (1.40 Mt in depth) were introduced on both the main façades (see fig. 1). This strategy involves all the façade, allowing to introduce an addition on each floor and providing a simple structural solution.
On the north side this volumetric addition offers the opportunity to enlarge a single room to a double one and to provide a new bathroom for the existing double room. The loss of the terrace is balanced by the introduction of a new lodge.
The priority on the north side is to strongly reduce heat losses and for this reason the size of the windows of the added volume has been reduced when compared to the original ones (from 150x150 cm or 70x220 cm to 70x150 cm). Insulation is provided through the implementation of the envelope and the existing walls are transformed in internal partitions.
High performance insulation solutions are needed for the winter period, while a more complex behaviour of the envelope is required during summer time, when the main problem is reducing the heat indoors deriving from solar radiation. On the south side, the addition acts as a large lodge with an openable glass working as a greenhouse during the winter maximizing passive solar gains. Some PV panels are integrated on this glass envelope in order to obtain from renewable sources

part of energy needed. During the summer, a section of the glass envelope can be opened to favour natural ventilation and the PV panels can be oriented and adjusted to act as shading system. The objective is to minimize the interventions for the modification of the existing space and put all the economic resources and concentrate all efforts in the new volumes that provide new comfortable living spaces at minimum cost and optimize the overall energy performance.
On the south side, a thermal buffer zone is obtained through the addition of a lodge, which can be used as living space during summer and winter garden during the cold season. Furthermore, an additional room can be obtained through the modification of the configuration of the living room and the kitchen with a small increase in the budget.
Additions provide a 25 % increase in the unit surface therefore servicing a higher number of users. Figure 1 shows the main effect of the renovation strategy simulated in the model.

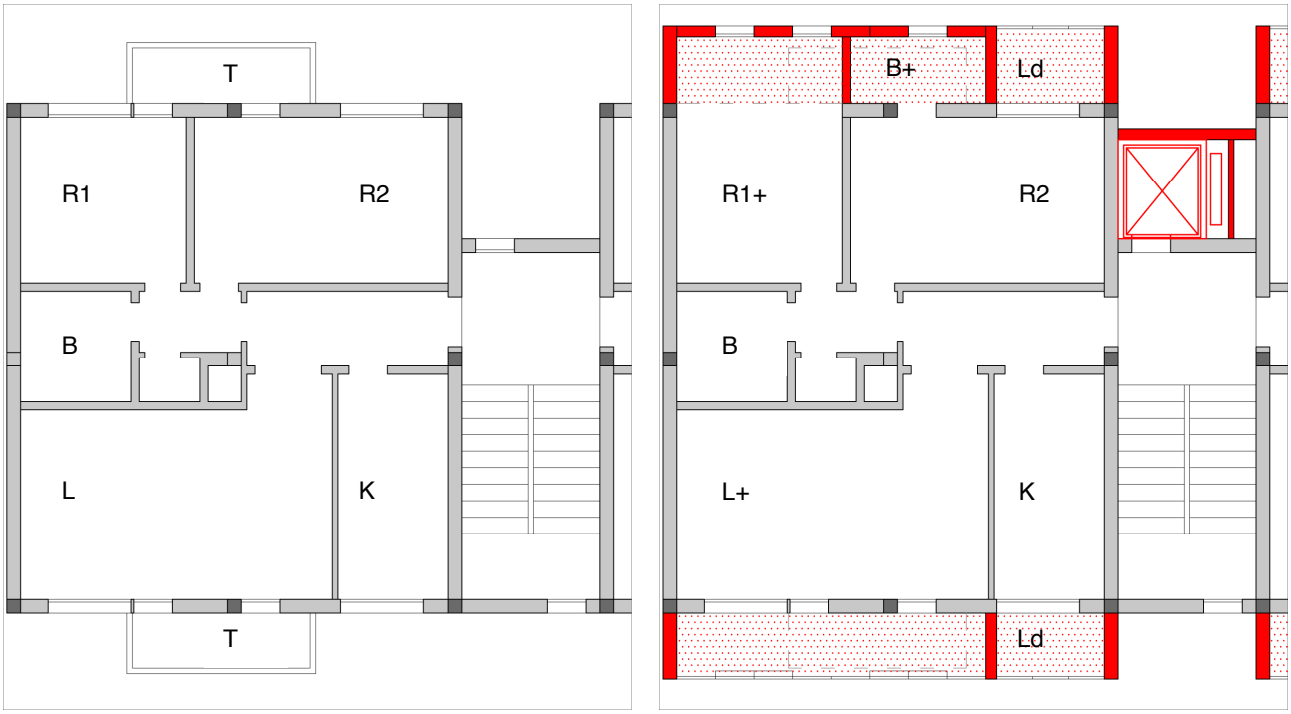

Fig. 1: plan of the typical unit considered in the model. On the left before intervention and on the right after renovation [R1-single room, R2-double room, B-Bathroom, L-Living room, K-Kitchen, T-Terrace, Ld-Lodge, + Addition]

The additions imply a reconfiguration of the main facades (north and south side) and provide a new image to the blocks. In order to increase the quality and the accessibility of the building as a whole, a lift is introduced on each staircase.

3.2 Technological choices and performance evaluation

In order to optimize the energy balance of the renovation action, several technological solutions were evaluated considering also LCA implications. The first requirement was to find a lightweight solution to reduce structural interventions and avoid significant consolidation works on the existing building. In this case the choice favours pre-fab panels of cross laminated timber which are used as support for the additions throughout each façade elevation. A horizontal panel (9.00 meters per 1.20) is used to extend the floor slab: this element is partially supported by the existing terraces slab, and mainly supported by vertical panels extending from the ground floor to the roof. The construction phases foresee a removal of the pre-fab panels, composing the terraces railings and their flooring, and then an installation of the new wood deck and vertical elements to be connected to each other and to the existing structure by steel joints. The vertical wood elements are pre-fab integrating the insulation layer, the condensation and waterproofing membranes as well as the cladding (which can be chosen according to morphological and technological criteria).

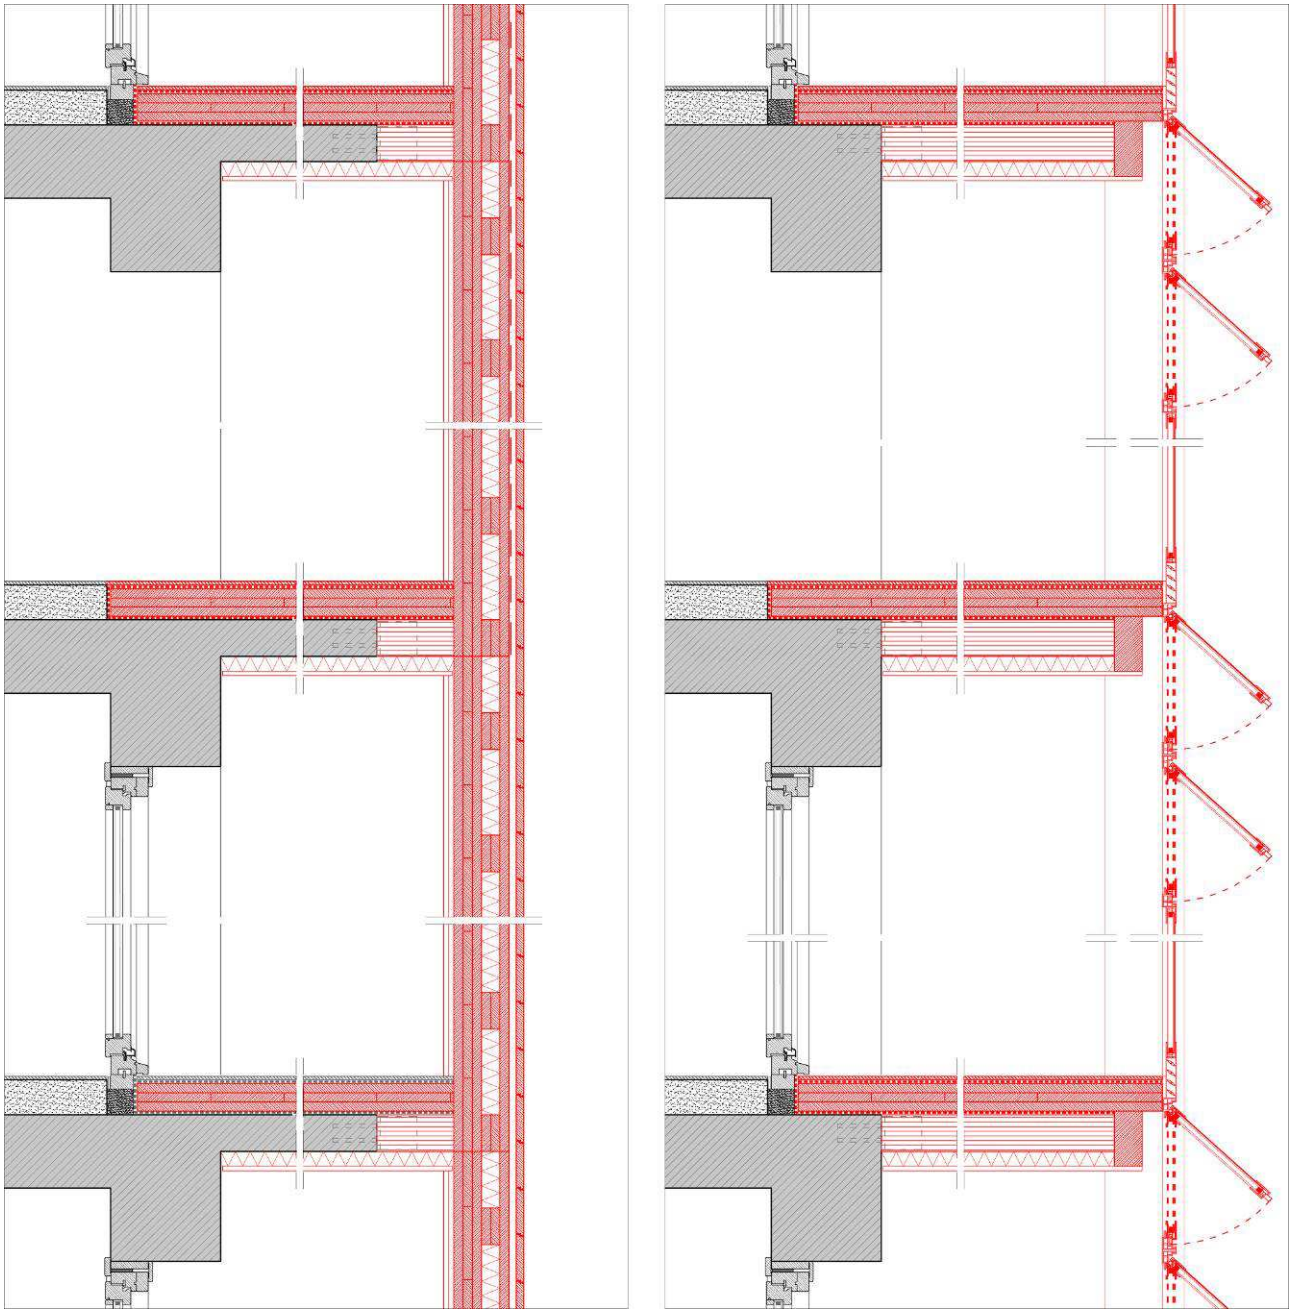

Fig. 2: detailed cross section of the addition on the north (left) and south side (right). The new deck is obtained using cross laminated panels while the vertical elements are pre-fab wood panels with integrated insulation layer. PV elements are installed on the glazing of the south facade to exploit renewable energy sources and provide a shading system, supporting natural ventilation therefore mitigating the indoor conditions during the summer.

This technological choice produces a very high performing envelope, which reaches in its typical section a thermal transmittance value approximately equal to 0.22 W/m^{2}K meeting the requirement of a significant performance increase of the envelope on the north side. The new wooden windows with double-glazing and the glazed modules on the south side reach a transmittance equal to 1.5 W/m^{2}K (the limit by law is 2.2 W/m^{2}K). Despite the reduced weight of the closure and the large glazed surface on the south side, the addition operates as an excellent buffer zone both in summer and winter. Simulation performed on the model showed that during winter the buffer effect and the passive solar gains balance the lower insulation level obtained on the south side while the natural ventilation and the PV shading system offer comfortable conditions during summer.

Despite the fact that few studies have been made on this subject and that no conclusive results are therefore available, the current condition of the existing Italian stock shows that the energy demand for cooling is about 2/3 of the one for heating. Consequently, it is important to provide an effective solution to the building energy needs during summer.
Simulations showed that the proposed interventions allow to significantly reduce dispersions and produce remarkable energy savings. In the analyzed model the existing heat generator is replaced with the new one with the aim to increase the efficiency of the system. Furthermore, the refurbishment action also provides the installation of solar panels for the production of hot water, on the addition roof, in order to reach a final EP index value equal to 15 kWh/m^{2}y, this being the value expected.

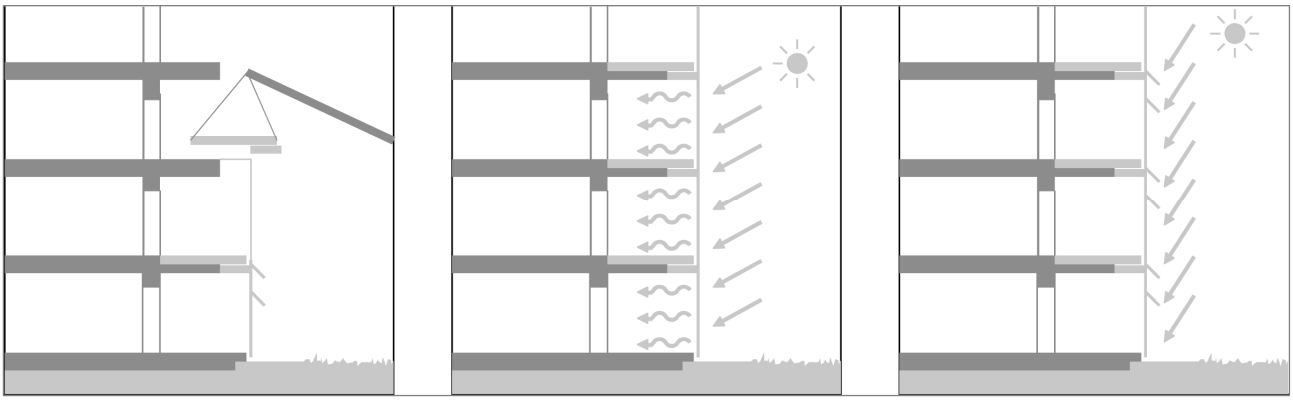

Fig. 3: Pre-fab panels assembled scheme and outline of the behaviour of the addition on the south side during winter (center figure) and summer (on the right).

The advantages of this approach to renovation are not only related to the benefits deriving in terms of energy savings and reduction in operating costs, but also to the optimization of the construction process. The addition can be realized with pre-fab elements ensemble on site without having to move the users out and the very small amount of demolitions and modifications required can be performed in a very short time.
Some further development of the proposed solution, such as the replacement of all the existing windows and radiators and the refurbishment of the building finishing, which would certainly increase the quality and the comfort, have not be considered in this study due to budget constraints. However, the proposed methodology allows to calculate the costs of the possible solutions, by comparing them with the current status.

4. Comments on results

Even if a volumetric addition seems to be much more expensive when compared to an implementation of the building envelope, the scenario proposed above shows a difference of just 9% in terms of construction costs. There is, of course, an additional cost for the new structure, but the choice of using wood elements limits costs in financial terms as well as in energy investments ones. The investment needed for the new glazing is closed to the one needed for the replacement of the original windows, therefore avoiding the need for a much more expensive and complicated solution in terms of insulation of the building envelope. In order to assess the cost effectiveness of the proposed strategy a financial analysis [8] was performed including the initial costs and the energy investment of the solution as well as the energy savings that can be obtained in the expected lifespan. The payback period for the renovation scenario, investigated through the simulation model, is of 12 years.
For what concerns annual management and maintenance costs (which were described in detail in the calculation models) an increase of 3.3% per year (in relation to the Italian trend) is expected while the discount rate was assumed of 5%. The calculation model takes into account a forecast trend in inflation equal to 7% for factors related to energy supplies and costs, as defined by the Electricity and Gas authorities.
A feasibility analysis including a financial evaluation (based on a multicriteria approach and also

including quality and energy issues) seems to be an unavoidable step in the development of any effective and conscious renovation action. The cost/benefit ratio evaluation is an essential tool in order to steer the design phase towards the most effective solution. Therefore sharing the decisional process with the end-users for what concerns the management activities, the functional features and the ordinary use can be a strategic factor to define effective solutions. The evaluation process can also influence the choice of the construction methods and the technological solutions.
From a methodological point of view, the experience tested in the simulation model allowed to point out some fundamental steps for the retrofit actions. The functional program, the typologies and the possible construction systems should be flexible in order to be able to adapt them to the results of the financial evaluation and to ensure a successful results of the project in terms of economic investment, quality improvement, energy savings requirements, environmental standards, etc.
Even if the main goals of the refurbishment are an improvement of the indoor comfort and of the energy performance – by controlling the heat exchange through the envelope – the economic impact of each action initial investment is still one of the first choice criteria potential investors look at. The aim of the proposed methodology and simulation model is a comparison of the costs-benefits ratio for the different solutions.
The simulations run during the research demonstrated the efficiency of the assessment approach even if the results are still affected by a certain degree of uncertainty due to the difficulties in predicting costs, trends of energy costs, tax relief policies and financial aspects.
The obtained results and the adaptable character of the methodology proposed encourage to continue this research through a further development of the proposed technological solution in collaboration with some companies specialized in the production of multi-layer wood panels, pre-fab and customized that can be adapted to the different requirements of the building.
Once the basic components for the construction system are defined further test will be carried out in order to check the actual performances. Therefore the objective is to find a cost-effective and high performance solution.
In conclusion, this research focuses mainly on a series of comparison of different solutions, in terms of an assessment of the cost-benefits ratio.

Short Summary

The **prefabricated reinforced concrete large-panel construction** method was spreading throughout Europe during the reconstruction work following the World War II in order to decrease the general housing shortage. During the 1970s and 1980s, altogether 510.000 flats of this type were built throughout Hungary, therefore their refurbishment is inevitable and urgent.

This study focuses on **the environmental optimisation of the retrofit** of the existing precast large-panel building stock in Hungary providing **a decision support tool** for the architectural design process by identifying the largest environmental impacts and optimizing the design. During the research a **comparative analysis** was developed for the refurbishment possibilities of existing buildings based on Life Cycle Assessment that studies the environmental aspects and potential impacts throughout the building's lifetime. Different refurbishment scenarios were studied in order to compare their relative environmental impacts.

The **typology of the precast large-panel building stock** was set up by grouping buildings according to their age, architectural and technical parameters. After assessing the environmental performance of the determined types the mitigation potential of the building stock was estimated. The analysis focuses on the most common impact categories generally applied for buildings e.g. the cumulative energy demand, the global warming potential, and the acidification, eutrophication and ozone depletion potential**. Normalization** was applied to understand the relative significance of the impact category results.

The methodology is demonstrated on **a case study area**: the Kelenföld housing estate in Budapest (Hungary) built in 1968-74 was chosen for the analysis and after assessing the environmental performance of the determined types the mitigation potential of the housing estate is estimated.

Keywords: life cycle assessment; scenarios for refurbishment; life time; concrete building; building typology

1. Introduction

The European Union has recently confirmed its commitment towards a sustainable future by adopting the 20-20-20 target: reducing the greenhouse gas emissions at least 20% below 1990 levels, reducing energy consumption by 20% and increasing the share of energy from renewable resources to 20% by 2020. The energy consumption of the building sector is significant all over Europe, accounting for around 40% of the energy consumption in the EU providing a great potential for cost-effective energy savings. There are more options to reduce the energy consumption in case of new buildings but the **sustainable refurbishment of the existing building stock** is an urgent task.
The goal of sustainable rehabilitation is the modernization of the existing building stock meeting the demands of present times and focusing on technical and ecological aspects at the same time, as well as the lengthening of their life-span and the conservation of built heritage. Besides the aesthetical and economical questions, energy efficiency and environmental impacts are important factors of decision making about the retrofitting of an existing building. Life Cycle Assessment (LCA) provides a scientifically sound solution for optimising the environmental performance of building.
The **reinforced concrete precast large panel construction** method was spreading throughout Europe during the reconstruction wave following the World War II in order to decrease the general housing shortage. Today their overall refurbishment is inevitable and urgent. The main problem this building stock presents is that the operational energy use is extremely high, due to design, constructional and structural errors. This paper deals with the question 'What makes the existing reinforced concrete high-rise building stock sustainable in the long term?'.

2. The existing building stock

In Hungary the first initiatives of the prefabricated reinforced concrete large-panel construction method were carried out in 1954, later in 1966, and the large-scale "production" of large wall panel blocks became possible. During the following decades, about 30-35,000 flats were built annually. Altogether 510,000 flats of this type were built throughout the country (nowadays appr. 13.5% of the people live in these high-rise buildings).

Since the primary aspect of designing these so called 'panel buildings' was the large number of production therefore many uniform features can be recognized concerning the geometry and the materials. The typical height of the large-panels is 2.80-2.85m (result in 2.65m headroom), the width of the panels was changed during construction period, in the beginning 2.70m and 3.6m were representative and later the 5.4m width was spread but more types of panels were applied in a single building. Considering the economical requirements of that period, mainly four and ten storey-high blocks were built, in the form of housing estates. The size of windows and architectural form of balconies and loggias were uniformed also.

There are not adequate statistical data available about the determined types of panel building stock but according to their age: almost the 55% of these prefabricated reinforced concrete large-panel buildings were built before 1979. The **typology of the precast large-panel building stock** was set up by grouping buildings according to their age, architectural and technical parameters: the most frequent types based on expert judgements are the detached building with almost a square shape, the 'terraced panel buildings' with more narrow or wide strip blocks and the 'H' shaped multi storey buildings the so called 'building with ears' with internal staircase [1], see Figure 1. Several subtypes can be determined but in this study 3 typical types of **the Kelenföld housing estate** in Budapest were chosen for analysis and after assessing the environmental performance of the determined types the mitigation potential of the housing estate are estimated.

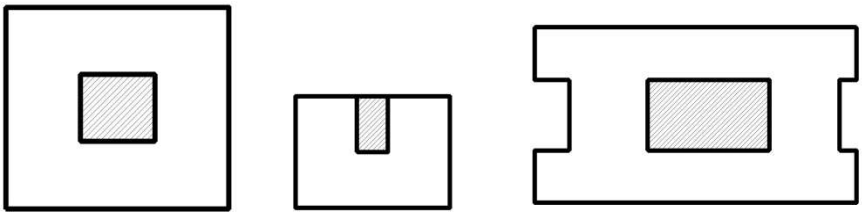

Figure 1: the sketch of the floorplan of the building types (the grey area is the staircase and the corridor) in order: detached building, terraced panel building and 'building with ears'.

3. The environmental evaluation of building refurbishment

During the research **a methodology was developed** for the analysis of the refurbishment options of prefabricated concrete buildings in order to reduce their impact on the environment. The method is based on **Life Cycle Assessment (LCA)** that studies the environmental aspects and potential impacts throughout a building's life from raw material acquisition through production and operation to disposal. A comparative analysis was developed: different refurbishment options were studied in order to compare their relative environmental impacts. The methodology is demonstrated on a case study.

4. Case study area: Kelenföld housing estate

The Kelenföld housing estate in Budapest can be considered to be one of the first realised results of prefabricated panels construction in Hungary, which was developed in the capital between 1966-75, mainly 10-storey, multi-storey, strip blocks with sections consisting of three or six flats of staircases among them 15-storey high-rise buildings, 1 or 2-storey service buildings were attached to the blocks. One of the largest housing estates of this type in Budapest consists of altogether 53 construction blocks roughly with some 8500 flats, that means the homes of about 20.000-25.000 citizens.

The analysed buildings are: the 'terraced panel building' erected in the beginning of this industrialized period, the 'H' shaped building with 6 flats per storey (the code is 'Kf10') and the 'A10' building with 10 flats per storey. All these buildings are 10-11 storey high and widely spread not only in the analysed housing estate but in the whole country.

Figure 2-4. Three typical prefabricated reinforced concrete large-panel buildings in Hungary: building codes in order: terraced panel building, A10 and Kf10.

4.1 General description of the building constructions

The analysed apartment houses were built from 1968 to 1972 by the first Hungarian Construction Factory according to the original Soviet technology located in the Kelenföld housing estate, in Budapest.
Regarding **the building constructions and the building materials**: the one-storey high reinforced concrete wall or floor panels are welded on their edges and assembled by fixing and concreting on the site in order to realise their box-structure, therefore the weak points of the

structure are mostly the **joints**. Considerable attention should be paid to both satisfactory joint sealing (heat-insulation and waterproofing) and the protection against corrosion of joining reinforcing bars.
Outside perimeter wall panels with built-in insulation are made of sandwich-structure: reinforced concrete elements with polystyrene thermal insulation. The thickness of the thermal insulation in the sandwich-panels decreased to 2 cm at the joints resulting in extreme thermal bridge losses on the façade (see Figure 5).

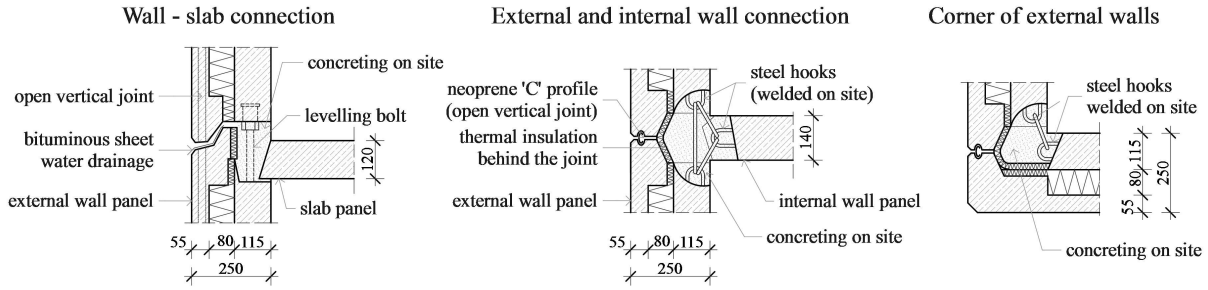

Figure 5: General details of the external panel connections (based on [2])

In the Kelenföld housing-estates a double-shell (ventilated) cold roof covered by bitumen membrane water proofing was generally applied with a low-insulation level, and lots of drainage problem nowadays.
The original wooden windows had obsolete construction, with very poor insulation capacity and high filtration rate. In most cases they were made with reveal shape and installed without any external shading devices.
Regarding **the building services** district heating systems with no possibility of local control were usual until the middle eighties. The heating systems are often unbalanced, resulting in overheating and under heating in different flats of the same building at the same time.

4.2 Methodology

This study focuses on the environmental optimisation of the retrofit of the existing precast large-panel buildings in Kelenföld housing estate. This method provides a **decision support tool** for the architectural design process by identifying the largest environmental impacts and optimizing the design of the refurbishment. The method of life cycle assessment (LCA) was applied, following the norms ISO 14040 [3] and ISO 14044 [4].

The main goal of the study was to evaluate the environmental impacts of the refurbishment of three typical existing high-rise large panel residential buildings in Hungary and the contribution of the different life cycle phases of refurbishment, maintenance, operation and disposal. Seven different scenarios are compared to support the decision making.

The **functional unit** was a high-rise prefabricated reinforced concrete apartment building in Budapest (Hungary) to provide housing for 100 additional years. An **Excel-based tool** was developed for the analysis and the calculations are based on real building documentations.
The reference **inventory database** used for the assessment in this study was the Ecoinvent v2.0 database by the Swiss Ecoinvent Centre, which contains high-quality inventory data of more than 2,500 products and services [5]. Since the sources of this database are mainly the Swiss and German industry the building materials produced in Hungary required certain modifications. The composition of the Swiss and the Hungarian electricity mix differs significantly; hence these modules were changed accordingly. The buildings erected by industrialized technology in Hungary are supplied particularly with district heating, and based on the data given by FŐTÁV (the district heating company of Budapest), the district heating mix of the assessed area was composed. For products absent from the database new datasets were developed based on the material composition [6].

During the research the **non-renewable cumulative energy demand** method the **CML method**

was used to assess the environmental impacts, both are internationally accepted and widely used. The whole remaining life cycle of buildings was considered. The **life cycle was divided into five phases:** production, operation, maintenance, retrofit and disposal.

During the production phase, the **construction** of the building requires energy and building materials transported to the site. In this study 15 MJ/m2 of diesel and 2 kWh/m2 of electricity were assumed for the construction based on the ecoinvent data. Based on the building geometry and composition of the building elements, the built-in weight and the embodied energy of the materials was calculated with an average 5% mass added to account for construction waste.
In the **operation phase**, the energy demand of the building service systems was assessed according to the Hungarian building energy calculation method [7] based on the Energy Performance of Buildings Directive [8]. The user-related components of the energy demand (e.g. the air change rate, internal gains and domestic hot water need) are defined in the Hungarian Government Decree on the energy performance of buildings. The annual energy demand for lighting was neglected, as it is allowed by the regulation in case of residential buildings. The **gross energy demand** including the efficiency and losses of the systems was calculated using the tabulated values of the Decree [7].
Maintenance activities involve small repairs and periodic replacement of building elements and service systems based on their expected life-span, this includes the production of the new elements. No modernisation, thermal performance upgrade or major rebuild, enlargement, conversion etc. were considered during the maintenance phase. For the maintenance works 1 kWh/m2 electricity was assumed. The values for the life-span of the building elements were estimated based on the literature sources [9][10][11].
The **retrofit phase** includes a comprehensive refurbishment reducing the operational energy need for the remaining prolonged lifetime. The phase includes the transport of the new building materials to the site (e.g. the new windows) and the transport of the replaced old elements to final disposal (e.g. the old windows), the production and installation of the new materials and the disposal of the exchanged building structures.
The last life cycle phase includes the **disposal** of the replaced building materials in the maintenance phase and the demolition of the building at the end of the effective life, separation, transport and processing of materials according to their end of life scenario and re-cultivation of the deposit site. For the demolition process itself, 30 MJ/m2 of diesel was calculated based on the ecoinvent data.

According to the literature, **the physical lifetime of large-panel buildings** is assumed to be between 80-120 years in Eastern Europe [1]. The expected lifetime of the building constructions and building service systems are not fundamentally different from traditional building elements. In this study the expected life time of a large-panel building is 80 years.
The case study buildings were built in 1968-72, so in the analysed moment these are 40-45 years old (rounding to 40 years), so the remaining life time is 40 years more.
It is assumed that the retrofit (especially the thermal insulation of the external walls) is expected **to increase the remaining life span of the building.** Due to the additional thermal insulation, the expansion of the external reinforced concrete layer of the sandwich panels' decreases, and the joints between the panel elements are completely hidden eliminating the possibility of moisture penetration. By the new thermal insulation boards on the façade the thermal bridge effect caused by the lower thickness of thermal insulation in the external panel joints is eliminated. Therefore the risk of internal condensation is reduced. Thus, due to the retrofit we assumed that **the expected life time of the building increases** by 20 years (20%).

The scenarios proposed for the retrofit to be compared, in case of a 40 year-old large-panel building:

- *No overall renovation:* retaining the current building in its current state, only maintenance work is done. The demolition is due at the end of the expected life time, in 40 years, when a new building will be erected with lower energy consumption.
- *Retrofit:* undertaking a comprehensive refurbishment, therefore the operational energy need is reduced for the remaining lifetime, the renovation prolongs the life time of the building, hence

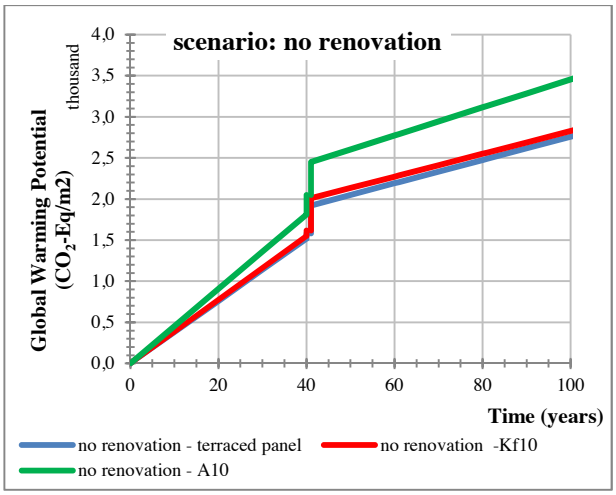
the demolition and the erection of a new building is delayed. The different levels of possible refurbishment in point of the energy performance:

- retrofit 1: to achieve the current energy performance regulations in Hungary;
- retrofit 2: increased thermal insulation level of the building envelope;
- retrofit 3: increased thermal insulation level with upgrading the existing heating system and installing heat recovery ventilation;
- retrofit 4: retrofit 3 complemented by installing flat-plate solar collectors on the flat roof.

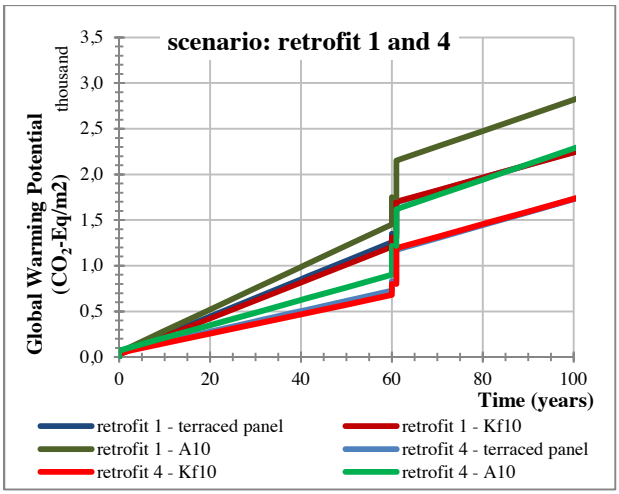
After 60 years, at the end of life, the renovated building will be demolished and a new one will be erected. Due to the increasingly stringent international regulations on energy performance it is assumed that the erected new one will have 40% lower energy consumption than the 'new building 2' scenario.

- *Demolition followed by the erection of a new building:* demolishing and constructing a new building (of the same shape, of the same size). Two different levels regarding the energy performance were considered:
  - new building 1: high-level thermal insulation and windows with gas heating system and heat recovery ventilation ('A' category)
  - new building 2: high-level thermal insulation and windows, heat recovery ventilation with solar energy use ('A++' category)

The long-term thinking suggests including **the embodied energy of every building component in the calculation,** not only the envelope. Those elements do not influence the operational energy consumption directly, but they account for a significant section of the embodied environmental impacts, especially in case of multi-storey buildings [6].

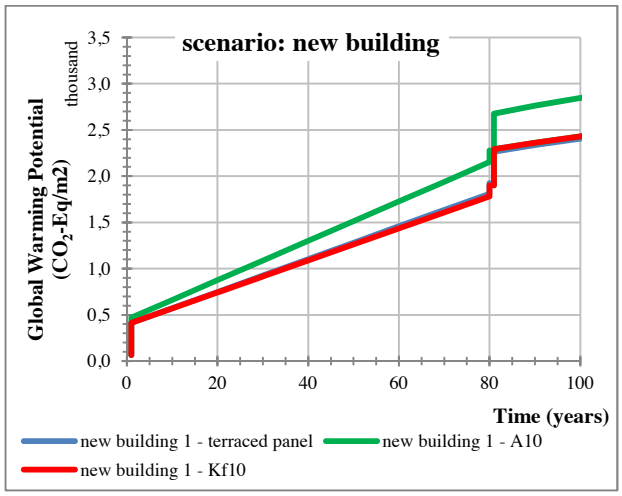


4.3 Results



LCA professionals use different impact assessment methods, with several **environmental indicators**. In this study, beside the **non-renewable cumulative energy demand** the **CML method** was used to assess the environmental impacts. The used CML categories were: the global warming potential, 100 a (GWP), the acidification potential, average European (AP), the ozone depletion potential, steady state (ODP) and the eutrophication, generic (EP).

Normalization, an optional step of life cycle assessment was applied to understand the relative significance of the impact category results. In accordance with EN ISO 14044, normalisation is the calculation of the magnitude of the category indicator results relative to reference information. The obtained results of the impact categories are converted to common units; therefore the relative significance of the category results can be compared. In this study, the reference values (normalisation factors) given by Guinée were used referring to the intervention in Western Europe in 1995 [12].



All normalization figures of the 'terraced panel building' (of all the other retrofit scenarios) show that buildings have the most significant contribution in the category of global warming (GWP) and also the acidification potential (AP) is relevant, but the contribution is less than half of the GWP. The normalised ozone depletion and eutrophication caused by the retrofit are insignificant.

According to the results of normalization in this paper the **global warming potential**, as the most significant environmental indicator is demonstrated in more detail. Figure 6-7. and 8 show below the global warming potential of the most significant scenarios of all the analysed buildings, referring to one year and to one square metre of floor area as a function of time.

Figures 6-7: The global warming potential of the three analysed buildings in case of 'no renovation' and 'retrofit 1 and 4' scenarios

Figures 8: The global warming potential of the three analysed buildings in case of demolition followed by the erection of a new building

As the figures above show the results of each scenarios are similar the difference is around 20%, the terraced panel building and the Kf10 building are almost the same only the A10 building differs. In this study the results of 'Kf10' building will be reviewed.

Figure 9 shows that **for the first 2-3 years** after the decision point, the 'no overall renovation' scenario seems to be the best decision. However, after this time, all retrofit options have a lower environmental impact.
Until year 60 after the decision point, the 'retrofit 4' scenario has the lowest global warming potential, which is the high level retrofit of the existing large-panel building. At that moment the retrofitted building will be demolished and a new one will be erected but with a lower energy consumption and lower global warming impact, since many emissions are directly linked to the energy use.
The **steps of the designed 'retrofit 4' scenario are:** increased thermal insulation of the external building envelope (16 cm polystyrene on the external wall, 10 cm wood wool insulation on the basement floor and 24 cm polystyrene on the flat roof); the change of the existing wooden windows in the flats and the staircase for multi-chambered PVC thermally efficient windows with low-e glazing (u=1.1 W/m^{2}K) and the installation of new metal main entrance doors (u=1.1 W/m^{2}K). To avoid thermal bridge effects the insulation of the parapet walls of the loggias, balcony slabs, plinths, and the attic walls will be carried out. Finally in the course of the modernization of the

building services thermostatic valves are fixed to the radiators in the flats in order to be able to control the heat flow and mechanical ventilation is implemented with heat recovery (70% efficiency) completed by flat plate solar collectors installed on the roof (app. 2,0m^2/apartment) and the necessary puffer water tanks in the basement.

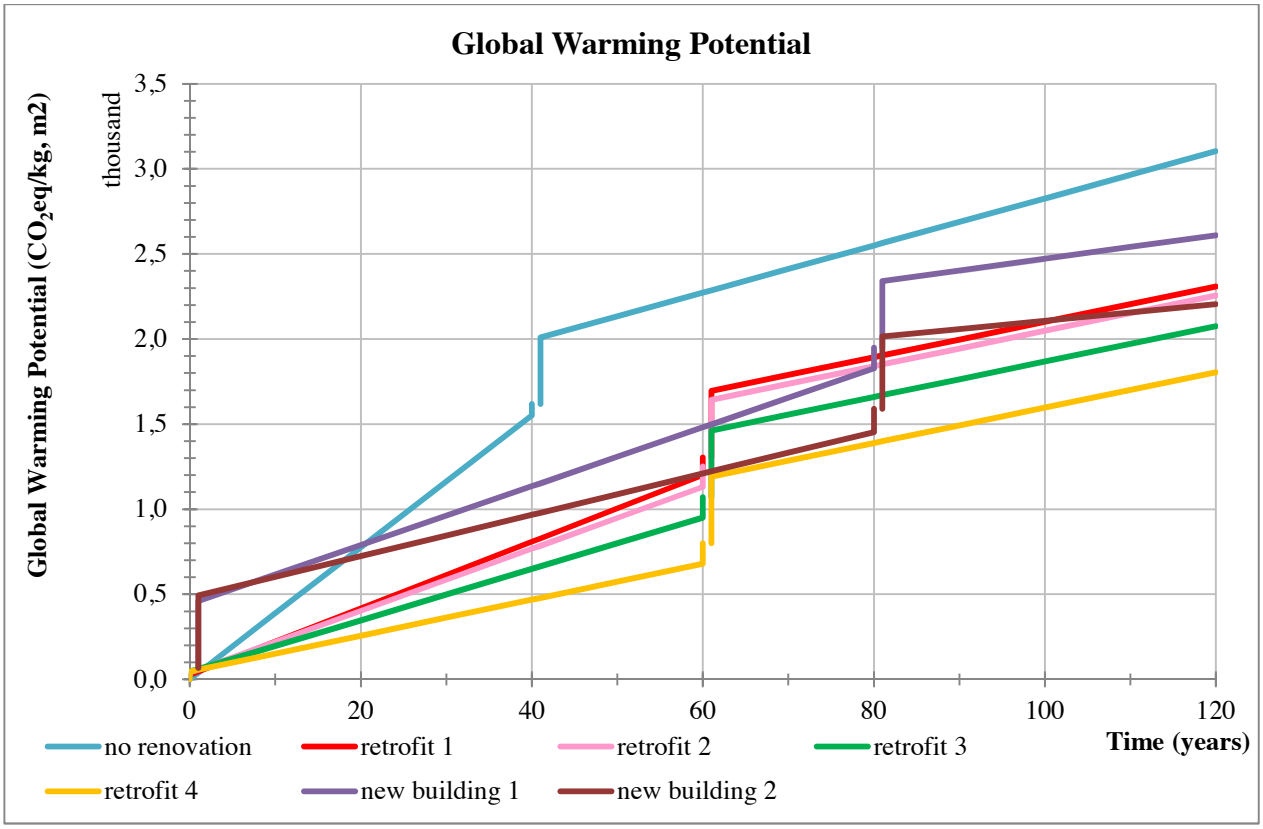


Figure 9: The global warming potential of all the alternatives in case of 'Kf10' building

Analysing **the longer term – 60 to 80 years –** due to the high level of uncertainty in the energy mix and the future regulations about the energy performance of buildings it is difficult to decide whether the immediate demolition of the building and the construction of a new low-energy building (scenario: new building 2) or the retrofit 4 scenario has the lowest life cycle CO_2 eq emission.

The same tendencies can be observed in case of the **ozone depletion potential** of the alternatives, consequently the operation phase is dominant. The 'retrofit 3' and 'retrofit 4' scenarios have the lowest ozone depletion potential during the assessed period of time.
Regarding the **acidification potential**, the production phase is more significant than from the point of view of CED and GWP: the construction of a new building is around 28-31% of the total emission. All retrofit scenarios have lower acidification impact than the new building scenarios.

Similarly to AP, the production phase of the new building scenarios is relatively dominant in the category of the **eutrophication potential**. Production phase of the new buildings is 34-35 % of the life cycle impacts. The **cumulative energy demand** is suitable as a screening indicator in the environmental assessment of buildings. Since the burning of fossil fuels is dominant in greenhouse gas emissions, and the analysed buildings are heated by district heating based on natural gas in the Kelenföld housing estate, the CED and GWP values were highly correlated in this assessment also. The relatively high significance of the end-of-life phase is remarkable; it is around 17-18% of the total.

Altogether 23 of the 'terraced panel buildings' mentioned above are located at Kelenföld housing estate, generally built with 3-4 narrow strip blocks each and some with wide blocks. The number of the so called 'building with legs' (code: A10) is significant, altogether 12 buildings. In addition 3 more 'Kf10' buildings are located around the park in the middle of the area. Altogether there is

approximately 280,000 m^2 area of flats at this residential area.

From the results of the individual buildings the total energy saving and the mitigation potential of the housing estate can be calculated taking into account the number of building types per district.
The **global warming mitigation potential** of the analysed area is 5,2 ktons CO_2 equivalent per year. In average the mitigation potential is 44.4 % that would be achievable if the buildings were upgraded to fit the requirements of the current building code (retrofit 1 scenario). In case the existing large panel buildings were be retrofitted according to the retrofit 4 scenario the decrease of global warming potential would be 64.6%.
Since the energy mix of the district heating is based on fossil fuels the **non-renewable cumulative energy demand and the ozone depletion potential** are quite similar to the global warming indicator.
Concerning the **eutrophication and the acidification potential** the decrease is lower approximately 26.6-26.7% in case of general retrofit measures (retrofit 1) but there is not significant change if the retrofit 4, the high-level refurbishment were taken into account (24.6-27.3%).

5. Conclusions

For energy efficient retrofit, the payback time is usually calculated on the basis of the investment and the savings. But when the question is whether a retrofit is worth doing or not, all relevant aspects have to be considered, not only the payback time.
The 'no overall renovation' scenario has the lowest life cycle CO_2 eq emission in the first 2-3 years, but after this time the retrofit options have a lower global warming potential: the energy and the environmental impact invested into the retrofit is quickly recouped. The **comprehensive retrofit is the most environmental friendly option until about 60 years**, when the renovated building reaches the end of its expected life time. In an even longer term (60-80 years), as it is difficult to predict the future regulations about the energy performance of buildings and the possible changes of the building materials in the long term, there is an increasing uncertainty involved in the assessment.

The analysed time period depends on the decision makers. Investors are generally interested in the very short term. The government or the local governments are able to think 10 to 15 years into the future in case of buildings, but their actions depend on the political decisions.

In order to analyse the mitigation potential in each impact categories during the remaining life cycle of the whole prefabricated large panel building stock more research is necessary: develop further the building typology and make further life cycle assessment calculations.

6. Acknowledgement

This work is connected to the scientific program of the "Development of quality-oriented and harmonized R+D+I strategy and functional model at BME" project. This project is supported by the New Hungary Development Plan (Project ID: TÁMOP-4.2.1/B-09/1/KMR-2010-0002).

The work and the publication is supported by the TÁMOP-4.2.2.A-11/1/KONV-2012-0041 project. The project is co-financed by the European Union and the European Social Fund.

Short Summary

The existing building stock in Austria consists of a variety of buildings from the post-war period. Due to their poor quality of construction those buildings consume an enourmous amount of heating energy.
In Kapfenberg one of these bad energy performing social housing buildings from the sixties is being renovated to become net zero building. The sixties bloc will be converted into a futuristic showcase. The house in Kapfenberg has 32 apartments on four floors. 200m2 building integrated solarthermal collectors and up to 1.200m2 photovoltaic modules have been mounted on a large scale solar wing that extends far beyond the existing roofscape. In the annual average energy balance, the building will produce more energy than it consumes on the primary energy level. Johann Böhmstrasse is a „Building of Tomorrow“ flagship project funded by the BMVIT.

1. Introduction

The existing building stock in Austria consists of a variety of buildings from the post-war period. Due to their poor quality of construction those buildings consume an enourmous amount of heating energy.
In Kapfenberg one of these bad energy performing social housing buildings from the sixties is being renovated to become net zero building. The sixties bloc will be converted into a futuristic showcase. The house in Kapfenberg has 32 apartments on four floors. 200m2 building integrated solarthermal collectors and up to 1.200m2 photovoltaic modules have been mounted on a large scale solar wing that extends far beyond the existing roofscape. In the annual average energy balance, the building will produce more energy than it consumes on the primary energy level. Johann Böhmstrasse is a „Building of Tomorrow“ flagship project funded by the BMVIT.

2. Development of prevabricated facade modules

The refurbishment concept of the Johann Böhmstrasse is based on efficiency measures (highly insulated, prefabricated active energy roof and energy facade elements with integrated building services), on a high percentage of renewable energy sources as well as on a smart integration of energy supply towards heat and electricity networks. The concept makes a significant contribution to the achievement of three EU goals:

- 80% energy efficiency – reduction of energy demand
- 80% share of renewable energy in total energy consumption
- 80% reduction in CO2 emissions

The high-quality refurbishment towards the plus-energy building standard is only possible becouse of an integrative refurbishment and energy concept. The high-quality thermal renovation of the building envelope with Passive House components, the interaction of energy-producing active elements – thermal collectors, PV – and a grid integration of electricity and heat. Using existing energygrids for storage and distribution makes it possible to reach plus-energy building standard in the renovation.

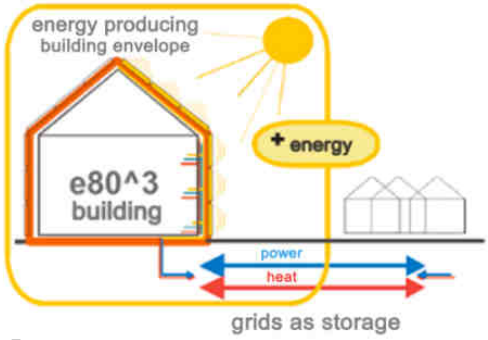

Fig. 1: Principle, source: AEE INTEC

The basis of this innovative and inclusive reconstruction concept is established by a required brief analysis of the status quo. Building typologies, construction characteristics and typical building physics and static standards of multi-family houses (MFH) which were built from 1945 to 1980 provide the preconditions for the further development steps and point out the potential for economic feasibility.
Special attention is given to the overall building systematic and respective inclusion into the considerations. Analyses for an optimal energy-efficient coverage of consumption peaks through renewable energies and usage of synergy effects within settlements have been considered. Concept design mainly focuses on the development of the rearrangement of all the building services – manholes, walls etc. to be moved from the building interior into the new building envelope. During the development of technology and components of prototypes of prefabricated facade elements and supply and disposal systems, the structural engineering and building physics aspects are particularly considered and included in the considerations. Building up on already implemented innovative house of the future projects (such as Linz, Graz and Makartstraße, Dieselweg) these guiding or flagship projects are to be developed, optimized, perfected and thus transferred from individual manufacturing to mass production. Through the evolution of prefabricated facade, as well as new, external home automation modules for up to 4-storey buildings, it is possible, to economically refurbish all the buildings of this epochs. The facade- and basic roof modules incorporate conventional rear-ventilated constructions as well as the new power-generating active elements ("plus" energy producers) such as solar collectors and photovoltaic systems. Thus, the number and arrangements can be adapted and optimized to suit the respective situation given (zero energy or positive energy).

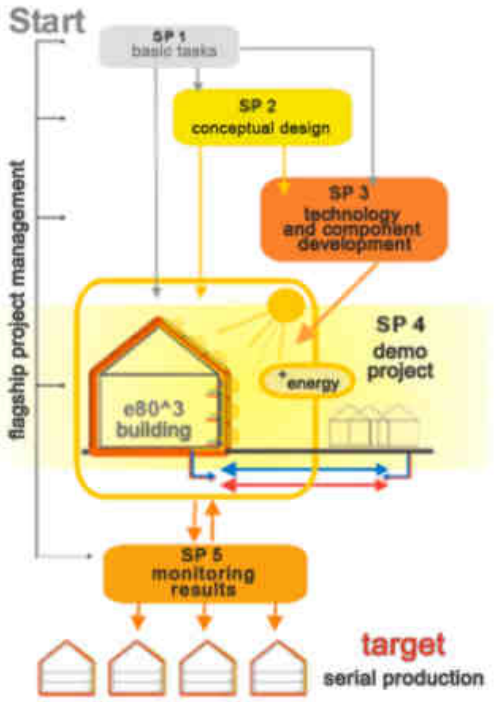

Fig. 2: Project schedule, source: AEE INTEC

3. Energy Concept of Johann Böhmstrasse

The main heat supply is achieved by the district heating system of the Stadtwerke Kapfenberg. This is mainly done by the waste heat of the Böhler-Werken. On the southern side of the building there are solarcollectors (about 200m2) attached which contribute to the heating and the provide warm water. The exhaust fan is equiped with heat recovery and a heat pump. Through these three measurements the energy storage is being supplied. The energy being produced supplies the energy storage and is then passed on to each apartment for heating and warmwater. On the roof of the building, which changed from a steep roof to a flat roof photovoltaics are introduced in a size from about 400m2 / 50kWp. On the eastern and the western facade photovoltaics contribute to the high energy performance of the building. Surplus energy is being transferred to the public net. On the first step the domestic current should be reduced to a minimum. There is a possibilty to introduce even more photovoltaics to the building in further developments.

4. Conclusion

The building envelope as an active rather than a passive element, as an energy converter meets more functions than just the separation of the outer space from the interior with more or less thick insulation. There are still too few approaches and economically implemented examples of prefabricated facade and roof elements.
The implementation of systematic and integrated wiring outside the original facade in combination with the new building envelope would be an innovation for the market. The integration of existing and planned grids as storage and distribution elements allows for future realisation of refurbishments towards energy-plus buildings in settlements.

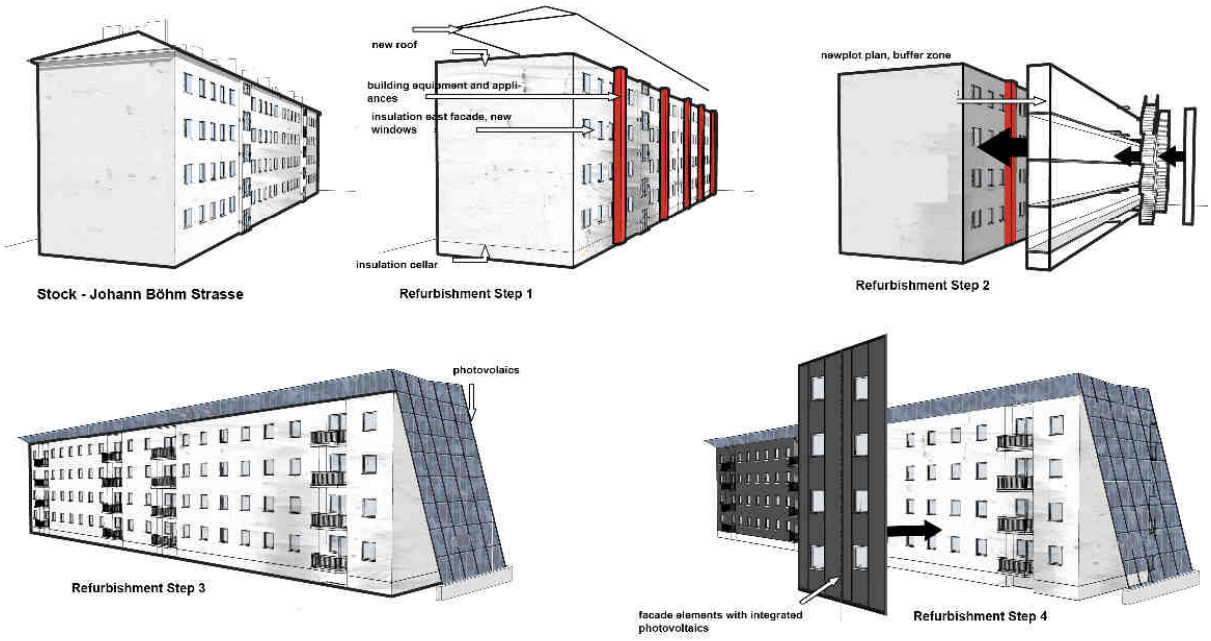

Fig. 3: Schema of the refurbishment

Fig. 4: On the left the newly refurbished building can be seen as a comparison to the old building on the right

To reach Net Zero, not only the large scale solar integration is needed. Also the operational energy of the building will be reduced by 80% after the renovation. Therefore the existing building facade is beeing renovated with forty feet high prefabricated wooden modules. The new building services, active solar elements as well as doors and windows are already integrated into these highly insulated timber façade elements. Thanks to the prefabrication a high precision in the details is achieved, which is needed to exploit the potential for energy improvement which is necessary to reach net zero. Furthermore the construction time on site can be reduced drastically and the building can stay inhabited during the renovation process. The joints and connection details of the completely prefabricated elements are designed in a way that after the assembly on site all the

required building physical functions such as fire protection, air tightness and sound insulation are guaranteed.

Summary
A rundown 1958 post-war housing estate in the west of Munich was first an object of study, then a planning model and finally a showcase project for holistic wood renovation. For an ideal lifecycle balance and overall economy, the following is vital: maintain the carrier substance, rebuild, recompress, passive-building envelope pre-fabricated in wood, timeless design and regenerative energy supply.

Keywords
Solar construction, renew stock, recompress, set of objectives, lifecycle balance, grey energy, wooden construction, pre-fabrication, passive house, solar energy

Structural planning	MKP Merz.Kley.Partner/ EST Energie.System.Technik
Funding/ Research	KFW, dena, LH München, E2ReBuild
Construction dates	Original 1958/ Constr. Phase 1 2010-11 (Phase 2 2012-13)
Net dwelling area	3.323 m2 (originally 2.012 m2, + 65 %)
Units	46 flats/ district housing office (originally 36 flats)
Envelope quality Ht'	0.26 W/m2K (originally 1.56 W/m2K)
End energy	22 kWh/m2a (originally 280 kWh/m2a)
Primary energy	22 kWh/m2a (originally 340 kWh/m2a)
Building cost	950 €/ m2 GFA (German DIN cost groups 300/400, gross

How is our ‘big house’ doing?

‘Holistic’ solutions for building restoration – is that just a new name for an age-old problem? We don’t think so. I would like to try to briefly explain why, an idea and a concrete project example. The question here is what does sustainable mean? The answer is to get started with the holistics .. let me start with a very personal story. My children, Leoni, 16, and Lucia, 13, grew up in the south of Munich. Their ecological footprint on the world is still small – and it should stay that way. But if we listen to serious forward thinkers – which we definitely should – by the time they reach our age, their world should be a completely different one than today...

Should we be afraid of that? Well, we probably don’t need to be and fear is never a good starting point when trying to find sustainable solutions. The term ‘respect’ fits better here – faced with the boundless complexity of global events as a result of a burn out of our knocking off economy. The more we think we know, the less we manage to maintain a natural balance. Prof. Radermacher, for example, calls it the boomerang effect. No wonder that there are children who say: we cannot leave the shaping of our future up to the adults anymore. What more can you say to that?

How to handle this ‘seven-headed Hydra’? I have found a suitable approach for myself: it is the daily effort to constantly contribute to a solution instead of the problem. Only by living out that idea can a temporary state of calm be reached. Planning and construction offer a rewarding area of work in this respect. The key functions of energy, material and capital circulation are each approximately half directly or indirectly linked to our building construction and present the highest potential by far for sustainable collaboration with their owners and users. Success solely depends on us, the social skills towards high priorities, strength of character and communication.

Challenge and objective

Buildings are and will remain our most costly and longest lasting commodity. We are faced with the simple fact that with the turn of the millennium, we entered an era in which we need to reflect on those unique key energies and materials, which have always made living even possible: our sun, its light. High-tech on the roof, smart-tech in the house and/ or religious beliefs of divine salvation is not enough. But what is ‘solar construction and restoration’? Integral planning concepts are aimed at a rational, sustainable overall context of:
- Induced energy and land consumption in urban building or landscape preserving credibility,
- energy consumption due to production and transport and the minimisation of synthetic materials in construction,
- of operational energy consumption when using the building and installations, linked to optimised quality of use,
- energy input and problem waste on ‘re-use/ down-cycling/ disposal’ after restoration or demolition,
- and the easing or reshaping of our social, cultural and economic network of relationships.

Energy, anything material and also our culture are not reproducible. Solar architecture is about the complex equilibrium of energy and material balance of our earth. Above all, it is pleasing and works simply, is flexible and long-lasting – three barely perceived, but ultimately decisive multiplier properties for the ecologically rational lifecycle balance. This suggests a decisive turnaround against our political and economic behaviour, our smart and responsible contribution towards an open solution process – as an essential contribution towards peace and the well-being of generations.

The building owners may ask: Who should pay for that? The counter question is: what is the future worth to us? Stay calm, thinking helps. Independent expertise and creative reflection are by far the most cost efficient resources for real sustainable construction. A macroeconomic observation – compiled under ecological cost transparency – leads to extensive different decisions than in today’s building industry. Relevant research results have expressly proven this several times. The simple, comprehensive dynamic CO2 taxation would be a highly effective motor.

Long-term ecology will become long-term economy by the time the overdue internalisation of external costs at the latest. ‘Holistic and sustainable’ will become the only form of building construction we will be able to afford in the future. Good architecture has so much more to offer than low energy demand values, but only when architects and engineers take on this system-changing planning attitude in design realisation and render a backward-looking, knotted sustainability certification redundant, will a substantial economy, new ‘archi-culture’ and genuine quality of life synergistically arise – wouldn’t that be a legacy worth striving for?

The example: From object of study to prototype

A large part of the overall housing stock in Germany is functionally outdated, has high operational costs, is inadequate in terms of energy consumption and does not comply with society’s living standards of today, let alone of the future. That means, that our central construction tasks lie in the renewal of our existing building stock. This necessity poses many dangers, however, when thought through it poses unique opportunities: it calls for a fundamental approach and new interpretation of old housing. Structural sins of the past can be alleviated or even eliminated and the demand for a more sensitive recompression and redesign presents the possibility of sustainable urban corrections linked with high overall economic efficiency and an attractive future orientation.

As an example we present a Munich GWG housing estate in Sendling: Mass commodity in the 1950s, masonry bolts with unit floor plans and individual room heating, after two generations it is still in its original condition for the most part. The heating requirement is approximately at factor 4 above the new construction value according to EnEV2009. It was only the excellent location, that kept the building from permanent vacancy. In 2006/7 we had focused on a study design about sustainable development goals by the chair of wooden constructions at the TU Munich – with remarkable results. A research project ‘TES Energy Facade’ subsequently followed, then the contract for the planning and implementation by the public housing association to our ArGe Kaufmann.Lichtblau – in short: it got serious!

Fig. 2: Renewal post-war housing estate Munich, path of the sun 21 March / Sept.

So the modern engineer’s wooden construction was to become the renovation method of building stock?! Until now, a lot was theory as in architecture. The design, it is said, shows the talent; the art begins with the implementation and realisation. The building owner and our planning team – after detailed preliminary discussions – agreed on a set of objectives. This corresponds entirely with the requirements and, among other things, the widest possible preservation of existing primary structures to the prevention of grey energy and waste from demolition and reconstruction. An upgrade-free economic life expectancy of at least 40 years for complete renovation – 46 flats and new regional administration in the lowest energy standard – essentially covers three areas, our set of objectives:

A / The use: Quantity, quality and environment
- Compress rentable living areas of the 1b site by more than 50 % - use building ground, ensure revenue,
- Create market-conform mix of flats with light, attractive layout – offer new living quality,
- Interlock disabled, elderly and child friendly functional residential use – include demography,

- Make the new living environment spacious, social, close to nature and robust – design urbanity,
- Studies of the sun show daylight quality in each residential area in the quarter.

B / The energy concept: Standard, maintenance, economy
- Lower the energy demand, heating, air and light to under 50 % of a new construction – achieve maintenance security,
- As much as possible, provide regenerative residual energy from heating and electricity – achieve zero emissions,
- 'triple win' – ease the burden of the owner/ tenant/ environment – produce overall profitability,
- Offer simple, safe, long-lasting technology for ease and cosiness – promote health and comfort.

C / The structure: Ecology, process and design
- Perfectly ecological assembly system of high quality and precision – optimise life cycle balance,
- Constructive integration of sound insulation and fire protection, as well as statics, hvac and solar active components – understand flexibility
- Digital on-site measurement and an maximum pre-fabrication, low weight and short construction period – track process efficiency,
- Low maintenance surfaces and many selectable design variations – enable time-less, attractive architecture.

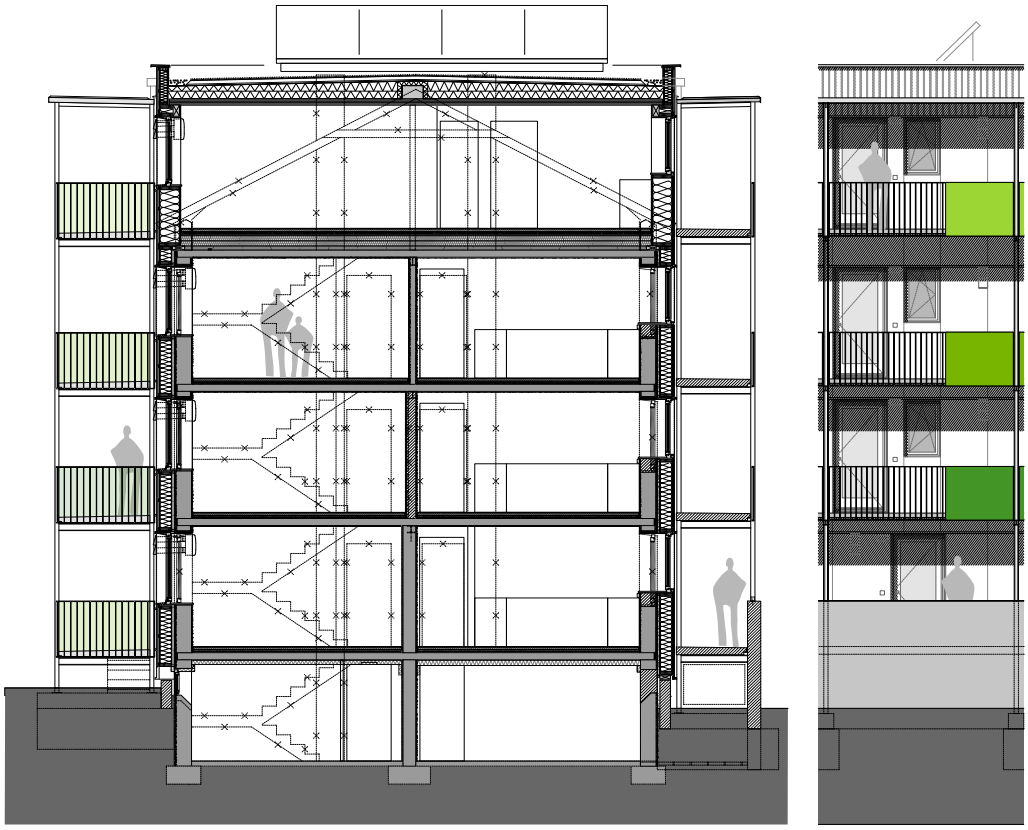

Fig. 3: Renewal post-war housing estate Munich, layout construction in wood

The provocative demand of the building owners to the planners: all aforementioned objectives should be reached cost-neutrally within public housing subsidies. The unavoidable extra costs for prototypes with 'sustainable attributes' must be financed in full by appropriate subsidies for energy renovations and 1 € / m2 rent exclusive of service charges as a user contribution for minimal energy costs. That should occur through the holistic added value as described, and furthermore a new 'league of efficiency' will be reached. Despite obstacles and risks we accepted the challenge.

Almost 3 years' work passed by. The first construction phase of the pilot project is finished, the GWG administration and new construction flats as well as the comprehensive renovation of both

existing buildings along with additional stories are being used, the outdoor areas are almost done. With a widely successful completion of the comprehensive mutual set of objectives, K.L.A. has consciously entered new territory for GWG and in doing so has also reached unforeseeable limits to the affordable input of working time. We owe that to our cause, our building owners and their (happy) tenants. An extensive monitoring for result validation will be carried out by the end of 2013, the second construction phase with the replacement new construction has begun.

Provisional conclusion: The obtained result is an example of the simple fact that the renewal of existing buildings with the title 'real sustainability' – on today's conditions – is achievable, of course not by means of standard planning, standard processes with standard partners and at standard costs. We also had to deal with obstacles and risks, as well as priority struggles and completely new solutions. Follow-up work shows plenty of valuable experience and learning success, which we will hopefully be able to consistently develop. We cannot go back. The reward for all our efforts lies in durable high use and structural quality with unbeatable overall profitability, but with reference to the life cycle – just like in sustainable forestry.

The second chance: Future perspectives...

At this point a discussion about the new planning and construction techniques 'wooden prefabrication' would be appropriate. What systematic wooden construction is really capable of achieving for climate change was first shown at the 'Building with wood – ways into the future' exhibition at the architecture museum in Munich in 2011. It aroused an interest which never existed before in modern wooden construction, our GWG project was chosen as the restoration example in the next exhibition. We urgently demand a policy be issued to duly support planners and building owners on the development of this enormous CO2 reduction potential.

The focus is on attaining industrial cost-saving production and in doing efficiently increase building stocks' slowing restoration rate, using the most natural, healthy and environmentally friendly materials and processes as possible. Only through competently optimised planning under equal observation of effective land use, ecological structural engineering, zero-emission building operation as well as first class use and design quality is macroeconomic, affordable and real sustainability achieved. 'Solar construction and restoration' as we know it does not harm anybody, it presents the basis for personal freedom and in doing so embodies true modernism.

Therefore it should be up to us construction masters to change the attitude from the bottom up, to learn something new, to present results and to tell happy customers: it really works! Wooden construction marks the most sensible way of using raw material, whose abundance and innocence will finally pass. Every well-made, energy autonomous and nice looking wooden construction can become a clear sign of change. Let's protect our riches of timber against foreign desires and wrong usage. With wood as a construction material, warmth returns as a life metaphor, haptic trust creates a new confidence that there are solutions for our problem of the century: sustainability. They grow in the forest and demand nothing more than our sensitivity, fantasy and unity. That is why it is important to endlessly discover new things, rediscover and develop further.

I would like to finish the illustrated boardsheet with this: let me quote what occurred to me when I woke up in the night and luckily found a pencil and paper. I will take the liberty of including our partners and building owners: 'We have not dedicated our lives to architecture to later on have to say: we failed on the most important dimen-sion of construction: a universal sustainability. It may appear quite emotional to some people – nevertheless and now more than ever: we will not stop being nonconformist and controversial until we hand over to our children and grandchildren'. That is what we can do - and what you can do with us.

Thank you all the best ! FL1212

Renovation to plus-energy-standard schools – Rainbach im Mühlkreis/Austria

Architekturbüro Böhm
Austria, Linz
office@architekt-
boehm.at

Short Summary

The aim is to renovate the whole school complex to a plus-energy-house-standard.
A functional as well as a technical overall view are necessary due to the closeness of the two main structures, the shared facilities such as gym-hall, multi-functional hall, as well as the gas heating facility and water supply, the boarding for pupils and the shared cleaning staff.
With the construction of a new hall which unites elementary, secondary modern schools and gym-hall all different functions of the complex are interlinked. Moreover, the outer surfaces of the secondary modern school are reduced remarkably, and for the elementary school and the gym-hall this fact means that no separate thermal insulation is necessary at all.
To provide sufficient fresh air, the complex will be equipped with a mechanical ventilation system with heat recovery.
All windows will be provided with centrally controlled moveable sunblinds.
The existing water well will be used for the toilets.
Electric lighting is controlled in the same way as the sunblinds.
For the generation of electric current a 50 kWP photovoltaic plant will be established.
After thermal renovation heating will be effected by means of wooden chips.

Keywords: prefabrication, sustainability, comfort, economic efficiency, fire safety, cost effectiveness, recyclability, precision, integral planning, renewable materials

1. Situation

The market town of Rainbach is situated 720 meters above sea level in the north of the Province of Upper Austria. From the climatic point of view this region is characterized by its relatively high altitude above sea level and the frequency of defogged days.

The market town has about 3100 inhabitants. The structural weakness of the region also marks the financial situation of the market town.

The two schools of the market town Rainbach are situated near the market town center on a separate, adequately dimensioned school ground with sufficient open area. The nearby publicly owned sports ground is also used by the schools. The catchment area for pupils exceeds the community boundaries, a fact which shades cross-community importance on the construction of the schools.

1.1 Description of the status quo

The energy indexes of the three existing structural elements are between 104 and 120 kWh/m² per year.

1.1 Educational concept

Due to changes in the Austrian educational system structural adaptations are necessary. Both, the elementary as well as the secondary modern schools, are run with 8 classes. Changes in the numbers of pupils in different subjects call for bigger class rooms, which are not available in the present building and therefore necessitate amplification. Moreover, concepts like “Neue Mittelschule” or all-day-school and new ways of teaching have their impact on the room use and room size and thus require corresponding structural adaptions.
The concept of renovation unites both schools to one building complex which results in better use of room resources, shared facility and property managements. Similar synergies arise from building equipment and appliances and therefore can be used more effectively.

2. Intention

The renovation of the building in an energetic technical way leads to a sustainable reduction of total energy use without consumption of further building land and without construction of new building surfaces. In Austria 70 % of heating energy is used for buildings which are older than 20 years. These buildings mostly possess good structures and therefore the decision to renovate them instead of demolishing and rebuilding is often taken.

On the one hand renovation has a high potential of energy-technical savings and offers on the other the creation of modern room structures with sustainable materials and elaborate planning. A school is the “work-space” for pupils and teachers, the classrooms constitute the different “workshops”. Effective performance highly depends on factors such as ambient room, the materials, lighting, air quality and educational possibilities. It is the responsibility of the planners to consider all these facts and create best possible conditions for the pupils and their education. It is also the responsibility of the planners to leave buildings which can be maintained by generations to come.

An objective of the municipality is to maintain a renovated, optically attractive building. Furthermore the erection of a building should - on the long term – put only little strain on the municipality budget and also involve regional enterprises in the renovation. The building must be and remain affordable over its life time cycle in relation to the costs of reconstruction, energy, cleaning, disposal, etc.

The ecologic fundamental idea of the municipal council and the planners has been the focus for all steps of planning. The municipality is fully aware that by the implemented measures the school site Rainbach achieves an economic advantage. The financing of the ecological sustainable reconstruction is supported by a state-aided model-renovation program “Musterhaussanierung” and a special grant of the Province of Upper Austria.

3. Measures in insulation

3.1 Secondary Modern School and Gym hall

All the surfaces of the buildings were analyzed and the following measures will be implemented: the exterior walls of the Secondary modern school (will be run as “Neue Mittelschule” from autumn 2013 onwards) and of the gym-hall will be renovated with prefabricated wooden-framed-elements. In building projects with short execution times this is

a perfect method to previously transfer work flow to the production hall. The prefabricated wooden elements guarantee high end quality and can be produced independent from weather conditions.

Assembly time at the building site is reduced to a minimum, which is perfect for projects with short setting times.

The use of unified elements results in cost reduction.

Construction waste on the site is reduced as by the prefabrication adjustment work on the site is mostly omitted.

High costs for scaffold can be avoided.

These wooden framed elements have the advantage of separability of the materials when being disposed.
Windows, sunblinds and wires are already integrated in the prefabricated façade elements.

The application of prefabricated elements also means more intensive advanced planning and requires appropriate coordination of individual planners, optimizing of element sizes and compositions, careful examination of the static bearing capacity.

The choice of the best suitable structural grid depends on the sizes of the applied boards.

The sizes of the wooden frame elements depend on the matter of transport as well as the access routes.

3.2 Uppermost ceiling

Another important topic is the thermal losses through the uppermost ceilings and the flat roofs. The uppermost not accessible ceilings will be insulated with fireproof glass wool.

The new flat roofs with wooden bearing structure will be insulated with special mineral wool that can be walked on. This material constitutes also the fire protection for the wooden constructions.

The outer walls of the cellar will be insulated with XPS boards due to humidity.

3.3 Elementary school

The outer walls of the Elementary school will be insulated with an upgraded insulation with wood fibre insulating boards. This material holds the “natureplus” quality seal. The wooden fibre insulating boards are made from grain in a dry process. As the insulation material consists completely out of wood it can be disposed ecologically and easily at the end of its life circle.

On the uppermost ceiling not flammable glass wool will be applied.

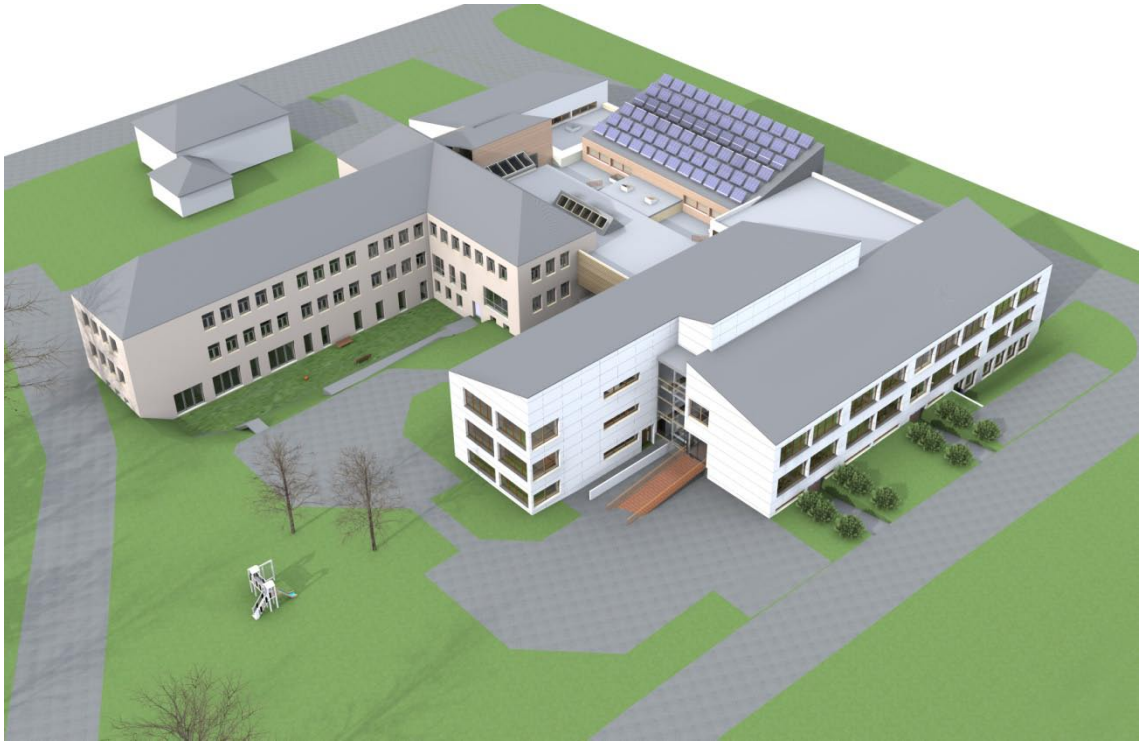
Thermal insulation in the basement will be done by XPS boards.

While in the Secondary modern school only a small part of the cellar floor will be removed and newly rebuilt, all the cellar floor in the after-school-care rooms of the Elementary school will be completely thermally insulated. The window openings will mostly remain the same size, except in those rooms where more daylight is necessary for future use, the windows are enlarged accordingly.

4. Transparent facades

Due to the wooden frame façade elements which are used in this project the windows cannot be preassembled.

The windows correspond to passive house standard and are carried out with triple glazing and wooden-aluminium frames – their thermal transmittance (k value) is 0.8 W/m²K.



4.1 Glass fronts

The bearing construction elements are made from spruce and aluminium profiles, their thermal transmittance (k value) is 0.8 W/m²K.
The thermal transmittance of all triple glazing itself is 0.6 W/m²K

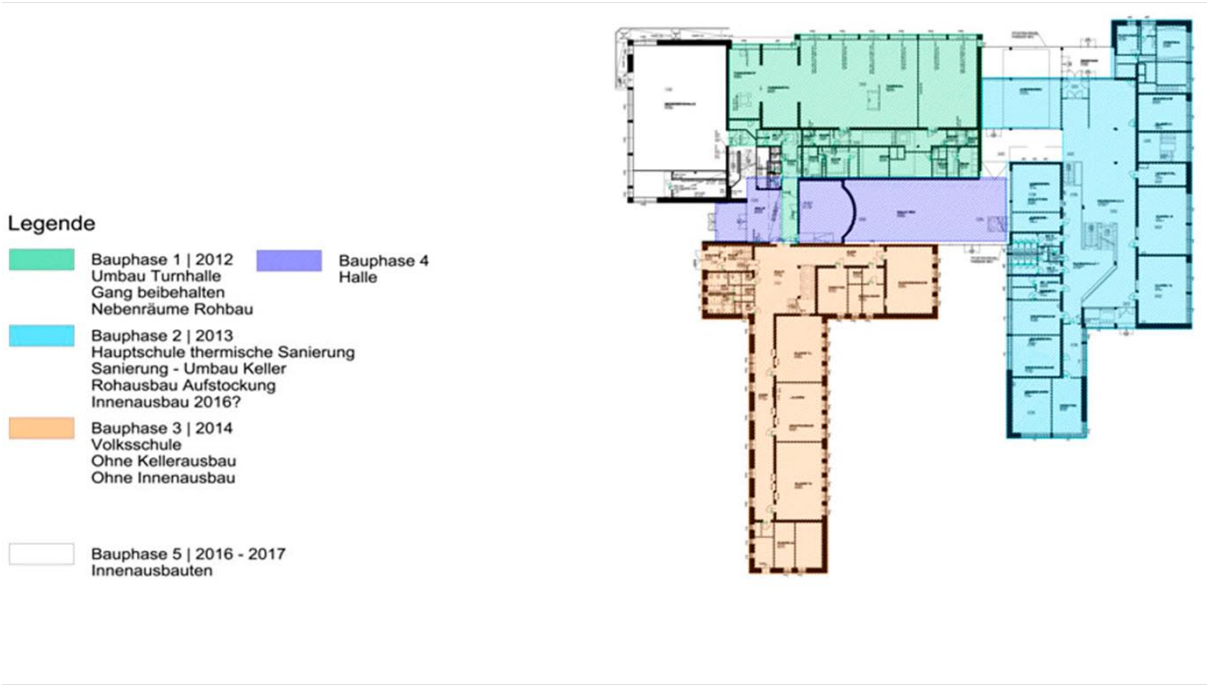
5. Structural measures

The requested new classrooms will be established in a heightening above the present entrance area on the north side. This is the cheapest way to produce extra room as the necessary fundaments and the base plate can be used. Only two exterior framings and a roof construction are required. With this heightening extra room can be provided without creating new outer surfaces. The same comes true for the extension of the school hall on the south side. A new glass façade is built as closing element of an existing recess. In this extra space the new elevator which provides accessibility for handicapped persons and mechanical maintenance is situated.

The new hall between Elementary school, secondary modern school and the gym-hall unites all the functions of the building complex. In this central hall overall tasks such as library, boarding of the pupils, gym-hall and a nearby function-room are interconnected. By this measure the outer surfaces of the Secondary modern school as well as of the elementary school and the gym-hall are reduced and therefore need not be thermally insulated any more. Once more new extra room is created without producing additional outer surfaces.

Due to effective standards for static load assumptions all the roof constructions have to be reinforced by 100 %.

To guarantee accessibility to the Elementary school an elevator near the existing functional room, which will not be renovated, will be established. In this way both, the elementary school and the functional room, will be accessible for handicapped persons.



The entrance of the Elementary school will be resituated to the existing entrance of the functional room. This measure means more space between traffic area and the entrance door and moreover provides a porch roof.

Within this new entrance area accessibility to the four parts – Elementary school, function room, Secondary modern school and gym-hall - can be controlled.

All sanitary rooms of the Elementary school as well as all the plumbing need to undergo a complete renovation.

The interior walls separating the class rooms rest on the basement ceiling. Removing these interior walls would imply high cost for underpinnings. Therefore the class-rooms will remain mostly as they are. Through openings in the wall to the new central hall the natural light quality in the corridor of the ground floor will improve remarkably.

6. Technical measures

6.1 Noise control

All classrooms need an improvement in regard to room acoustics. The most important element to achieve this improvement is the mounting of cost-efficient wooden ceiling-liners especially developed for this project. These liners are made of spruce, mostly untreated, as to preserve the naturalness of the material and its positive influence on the indoor climate. These ceiling-liners are also used for the ceiling of the gym-hall.

6.2 Measures for cooling

To prevent overwarming in summer time with the high insulation standard and the high number of persons in the rooms (especially in May, June and September), cooling with the cool night air will be applied. This aspect becomes even more important in regard to the future all-day school.

As Rainbach is situated at about 720 meters above sealevel there are only few nights with temperatures higher than 20°C which is an obvious plus for night cooling and no extra cooling energy is necessary.

The cool night air will be transported by the ventilation system as cooling by opening the windows manually.

Passive measures: Exterior sunblinds combined with an automatic daylight control also prevent overwarming by sunlight of non-populated rooms.

6.3 Hot water

For producing the hot water the biomass heating is used in winter. The existing hot water storage tanks close to the gym-hall and the new center hall are equipped with 16 m² solarcollectors to produce hot water in an ecological way for the there situated sanitary rooms.

6.4 Sun protection

All windows – except on the north side – will be equipped with centrally controlled moveable sunblinds. These sunblinds can be controlled individually, but foremost they are centrally controlled by light sensors.

6.5 Ventilation

Ventilation appliance: It corresponds to the passive house standard regarding energy consumption, heat recovery and tightness. With one single appliance ventilation of the whole complex with its different occupation times can be effectively done. The big advantage of this single unit results in little lower investment costs but above all in considerably lower costs in operation and maintenance.

The installed appliance not only convinces by the high extent of heat recovery (over 90%) but also by the recovery of humidity to reduce drying of the air remarkably which is important for health in winter.

Diffusion in the room: a low speed inlet system is applied as it allows reduction of the flow of air which results in better air quality and less draught.

6.6 Building physics, ecological concept

The mass of concrete in the ceilings is used as thermal storage for excessive heat. Therefore the ceilings in the halls and corridors remain without claddings and in the class rooms 1/3 of the ceiling surfaces can also be used for this aim.

6.7 Light control

Light control is combined with the control of the sunblinds. Dimming, occupation sensors and daylight control can reduce the consumption of electric energy of up to 70 %. The light control depending on the daylight results in a reduction of 30 – 40 % (about 4400 hours of operation) in electric energy consumption. This means a new energy consumption of 20.000 kWh per year compared to about 60.000 kWh for lighting up to now.
With this lighting and sunblinds control system and the modern LEDs and T16 lamps annual savings of about 40.000 kWh can be achieved by lighting alone.

6.8 Photovoltaic plant

As the roof construction of the gym hall had to be renewed anyway, it was redone with an inclination to the south and furnished with photovoltaic elements with a capacity of 42 kWh peak. Further elements with 8 kWh peak will be situated on the roof of the Elementary school.

Near the entrance of the Secondary modern school an ecological electric charging station for the vehicles of the staff and inhabitants of Rainbach will be installed.

7. Energy pass

7.1 energy indexes

Secondary Modern School:	Existing Building – 103,9 kWh/m²a After Renovation – **11,6 kWh/m²a**
Gym hall and new hall	Existing Building (gym hall) – 119,5 kWh/m²a After Renovation (gym hall + new hall) – **16,3 kWh/m²a**
Elementary school	Existing Building – 110,6 kWh/m²a After Renovation – **7,2 kWh/m²**

E-Office: a prime example for energy efficiency

Summary

The corporate headquarters of Energie Steiermark at Leonhardgürtel in Graz, fully renovated and converted between 2008 and 2010, are now a prime example of an energy-efficient, low-energy office block. These headquarters, which bear the title of "E-Office", replace four previous locations in the greater Graz area.
The building, originally dating from 1961, was fully renovated, expanded to 15,000 square metres of available surface and redesigned by architect Ernst Giselbrecht into an innovative low-energy office block for 620 workers. For anyone interested, a one of a kind, interactive experience exhibition on the ground floor – the "E-Wunderwelt" – offers a fascinating insight into the field of renewable energy. Guided tours can be booked. In total, the investments came to around 36 million euro.

Keywords
energy-efficient office, renewable energy, energy saving

1. History

The corporate development of the company, then known as Steweag, at the end of the 1950s gave rise to the establishment of a central administration office. It was specified that the site of the new administration building should be conveniently located for transport, whilst in an inner-city location. The site at Leonhardgürtel was chosen based on its direct proximity to the sophisticated road network, Ostgürtel, which was still being developed, as well as other development potential. However, as we now know, this road network was never expanded, which would have been a mistake given the routing of roads through high-quality housing developments.
The entire block area between Elisabethstraße and Leonhardstraße and/or Leonhardgürtel and Merangasse was untouched, excluding the construction of late 19th century-style buildings on the block perimeter around Elisabethstraße and Merangasse. Between 1958 and 1961, the Steweag administration building was constructed as a single 10-storey edifice, which was accessible from Leonhardgürtel. The three residential buildings at Merangasse and the associated garage building at Kroisbach were built considerably later, only at the beginning of the 1970s.

1.1 Description of the old administrative building

The building was a well-proportioned 10-storey structure with ground dimensions of approx. 40 x 20 m and had a clear façade design with continuous mosaic banding in three grey tones and flush-mounted aluminium framed windows. This was by all means a high-quality design, which was extremely modern for that time. The structure was built as a reinforced-concrete skeleton construction; the parapet recesses were manufactured with 12 cm masonry and 5 cm thick internal insulation using wood wool insulation board. The reinforced-concrete columns were also internally insulated using 2 cm thick expanded polystyrene sheets.

Significant deficiencies soon highlighted design and technical issues in the installation of flush-mounted aluminium framed windows on the façade. Furthermore, insufficient thermal insulation resulted in damage to the interior plaster of the parapet and the timber cladding on the columns and lintels. The non-insulated aluminium window design led to significant condensation. As the building was equipped with a 2-cycle air conditioning system, this problem could only be brought under control by dehumidifying the incoming air. It was only possible to lower the temperature over holidays and weekends by raising the dehumidification of the incoming air. If the interaction between the temperature inside and outside was not managed properly, the amount of condensation was so dramatic that employees suspected leaks on the flat roof.

The building was constructed before the first Styrian building regulations, the Styrian Building Code 1968, came into force. Otherwise there were no regulations whatsoever for high-rise buildings in Styria.
This may also have been the reason for the insufficient fire protection in the building. Given the lack of fire sections and fire extinguishers, plus a deficient escape route situation, any fire would have had catastrophic consequences. Attempts were made to reduce potential danger by replacing the cellar and stairwell doors, installing rescue hoses, replacing the goods lift with a fire brigade rescue lift, installing escape route illumination and organisational measures.

The mosaic façade itself had already been renovated several times to repair the many small damaged areas.

The building was fitted with an internal sun protection system, which given the large number of windows and the size of the windows, made a considerable contribution to heating the building.

Fig. 1: Façade from 1961

Fig. 2: Building before renovation

2. New administration office of Energie Steiermark

Competition on the electricity market due to liberalisation demands the use of synergies. After the merging of the companies, the fundamental need for a joint administration office for Energie Steiermark was clear. Following the merger of Steweag and Steg, five possible sites in the region of Graz were suggested. These were the Steg sites at Ankerstraße, Triesterstraße and St. Peter; the Steweag sites at Leonhardgürtel and Neuholdaugasse and the Steirische Gas-Wärme site at Gaslaternenweg.

After a decision process, which considered 6 sites in the region of Graz, the site Leonhardgürtel 10 was selected. All sites were compared economically whereby investment costs throughout the entire life cycle of a site, including operational and management costs, were evaluated. A duration of 40 years was set for the evaluation period, with a residual value for the properties.
After the purchase of the new administration office, only the Leonhardgürtel and Neuholdaugasse sites were required, and the other sites were sold. This considerably reduced infrastructure costs and cut the trip times of employees.

After determining the office space requirement for a total of 620 employees, it was clear that an extension in addition to the general renovation of the existing building was necessary. Another requirement was the creation of 250 underground parking spaces.

2.1 Architects competition and idea

Once the planning parameters had been determined, an architectural competition was held based on a feasibility study. The winning project was designed by architect DI. Ernst Giselbrecht.

Giselbrecht placed the necessary extension on the southern side of the existing building. This closes the gap between it and the 2-storey control room building. The extension enlarges the existing building by 50% (ground area of the old building approx. 40 x 20 m, extension ca. 20 x 20 m).

The winning project makes excellent use of the plot as an extension of the existing property and creates an unmistakeable landmark on the Graz cityscape. The entire western part of the plot accommodates the underground garage, however the area above ground could be developed into parkland.

The façade design includes a sun protection system with folding shutters, so the façade can take on a different appearance every day, regulated by the user. The folding shutter shades the window, whilst not obstructing the view outside. The skylights were fitted with LED strips, which enable a colour display of the façade. The interior of the building is based on a colour concept: each floor has a distinctive floor colour, which helps to identify which employees “belong” to which floor. The office space configuration includes individual offices and group office solutions.

3. The new E-Office

In the future, renovation will take up a much larger portion of the construction work. There are various reasons for this. Building conditions have often changed, meaning that similar developments would no longer be approved. The quality of the site is often crucial, often complete demolition and reconstruction is difficult on inner-city sites.

Various ideas for utilising the property were considered for Energie Steiermark's main office building. The decision in favour of the Leonhardgürtel site in the site concept meant building an extension in addition to renovating the existing building.
This includes completely gutting out the building, keeping only the load-bearing reinforced concrete skeleton.

The decisive factor for the general renovation was the absolutely terrible energy performance of the building and the technical ageing of its technical facilities.

The new building shell for the existing building and the extension were developed using the latest knowledge in façade technology.
In addition to an optimal thermal insulation value, particular attention was paid to new technology in the form of a folding shutter made of perforated aluminium that shaded the windows when folded back, thus preventing heat transfer in the summer and minimising the energy requirement for air-conditioning in particular.

One special feature is a specially shaped skylight strip that deflects light. Daylight that comes in through the skylight is reflected onto the ceiling via the window ledge that is fitted with a reflective sheet, and then deflected down into the office.
This, combined with the external sun protection system that both deflects heat in the summer and works as a heat buffer in the winter, creates optimal conditions for the indoor climate. Thus the new offices are bright and the entrance halls are also flooded with natural light thanks to glass walls in the corridor.

On the 10th floor the existing core zone was expanded, creating a conference and seminar area from which you can enjoy a fantastic view across all of Graz.

The façade surfaces in the southern and western area are partially equipped with photovoltaic elements, as is the canopy of the entrance and the flat roof above the 10th floor.

A split-level, underground garage for 250 parking spaces was established in the western part of the plot. This garage stretches directly from the existing buildings up to the western boundary. This has resulted in a difficult construction, including underpinning the existing building and securing the multi-storey buildings on the adjacent site.
A park was created above the underground car park. The paths were laid in "lightning bolt" shapes as a reference to electrical energy. The theme is "park instead of parking", since this area used to house a car park.

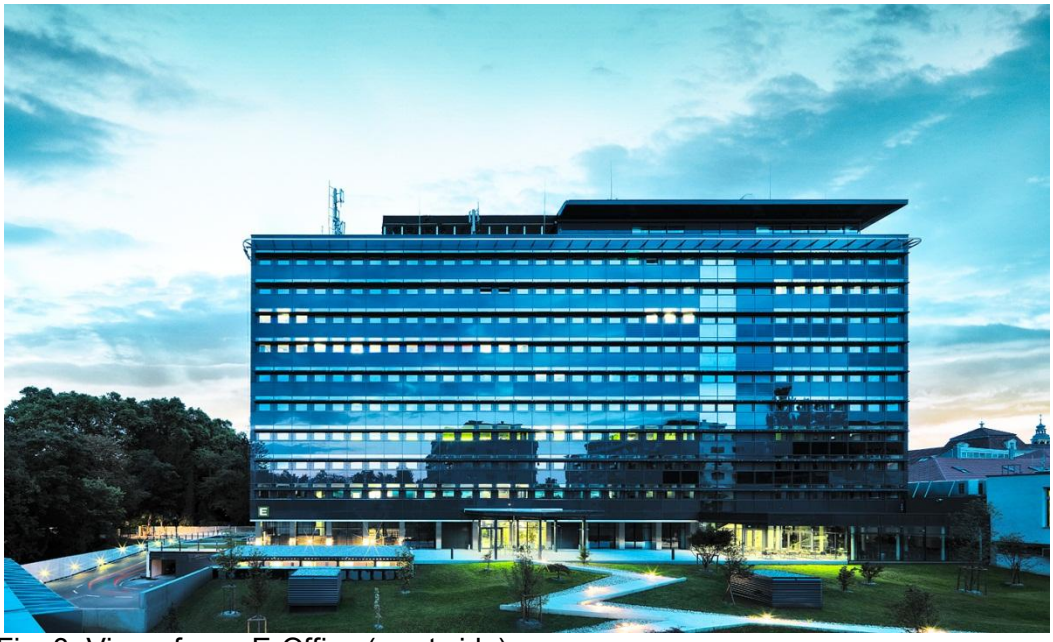

Fig. 3: View of new E-Office (west side)

Fig. 4: View of new E-Office (Elisabethstraße entrance)

3.1 Alternative energies & technical features

- Photovoltaic system with a surface of 550 m², installed on the façade, on the flat roof above the 10th floor and on the canopy of the entrance, which generates a yield of approx. 71,000 kWh/year.

- Heat pump system using geothermal energy as the energy source for supporting the heating and air-conditioning system, operated through deep holes with a total length of 1200 m. The annual yield is approx. 80,000 kWh.

- Use of rainwater for WCs, resulting in an annual saving of approx. 2,240,000 litres of drinking water.

- Solar energy plant for generating warm water for the canteen area and the showers in the workout room.

- Glass and aluminium façade with an insulation thickness of 18 cm using mineral wool. According to the energy certificate calculations of the firm Rosenfelder & Höfler, this generates a heating requirement of 22.8 kWh/m²a. With this value, the E-Office corresponds to Building Class A and can be referred to as a “low-energy construction”.

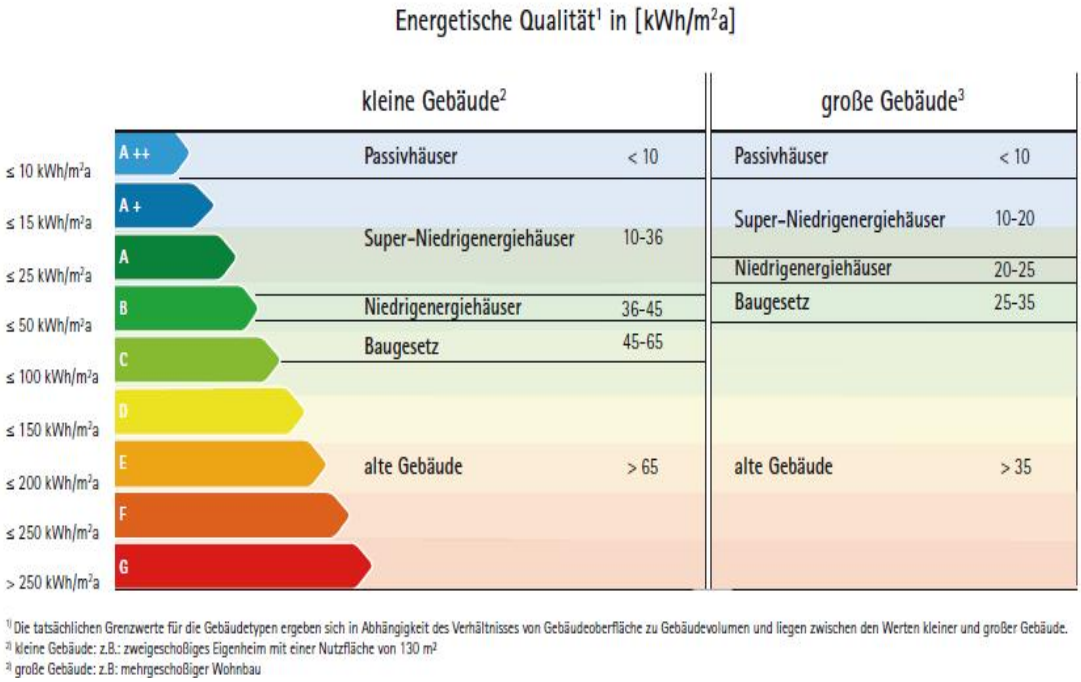

Fig. 5: Energy performance

- Shading system without darkening rooms, the folding shutter system prevents the sun’s rays striking the glass surface of the window. This considerably reduces the amount of heat transferred into the building in the summer, as the need for air conditioning is considerable higher than the need for heating in an office building with high internal heat sources generated by people, equipment (PCs, monitors, etc.).

- The entire heating usage in the new E-Office is 52% lower than in the old building, even though the gross surface area has increased by 50%.

- The total volume of electricity purchased for the new E-Office is 47% lower than for the old building, even though the gross surface area has increased by approx. 50%.

- Off-air management via heat recovery.

- Installation of window contacts that shut down the room technology (heating/air-conditioning) if a window in the corresponding room is open. With the option of being able to open the windows, it’s possible to ventilate the room with outside air. However, the contacts should prevent windows staying open for a long time.

- Office lighting using self-regulating standard lamps. These lights adjust the required light intensity according to the time of day by automatically switching on and off. The savings compared with conventional lighting with an on/off switch are approximately 40%.

- Light deflection through the skylight strip using reflective high-performance film on the skylight window ledge. Daylight is deflected down into the office by reflecting the sunlight onto the ceiling.

Fig. 6: Façade consisting of skylight strip, folding shutters (closed) and parapet glazing

- Elaborate, state-of-the-art fire protection system installed for the first time in Styria as part of the construction of a high-rise building. In addition to a complete sprinkler system, full protection through fire detection, fire dampers, a fire alarm system and fire compartmentalisation, also pressure ventilation systems, extraction systems and electromechanical window opening for evacuating the building and fire fighting were installed by the fire brigade.

- *E-Wunderwelt* on the ground floor is used to illustrate the energy source, alternative power generation and conduction, and demonstrates energy savings. *E-Wunderwelt* is designed for visits by lower secondary school pupils.

Key performance indicators:

- Investment costs totalling €35.1 million, €4.5 million of which for underground garage
- Total net floor space (without underground garage) 15,480 m²
- Investment costs totalling 2,050 €/m² net floor space (incl. costs for alternative energy, *E-Wunderwelt* and demolition of the old administrative building, planning, project management and additional costs (e.g. connection fees for sewage, etc.)

4. Conclusion

The E-Office is a showpiece in the area of energy efficiency, as a total of 550 square metres of solar panels were incorporated into the facade and roof of the building, providing energy for more than 30 households. Furthermore, 12 geothermal energy systems and a solar plant ensure the international low-energy standard is observed. More than 1.8 million litres of precious drinking water can be saved each year through the intelligent use of rain water. Interior motion sensors and the use of LED technology ensure a saving of up to 90 percent in comparison to traditional light systems.

Summary

Building assessment systems can serve as powerful agents of change in efforts to reduce the environmental impact caused by the building sector.

Building assessment systems provide building performance information such as energy consumption, materials used, and operational costs. Assessment systems define various levels of performance within the marketplace, above and beyond the minimum defined by codes and standards. As a consequence, building assessment results can be utilised as a marketing instrument, thus increasing the demand for cost-efficient, user-friendly, and environmentally sound buildings. At the same time, they produce a substantial reduction in environmental impact.
In Austria, the TQB building assessment scheme has been in place since 2001.

This conference contribution describes the development of the TQB assessment scheme, and the successful refurbishment of the lead project “e80^3-Buildings” of the research program “house of tomorrow – plus” will be shown in detail, presenting the development of high-performance retrofitting concepts, focusing on plus-energy buildings with the prefabricated façade elements, built-in building services and net integration.

High-performance refurbishments can only be achieved through an integrated design that includes advanced energy concepts. Specifically, this will require a high-quality thermal refurbishment of the building envelope with simultaneous integration of energy-producing active elements (solar thermal collectors and photovoltaic elements), as well as network integration for electricity and heat.

Keywords: sustainable buildings, building certification, energy efficiency, renewable energy, sustainable development, green building assessment scheme

1. Introduction

Energy consumption in the building sector accounts for more than one-third of energy consumption in Austria. Residential buildings represent the majority of the Austrian building stock: according to statistical analysis carried out by Statistics Austria, in 2001 there were 2.05 million buildings and approximately 3.86 million dwellings. Three quarters of all Austrian buildings are single-family houses and detached houses, and 14% are non-residential buildings. Concerning the number of flats, the distribution is more or less equal between single-family houses and detached houses, and apartment buildings. 21% of residential buildings were constructed before 1919, and 47% were constructed in the period between 1945 and 1981. [1,2,3] The latter portion is most important

in terms of constructed buildings as well as in terms of energy consumption and thus also energy saving potential.

While energy use for space heating and energy use for domestic hot water is predominant in residential buildings, energy consumption patterns are more diverse in non-residential buildings, depending on the purpose of the building: hospitals, shops, offices, schools, etc., and there is little statistical information. However, it is evident, that electricity consumption is increasing dramatically, mainly due to cooling needs. Studies carried out to analyse the impact of climate change on Austrian regions show that the number of days with temperatures above 30°C will increase fourfold in the East of Austria. [4] As a consequence, electricity consumption is likely to skyrocket if no precautionary measures are taken.

In order to reduce heating and cooling energy consumption in the building sector, and to optimise buildings as a whole in terms of sustainability, several policy instruments have been applied in Austria. The social housing scheme is one of these.

The social housing scheme has a long tradition, and has been a driver for sustainable buildings in the residential sector. Criteria have been established so that the majority of Austrians is eligible to apply. For many years, the social housing scheme has been extended towards including energy efficiency criteria, addressing renewable energy systems, and subsequently also to criteria targeting ecological materials. The social housing subsidy scheme provides additional money upon condition that energy and other ecological criteria are met. Heating energy consumption has been decreasing due to defined heating energy indicators required by subsidy schemes, and since 2009 also by the revised building codes, as required by the Energy Performance of Buildings Directive (EPBD).

Green building assessment schemes offer the opportunity to substantially facilitate the transition towards a sustainable building sector by setting up performance requirements regarding energy, materials, water, land, indoor air quality, emissions, and many others. Green building assessment schemes address residential buildings outside the social subsidy scheme, and - even more importantly – also address the non-residential sector. The application is voluntary and requirements are more ambitious than those of the building code and social housing scheme. Therefore, building assessment systems can serve as powerful agents of change in efforts to reduce the environmental impact caused by the building sector.

2. Total Quality Building – development of TQB assessment scheme

In 1997, Austria joined the Green Building Challenge, an international platform for the development of green assessment schemes for buildings (successor organisation IISBE - International Initiative for a Sustainable Built Environment). At that time, the BRE Environmental Assessment Method (BREEAM, developed in UK) was in place and experiences delivered valuable input for establishing an international platform for green building assessment. However, in terms of practical implementation it soon became evident that data generation, collection, and examination had to be adjusted to the Austrian planning and construction practice, in order to avoid high transaction costs. In Austria, small and medium-sized companies are predominant, and it was the objective to provide a cost-efficient tool for widespread application. In 2001 the Total Quality (TQ) assessment scheme was developed, and after a testing phase went into full operation in 2003. [5,6]

In 2009 the system was revised based on lessons learnt and renamed as Total Quality Building (TQB) assessment scheme.

Since 2009, the ÖGNB – Austrian Sustainable Building Council – has run the TQB assessment scheme and the third party certification. ÖGNB also provides a platform for further developing the

criteria framework and a platform for creating innovations that may be necessitated by the performance requirements in the construction sector and associated industries.

Development of the TQ assessment scheme was based on a survey conducted among developers, which clearly pointed out that performance criteria limited to energy efficiency measures, renewable energy technologies, and ecological materials would lack acceptance. However, developers were willing to apply a comprehensive building assessment scheme, which would include aspects such as noise protection, indoor air quality, flexibility, and others besides environment-related criteria. Furthermore, the assessment scheme should be useful as a quality control tool as well as a marketing instrument.

The TQB assessment scheme was therefore developed as a comprehensive set of criteria to be applied at the very beginning of a project to adjust design targets and to achieve a good assessment result.

In order for buildings to pass the TQB assessment, checks are made twice, first at the end of the planning stage and then after completion of construction. The objective is to ensure that the building was constructed in compliance with the design, which will be especially important if the building is designed in an integrated way. In this case, architectural aspects and energy technology aspects are intertwined and small changes during construction to reduce costs may result in substantial problems concerning comfort and energy performance during building operation. After the planning phase, drawings and calculations are checked, and after completion, compliance with the design is examined and measurements are carried out.

The next figure shows the concept of the Austrian building assessment scheme.

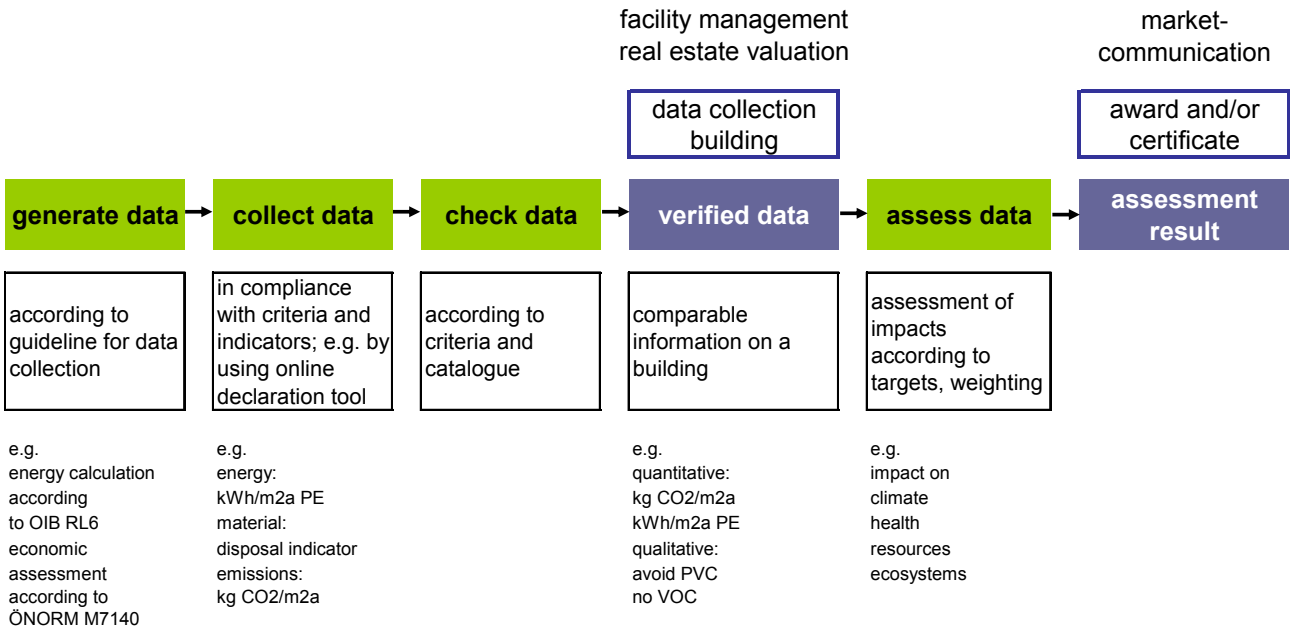

Fig. 1 The concept of the Austrian TQB green building assessment scheme

Since 2010, the TQB assessment is based on an internet tool, which is free of charge and publicly accessible at www.oegnb.net. The tool consists of an assessment framework with a detailed description of assessment criteria, a description of data that have to be provided and a guideline how to achieve the best score. The tool is free because it is the objective to encourage architects, designers and building owners to use assessment criteria for design optimisation and quality control during the design and construction process. Only if the building owner demands a third

party certification will costs arise for the certification procedure.

The TQB system does not assess architectural quality, but technical parameters that have to be taken into account during the process of designing the building. At the beginning of the design process, the design team and the client define the design targets for the building by means of criteria for the assessment framework and the scores they want to achieve; after assessment, a group of independent experts certifies that all the information used for assessment is correct.

The next table shows the latest version of the assessment criteria for residential buildings.

Table 1 TQB-Assessment categories and criteria (overview residential buildings, category and first level criteria, version 2.2, december 2010)

	Category and criteria (German original)	**English translation**
A	**Standort und Ausstattung**	**Location and amenities**
A.1	Infrastruktur	Infrastructure
A.2	Standortsicherheit und Baulandqualität	Security
A.3	Ausstattungsqualität	Amenities
A.4	Barrierefreiheit	Accessibility
B	**Wirtschaftlich und technische Qualität**	**Economical and technical quality**
B.1	Wirtschaftlichkeit im Lebenszyklus	Life cycle cost assessment
B.2	Baustellenabwicklung	Construction site management
B.3	Flexibilität und Dauerhaftigkeit	Flexibility and longevity
B.4	Brandschutz	Fire prevention
C	**Energie und Versorgung**	**Energy and water**
C.1	Energiebedarf	Energy consumption
C.2	Energieaufbringung	Energy production
C.3	Wasserbedarf und Wasserqualität	Water consumption and water quality
D	**Gesundheit und Komfort**	**Health and comfort**
D.1	Thermischer Komfort	Thermal comfort
D.2	Raumluftqualität	Indoor air quality
D.3	Schallschutz	Noise protection
D.4	Tageslicht und Besonnung	Daylight and sun
E	**Ressourceneffizienz**	**Resource efficiency**
E.1	Vermeidung kritischer Stoffe	Avoidance of harmful substances
E.2	Regionalität, Recyclinganteil, zertifizierte Produkte	Quality of products (local production, recycling material, certified products)
E.3	Ökoeffizienz des Gesamtgebäudes	Eco-efficiency of the entire building
E.4	Entsorgung	Demolition and disposal

Although the assessment scheme was developed according to developers' needs, market up-take was quite slow, and assessment results were not generally used in marketing communications. It turned out that estate agents did not know how to use the assessment result in the selling or renting process, largely because they were not trained in aspects such as indoor air quality, primary energy consumption of materials or CO_2-emissions. It seemed as if the barrier for the construction sector was too high, with exception of a few innovators. Therefore, green building assessment was integrated in the climate protection programme "klima:aktiv", launched by the Austrian Federal Ministry of Agriculture, Forestry, Environment and Water Management in 2004. The programme targets a substantial reduction of CO_2-emissions and a substantial increase in energy efficiency in the

building and transport sector, in industry, and households, by funding comprehensive activities such as the production of information material, consulting services, network development, and the elaboration of quality control procedures. [7]

The sub-programme “construction and refurbishment” offers the klima:aktiv building standard for residential and non-residential buildings, and for new build constructions as well as for refurbishments. This standard consists of selected criteria of the TQB standard with focus on outdoor and indoor environment, to communicate individual benefits along with the reduction of CO_2-emissions.

The criteria system comprises the following categories:
- A Design and Construction
- B Energy and Supply
- C Materials and Structure
- D Comfort and Indoor Air Quality

3. To lower the barrier with a step-wise system: energy certificate - klima:aktiv - TQB

Since the full implementation of the EU Directive 2002/91/EC (EPBD) in 2009, a step-wise system has been in place. The combined model was chosen to lower barriers for companies to become familiar with environmentally conscious design and construction. It was the objective to make use of the dynamism stemming from the EPBD, and to facilitate market penetration of eco-buildings by linking the voluntary building assessment schemes with the mandatory energy certificate. [8,9] Therefore, the klima:aktiv category “B Energy and Supply” fully corresponds with the energy certificate. On the way towards a sustainable building, the first step is a good energy performance documented by the mandatory energy certificate. If the developer or building owner seeks good performance beyond the energy sphere, the klima:aktiv criteria “A Design and Construction”, “C Materials and Structure”, and “D Comfort and Indoor Air Quality” can be fulfilled, and after a plausibility check the klima:aktiv label will be awarded. If the building owner or developer is ready to document that the building achieves high quality also in terms of noise protection, flexibility, and other criteria, then there exists the option to build upon the klima:aktiv data and to extend the data collection in order to receive the TQB certificate. As a condition, the building must pass a detailed check of data carried out by authorised staff.

klima:aktiv was developed based on a study commissioned by the Austrian Federal Ministry of Agriculture, Forestry, Environment and Water Management, and TQB was developed based on studies commissioned by the same ministry, the Austrian Federal Ministry for Transport, Innovation and Technology, and the Austrian Federal Ministry of Economy, Family and Youth.

Since 2009, the ÖGNB - Austrian Council for Sustainable Construction has been involved in both building assessment schemes. [10]

4. The role of research and demonstration

The Austrian research programme “Building of Tomorrow” is an integrated research program, which supports the process of change towards sustainability by funding research projects, prototype development, and demonstration building projects. Since 1999, numerous projects have been funded, among others the development of the TQB building assessment scheme. The building assessment scheme has served as a guideline on performance criteria and how to achieve them, and as a tool to make the building quality visible in the form of a building certificate.

Sustainability requirements resulted in development of new products and technologies, such as: [11]

- Thermal flat collectors to be used as 'facade collectors', which can be installed without any back ventilation onto facades. The new component represents a high architectural quality and style element for facades, and can be recycled after the lifetime has ended.
- Photovoltaic modules for building integration. PV-modules provide energy and at the same time take over additional functions such as building covering or shading. They can be manufactured on demand in various sizes, and due to their “break-through security” the modules are applicable for facades as well as overhead glazings.
- Single-stage adsorption chiller working with water as cooling agent and silica gel as adsorbent agent for a low range of performance (2 to 50 kW refrigerating capacity), and based on energy supply with hot water, provided by solar panels or district heating.
- Product development for the inside thermal insulation for houses designated as having special historic status, with restrictions concerning the insulation of outer walls.

Demonstration buildings were constructed using new concepts, products and technologies developed in the research programme. All demo-projects have been assessed and evaluated with the TQB-tool and are easy to be found with the “Buildings of Tomorrow” roadmap, which is available on the programme website. [12] TQB assessment results are available at www.oegnb.net.

In Austria, many of the buildings built between 1950 and 1980 are now being retrofitted or refurbished. If these refurbishments achieve a high level of energy performance, or even reach a plus-energy standard, they would represent a major step towards achievement of the European 2020 targets.

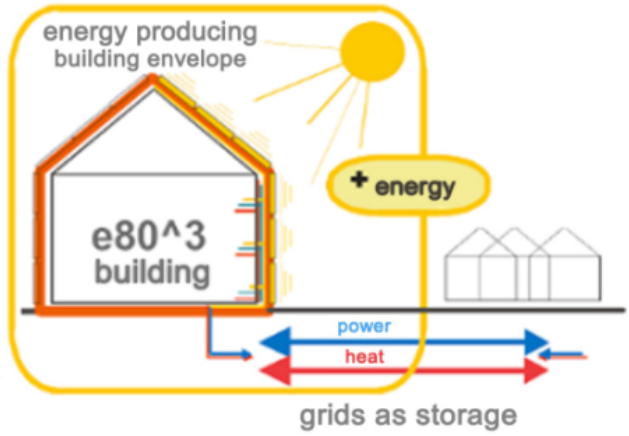

Fig. 1: Heat and electric power network

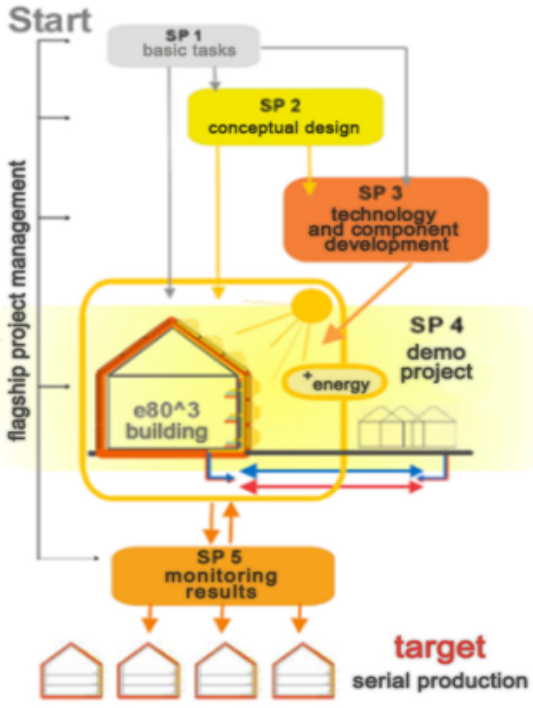

Fig. 2: Project stages

The concept contributes significantly to the achievements of three EC-objectives:

80% energy efficiency – reduction of energy demand
80% ratio of renewable energy sources of the total energy consumption
80% reduction of CO2 emissions

A change from buildings that consume energy to plus-energy buildings requires building functions and systems to be completely redesigned. High-performance refurbishments can only be achieved through an integrated design that includes advanced energy concepts. Specifically, this will require a high-quality thermal refurbishment of the building envelope with simultaneous integration of energy-producing active elements (solar thermal collectors and photovoltaic elements), as well as network integration for electricity and heat.

4.1 e80^3-Buildings - project

In the paper the successful refurbishment of the lead project “e80^3-Buildings” [13] - *reconstruction concepts towards energy plus house standard with prefabricated active roof and facade elements, integrated home automation and network integration* - of the research program “house of tomorrow – plus” will be described in detail. This project is realized as a case study – demonstration project – in Kapfenberg (Styria/Austria) by the property developer „Gem. Wohn- u. Siedlungsgenossenschaft ennstal“ in the years 2010 to 2013.

The aim of the project is to promote the high-efficient retrofit of existing buildings and estates built between 1950 and 1980 in urban areas. The retrofit concept is based on energy efficient measures, on a high ratio of renewable energy sources and on an intelligent integration of energy supply in heat and electric power networks (see *Fig. 1*). The project is divided into several subprojects, seen in *Fig. 2*.

5. Conceptual design

Within the first sub-project [14] a criteria catalogue was developed to select buildings with the highest energy potential within a building portfolio.

The decision whether to renovate or demolish a building is supported by assessment criteria grouped into four categories, applicable to all major building types.

- quality of the location and the building
- renovation potential
- potential towards a plus-energy standard
- potential for application of prefabricated modules

5.1 Conception of the thermal envelope

Through the regular facade structures, especially of buildings from the 60s and 70s, the project team decided on the development of a vertical facade module. Thus, large-format facade elements over the entire height of the building can be mounted between HVAC modules and other equipment. In the development process the transportation and installation on site plays a significant role. To allow an economic assembly, this must be possible without intermediate storage of the facade module by the use of one mobile crane. Another requirement for the facade module are the available sizes of components, such as windows and facade panels. An overview of the prototype can be seen in *Fig. 3*.

Fig. 3: The actual facade module

The thickness of the facade module (see *Fig. 4*) is defined by the functional and technical requirements, such as maximum heat transfer coefficient (U-value), static requirements and possibility to be compatible with existing tolerances of the existing buildings. Where as in the project the existing unevenness of the façade made it necessary to add an additional internal thermal insulation layer of about 4cm to compensate the tolerances.

To fulfill the requirements concerning moisture proofing, noise and fire protection as well as air tightness, special building materials such as oriented strand board (OSB) or mineral wool are used. To fulfill the moisture requirement vapor- and air-tight connection within the facade module for the windows as well as the connection between the modules are of particular importance.

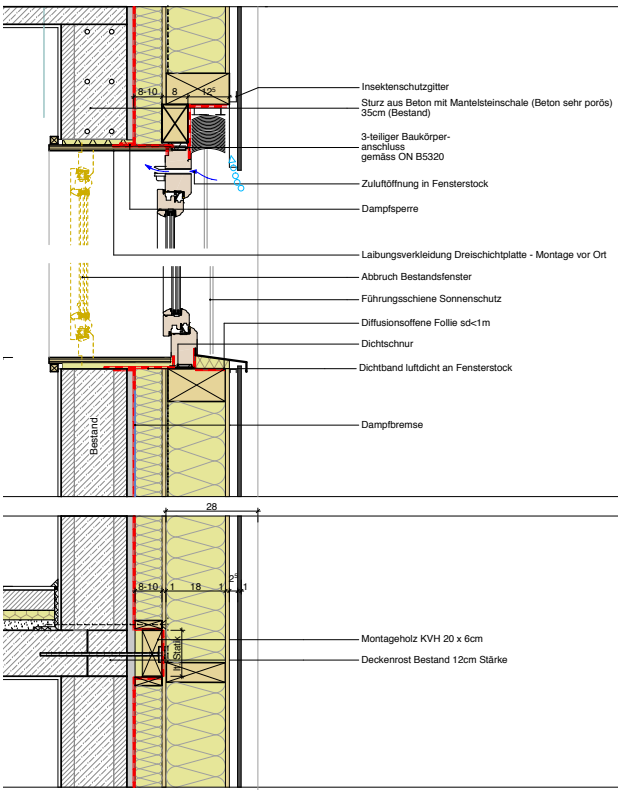

Fig. 4: Overview of the prototype (Nussmüller Architekten GmbH)

Another requirement for the facade module is the integration of active (energy producing) elements, such as photovoltaic, solar thermal panels or solar honeycomb elements. In *Fig. 5* a cross section of the integration of a solar thermal panel is shown.

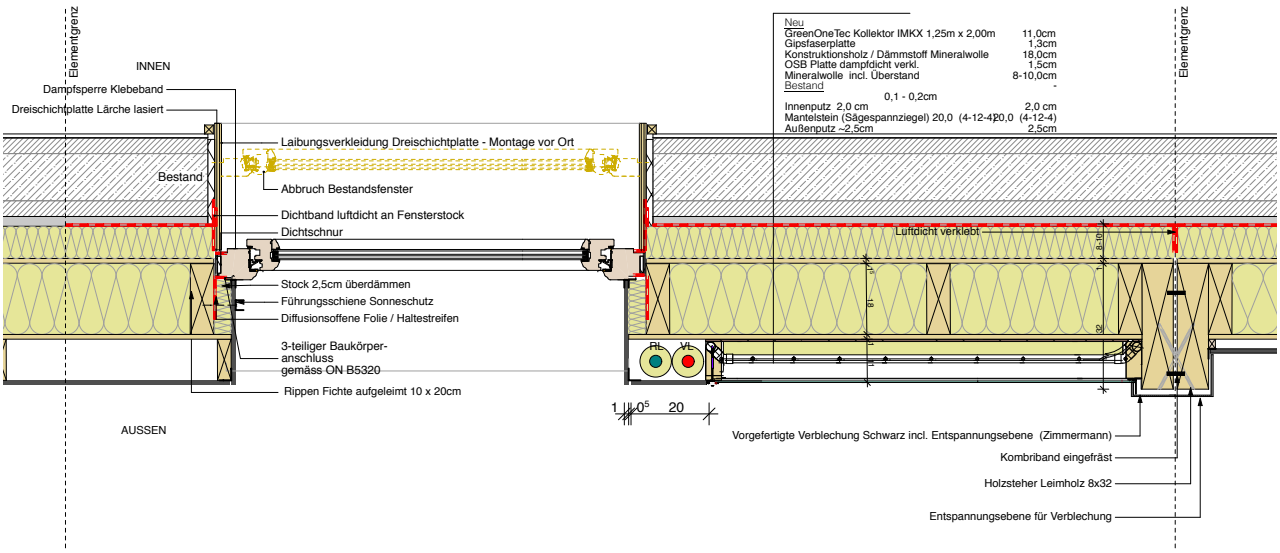

Fig. 5: Cross section of the facade module with integrated collector (Nussmüller Architekten GmbH)

5.2 HVAC modules

To achieve the goal of a plus-energy standard an innovative energy and building services concept needed to be developed. This means the design of technical building systems - HVAC (heating, ventilation and sanitary supply) and its integration into the façade (see *Fig. 6*, *Fig. 7*, *Fig. 8*).

In the project a façade integrated service module was designed to allow vertical and horizontal connections. The installation of the module and the technical building systems respectively has been integrated into the façade, which allows an easy way of inspection and fast replacement/adaptation of pipes and media.

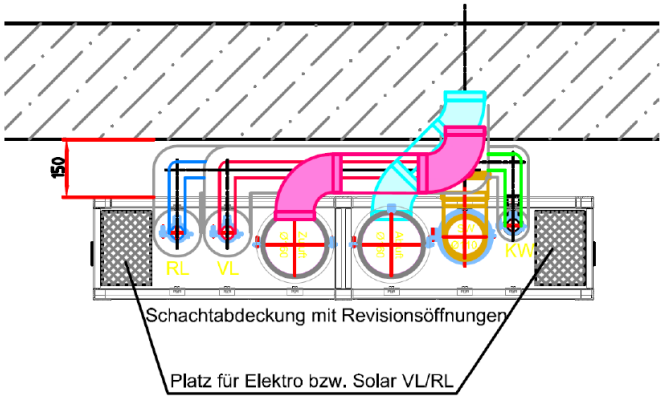

Fig. 6: Short description of building service modules (TB Hammer GmbH and Huter-Geberit)

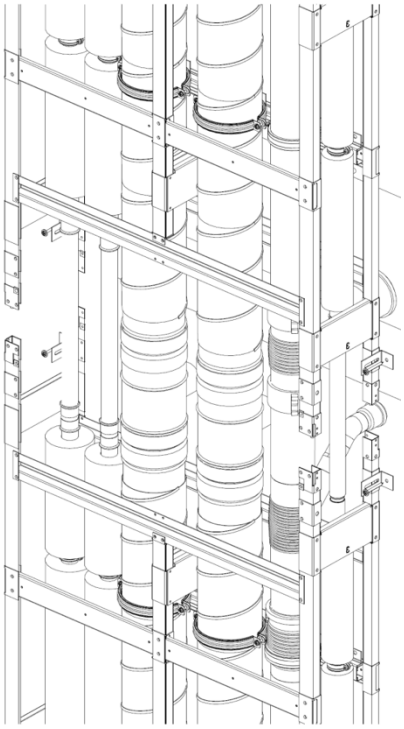

Fig. 7: Building service module (TB Hammer GmbH and Huter-Geberit)

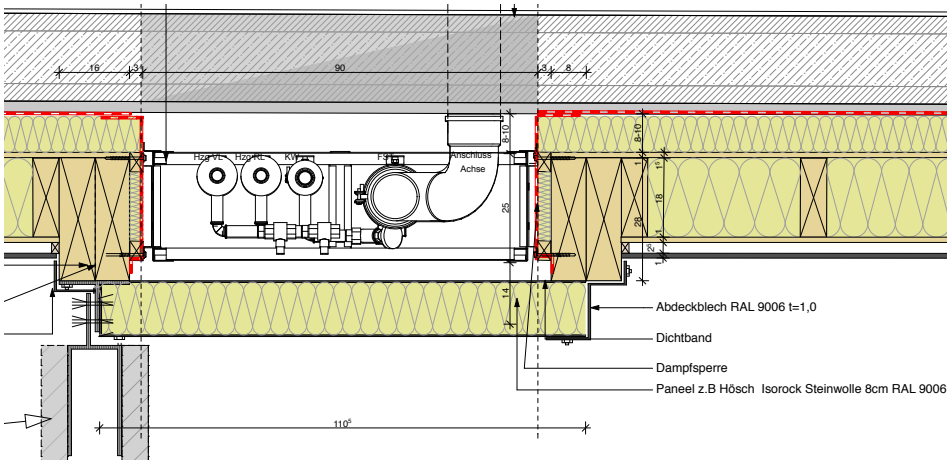

Fig. 8: Finished part of the building service module (Nussmüller Architekten GmbH)

6. Case study

The case study is located in the northern part of Styria, a City called Kapfenberg. The building owner is Gem. Wohn- u. Siedlungsgenossenschaft Ennstal reg. Gen.m.b.H. Liezen. The project consists of 32 residential units with a total gross floor area of 2.800 m^2 and total construction costs of approximately 3,5 Mio €. The case study is part of the research program “house of tomorrow – plus” as a so-called lead project e80^3-Buildings [13].

6.1 Architectural concept

One of the main issues of the architectural concept is to publicly display the installed innovative building elements in the facade and on the roof. With the integration of active elements like PV-modules and solar thermal collectors as well as passive components the transition towards energy generation of building becomes a visible element of the energy concept for the public (see *Fig. 9*).

Fig. 9: Rendering of the refurbished building (Nussmüller Architekten ZT GmbH)

6.2 Energy concept

The starting position for the refurbishment was a detailed site inspection and a calculation of the energy demand of the existing building. The heating energy demand was 101 kWh/m2*a. The main objective was to reduce this to approximately 15 kWh/m2*a.

To reach a plus-energy building the following key elements were integrated into the energy concept:

- high quality thermal refurbishment (opaque and transparent facade)
- controlled ventilation with heat recovery technology
- reduction of electric energy demand in households (e.g. smart meters and energy efficient equipment and lighting)
- use of solar (thermal) collectors for heating and hot water
- use of photovoltaic collectors ?

Main parameters (U-values) of the building envelope before and after the refurbishment are shown in *Table 1*.

Table 1: U-value comparison of existing building and restored building

Component	U-value of existing building in W/m^{2}K	U-value of refurbished building in W/m^{2}K
External wall	0,87	0,12
Window	2,50	1,00
Top floor ceiling	0,74	0,10
Basement floor ceiling	0,39	0,30

The energy concept of the refurbished building is pictured in *Fig. 10*.

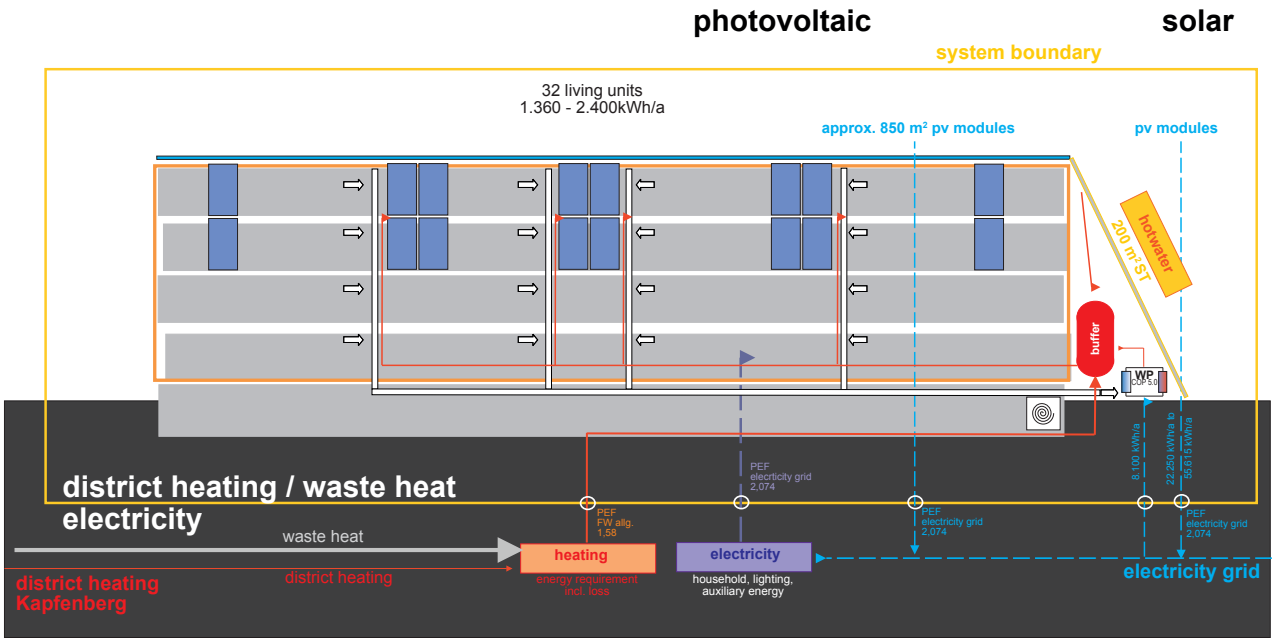

Fig. 10: Energy concept of the refurbished building (AEE INTEC, TU Graz)

6.3 Implementation on site

The various steps of the installation of the modules are pictured in Fig. 11 to 14.

Fig. 11: Manipulation on site with finished module (TU Graz)

Fig. 12: Fixing finished module (TU Graz)

Fig. 14: New finished building service module (TU Graz)

Fig. 13: Integrated PV-modules in facade (TU Graz)

7. Results of the sustainability performance

7.1 Building sustainability assessment

In the past few years, an increasing number of building certification systems have been placed on the market. In the current project a complete assessment by the use of TQB-assessment system [13,14,15,16,18,19] and monitoring [17] are part of the objectives for the research project.

The results for the first assessment in the planning phase are pictured in *Fig. 15*.

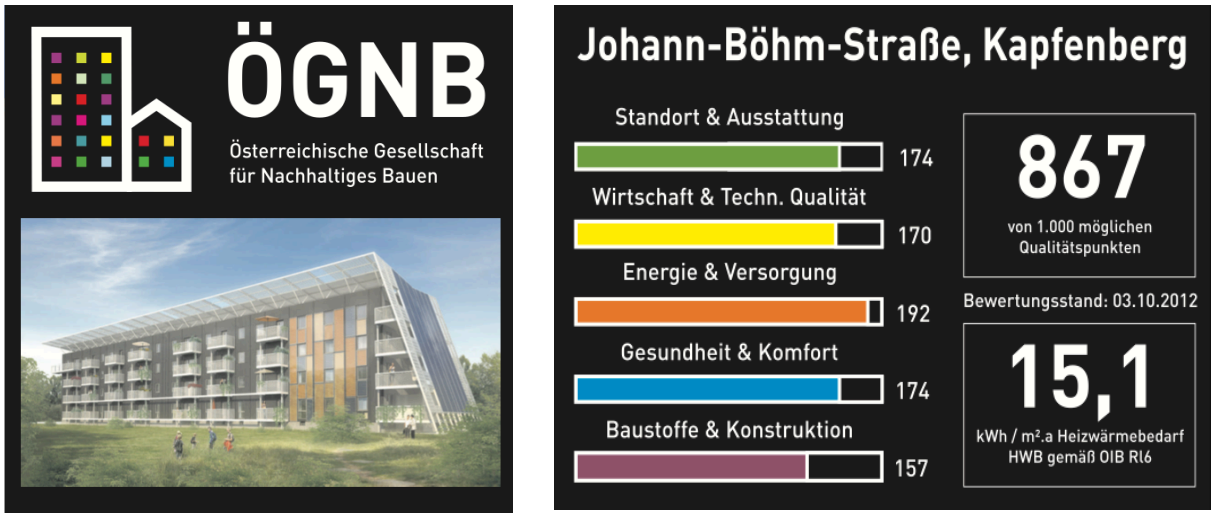

Fig. 15: Result of the TQB-certification

8. Conclusions and outlook

The demand on buildings, which allow the enhancement of the principles of a sustainable development, will gain more and more importance in the private as well as the public sector. This trend is based not only on marketing demands but also due to the need of better life cycle performance. One of the instruments in proving the performance is building certification, which includes aspects as e.g. LCA and LCCA as well as user comfort (as part of the functional performance) or technical aspects. The TQB building assessment scheme has an important role in the field of research and demonstration, and is very well accepted by innovators.

For the building sector this results in increased requirements primary focusing on new buildings. whereas the existing building stock offers the biggest potential to contribute to these targets.

In the current case study it is shown that a high-quality refurbishment towards plus-energy buildings is possible only through an integrated refurbishment approach including an energy concept. Thus requires a high-quality thermal refurbishment of the building envelope with simultaneous integration of energy-producing active elements (solar thermal collectors and photovoltaic elements), as well as network integration for electricity and heat.

By the use of prefabricated elements the goal of a more energy efficient and lower environmental building sector can be reached.

9. Acknowledgements

The research project *e80^3-Buildings* [13] - *"reconstruction concepts towards energy plus house standard with prefabricated active roof and facade elements, integrated home automation and network integration"* is funded by the Federal State of Styria and the program “Building of Tomorrow” of the Austrian Federal Ministry of Transport Innovation and Technology (BMVIT) via the Austrian Research Promotion Agency (FFG).

Summary

In the year 2004 the Medical University of Graz (MUG) was founded as an autonomous university and is currently split into several locations spread all over the city of Graz. A project called MED CAMPUS will provide an opportunity to merge the university with the existing university hospital in one unified location. Physical contiguity will do more than solving the difficulties of the current situation; it will enable teaching, research & development and patient care to reach an international level of excellence.
The project area consists of two construction sites where twelve institutes are combined in four centers. Facilities will include teaching facilities, administration offices, a library, a canteen an assembly hall, and space for start-up companies operating in related fields. The building as a modern university, research and communication center will have space for around 1700 employees and 4300 students.
From the project's inception, the rectorate managed its development as a sustainable and healthy property in the broadest sense, and this has resulted in sustainability quality targets having been included in the public competition requirements.
This case study presents the architectural concept of the project MED CAMPUS Graz. Further more the applied assessment method and the achieved level of building sustainability based on the assessment criteria of DGNB/ÖGNI certification of lab buildings [2] will be shown.

Short Summary

The total energy consumed by a building during its whole life cycle includes both embodied and operational energy. Embodied energy is 'embedded' in construction materials during all production processes, on site construction and demolition and final disposal, while operating energy is consumed in operating and maintaining the internal environment of a building. The accuracy of operational energy use and related carbon dioxide (CO_2) emissions prediction methodologies has been improved in recent years, resulting in more energy efficient building designs. As operational energy use is so reduced, the embodied energy and CO_2 emissions become proportionally more significant.

The project (IEA ECBCS, Annex 57, 2012-2015) is investigating methods for evaluating embodied energy and CO_2 emissions of buildings, to develop guidelines that contribute to practitioners' further understanding, and to find better design and construction solutions for buildings with less embodied energy and CO_2 emissions.

Keywords: IEA ECBCS, Embodied energy, Embodied CO_2 emission, Data base, Case study

1. Introduction

The evaluation of energy consumption and related carbon dioxide (CO_2) emissions due to the use of buildings is becoming increasingly accurate and is being applied in the design of more energy efficient building envelopes and systems. As such, the importance of energy consumption and CO_2 emissions due to stages other than the use of buildings is increasing, and, consequently, the methods used to estimate energy consumption and CO_2 emissions will become increasingly important. Therefore, the scientific basis of the embodied energy and CO_2 emissions for building construction should have been investigated by organizing the new Annex and an international team for the IEA ECBCS program.

The Annex 57 deals with methods for evaluating embodied energy/CO_2 of buildings in order to develop guidelines that contribute to improved understanding of evaluation methods and help developers to find better design and construction solutions for buildings with reduced embodied energy/CO_2.

2. Research areas of Annex 57

2.1 Basics

[1] Actual trends and activities related to embodied energy/CO_2 in the world
[2] Demands related to embodied energy/CO_2 by various groups of actors (survey)
[3] Integration of embodied energy/CO_2 into decision making process (survey)

2.2 Literature Survey

[1] Definition of key concepts and technical terms of embodied energy/ CO_2
[2] Characteristics of existing databases of embodied energy/CO_2 intensities and tools to quantify building materials and components
[3] Current trends and future perspective

2.3 Evaluation methods for embodied energy and CO_2 emissions

[1] Methodology for databases of the embodied energy/CO_2 intensities and quantifying volumes of building materials, components, equipment, and other elements
[2] Recommendations on how the databases and methods should be used

2.4 Design and construction methods for buildings with low embodied energy and CO_2 emissions

[1] Options for design and construction to reduce embodied energy and CO_2 emissions
[2] Use of recycled or reused materials and components
[3] Life of building and its prolongation
[4] Retrofit with low embodied energy and CO_2 emissions
[5] Consideration of GHGs other than CO_2
[6] Case studies and best practices

2.5 Deliverables

[1] The state of the art for embodied energy/CO_2 due to building construction.
[2] Guidelines of evaluation methods for embodied energy /CO_2 due to building construction.
[3] Guidelines of design and construction methods for buildings with low embodied energy and CO_2 emissions.
[4] Project summary report summarizing the technical outputs from Annex 57

3. Embodied energy/CO2 related to building construction in Japan

3.1 Input-Output (IO) analysis

IO table of Japan consists of 520x407 matrix, from which 401 symmetry matrix is derived. The inversion, GDP and final demand are expressed by the following formula.

$$\mathbf{X}=\{\mathbf{I}-(\mathbf{I}-\mathbf{M})\mathbf{A}\}^{-1}\{(\mathbf{I}-\mathbf{M})\mathbf{F}_{(D)}+\mathbf{F}_{(E)}\} \quad (1)$$

X:GDP(Yen/year) $\{\mathbf{I}-(\mathbf{I}-\mathbf{M})\mathbf{A}\}^{-1}$:Leontief inversion **I**:Unit matrix
M:Import matrix mi=**M**i/**C**i mi:Import parameter(-) **M**i:Import of industrial sector i (Yen/year)
Ci:GDP of industrial sector i (Yen/year)
A:Activity(-) $\mathbf{F}_{(D)}$:Final demand(Yen/year) $\mathbf{F}_{(E)}$:Export(Yen/year)

3.2 Energy/CO_2 intensities of industrial products in Japan

Final GDP shown by **X** can be derived by inputting final demand $\mathbf{F}_{(D)}$ in Equation (1). The value of **X** involves whole economic influences caused by $\mathbf{F}_{(D)}$. *Table 1* shows major energy consumption and CO_2 emission factors regading building construction. Assuming that 0.44kg-CO_2/kg-cement is

released in the cement resolving process, this value is added to CO_2 emission due to fuel consumptions. CO_2 emission due to residential construction (wooden) can be estimated 270 kg-CO_2/m^2 (=1,707/6.318) and non-residential (non-wooden), 395 kg-CO_2/m^2 (=2,704/6,844).

The intensities of equipment are similar between 1,727 and 2,408 kg-CO_2/Mln.Yen, which means the values are within ∓ 17%. It may be possible to estimate the embodied CO_2 of equipment by the average intensity and the total price of the equipments within the error of 17%. This estimation method is simpler for early building design stage.

Table 1: Energy/CO_2 intensities of industrial products in Japan by 2005 IO analysis (Rate: 1 Euro=137 Yen, 1US$=111 Yen)

No.	Industrual Sector	Energy (MJ)			CO2(kg-CO2)			Unit/Mil Yen

3.3 Profile of CO_2 emission

Fig. 1 shows the profile of CO_2 emission in Japan. Embodied CO_2 due to building construction and civil engineering is 19.2% and operation of buildings, 23.2%.

3.4 Fraction of embodied CO_2 in the world

Since Input-Output tables of 60 industrial sectors for OECD countries are provided at web site (http://epp.eurostat.ec.europa.eu), CO_2 emissions due to construction in major coutries can be calculated roughly with data of energy consumption in the countries. *Fig. 2* shows an estimation of the total CO_2 emissions in various countries and the corresponding fractions of embodied CO_2 due to building construction and civil engineering. The gray areas indicate the total embodied CO_2 in the world. In particular, fractions of embodied energy are higher in developing countries and often exceed the building operation energy.

As shown in *Fig. 2*, the embodied energy/CO_2 differs among countries depending on the building design, the energy intensity of materials, and the quantity of materials used in the building.

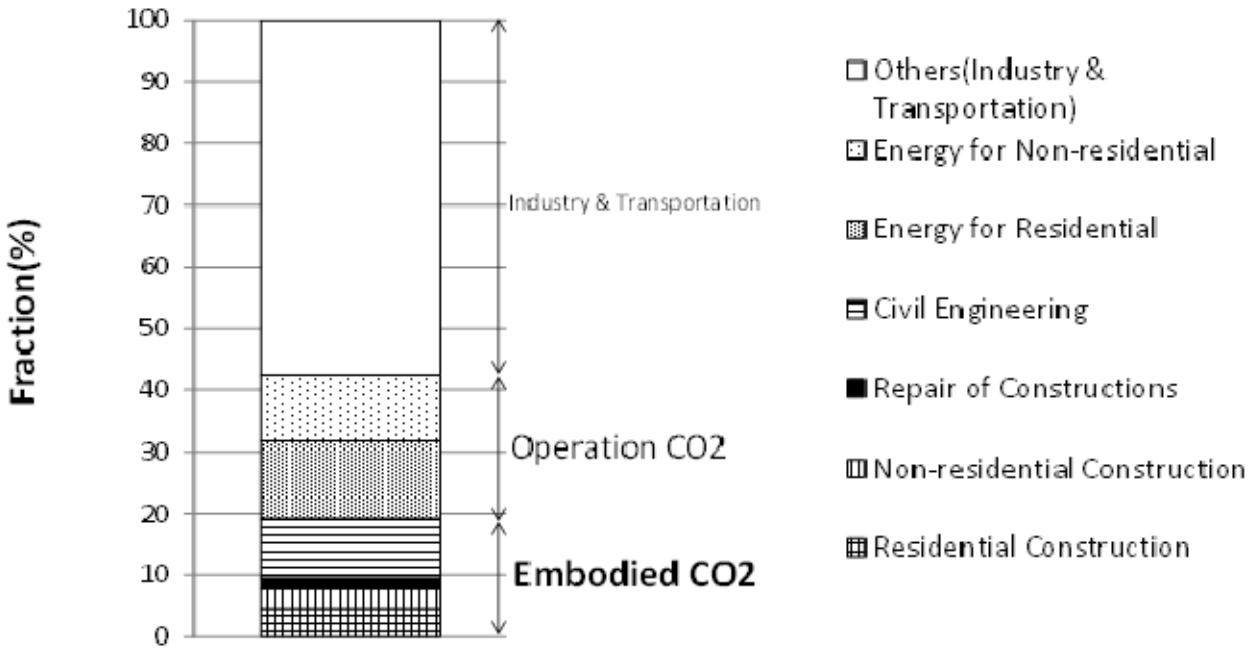

Fig. 1: Profile of CO_2 emission in Japan by Input-Output analysis (2005)

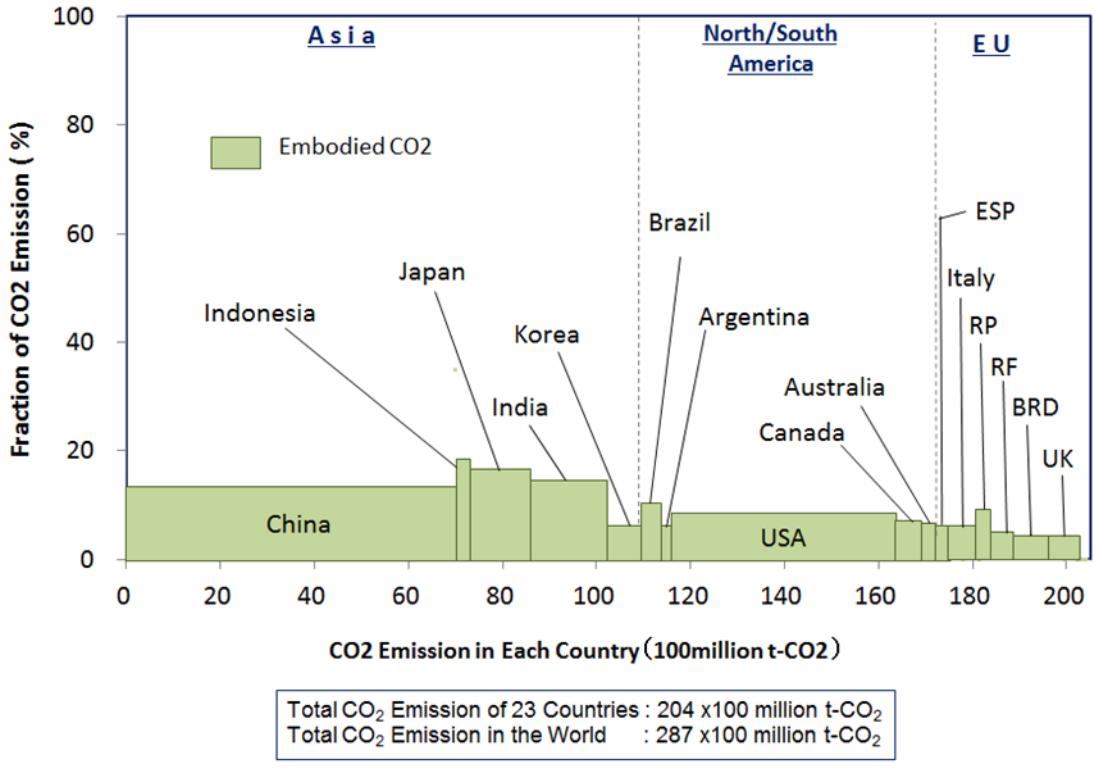

Fig. 2: The CO_2 emission of each chosen country (horizontal axis) and the fraction of embodied CO_2 (vertical axis) RP: Poland RF: France BRD: Germany

4. Some remarks regarding database and embodied energy/CO_2

4.1 Fraction of CO_2 emission in gate factory

The data of embodied energy/CO_2 for building materials complied with the International Organization for Standardization (ISO) or IO analysis are widely provided as tables for energy consumption and CO_2 emission factors. ISO tends to show the factory efficiency more than the embodied energy/CO_2 due to building construction. Although databases complied with IO analysis seem to be more relevant, the number of building component is much less than that of the ISO based database from a practical standpoint.
Table 1 shows the fraction of embodied CO_2 of building components in the gate factory, which is the final factory of the supply chain. These values can be calculated by IO analysis with Equation (1). CO_2 emission due to cement products is mainly in the process to produce cement. However CO_2 emission due to production of hot rolled steel is mainly in the process to produce pig iron and the CO_2 emission in the gate factory is very small. Generally the energy consumption and CO_2 emission in the gate factory is small compared with the whole embodied energy/CO_2, and therefore shows that the embodied energy/CO_2 of input materials into the gate factories should be estimated accurately.

Table 2: Fraction of CO_2 emission in gate factory

No.	Industrial Sector	CO2 emission in industrial sectors (%)					
		Cement products	Hot rolled steel	Air condit-ioning	Pump, refrige-rator	Wooden house	Non wooden building
1	**Cement**	**64.88**	0.04	0.29	0.18	17.61	18.00

Total		96.00	96.89	84.15	89.98	83.06	88.27

CO2 emission in Gate Factory

4.2 Approximate estimation of embodied CO_2 of buildings

Design and construction methods for buildings with low embodied energy and CO_2 are being improved by the use of recycled materials, prolongation of building life, retrofitting, and also reduction of non-CO_2 greenhouse gas emissions. Since approximately 90% of the building performance is determined in the initial design stages, it is effective to show designers the results of case studies to reduce the embodied energy/CO_2. An approximate estimation was made to find the significant factors to reduce embodied energy/CO_2.

4.2.1 Prolongation of building life

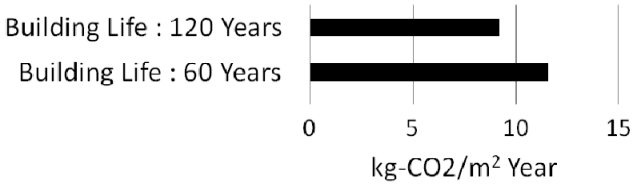

Table 3 shows the reduction of embodied CO_2 by the prolongation of building life in Japan. Although the quantity of steel is necessary more than 30% to prolong the building life, 21% of the whole embodied CO_2 can be saved per year.
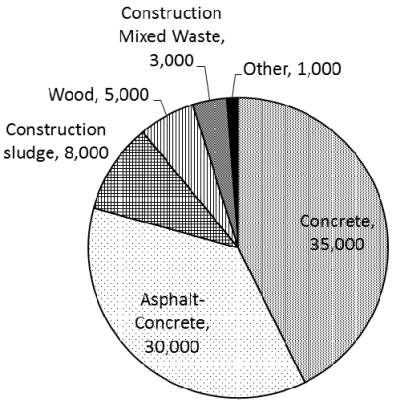
In the case that the quantity of steel for the building structure is 30% more than the requirement by the regulation, the structure is predicted to respond within the range of elastic behaviour at the time

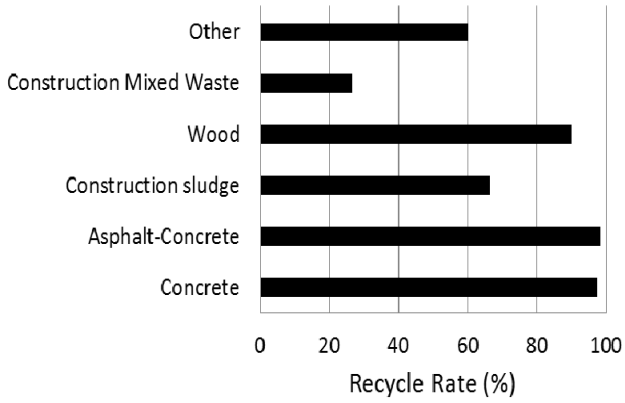
of the estimated maximum quake. This measure realizes the prolongation of the building life in Japan.

Table 3: Reduction of embodied CO_2 due to prolongation of building life

(a) Calculation process



Durability	Unit	Concrete	Steel	Other	Total	kg-CO2/Year
60 Years	Material/m^2	0.50m^3	180kg	320	697	11.6
	kg-CO2/m^2	134	243			
120 Years	Material/m^2	0.55m^3	234kg	640	1103	9.2
	kg-CO2/m^2	147	316			
Remark	-	Deeper covering between steel and concrete surface	Stronger structure against earthquake	-	-	Reduction of Embodied CO2 by 21%



(b) Reduced embodied CO_2 by prolongation of building life

4.2.2 Recycle rate of building materials in Japan

Fig. 3 shows the waste of building and construction materials in Japan. Most materials such as concrete are recycled by reusing in different industrial sectors. Metal products such as steel and aluminum are 100% recycled. Since a lot of kind of glass is provided for building construction, glass is difficult material to recycle completely.

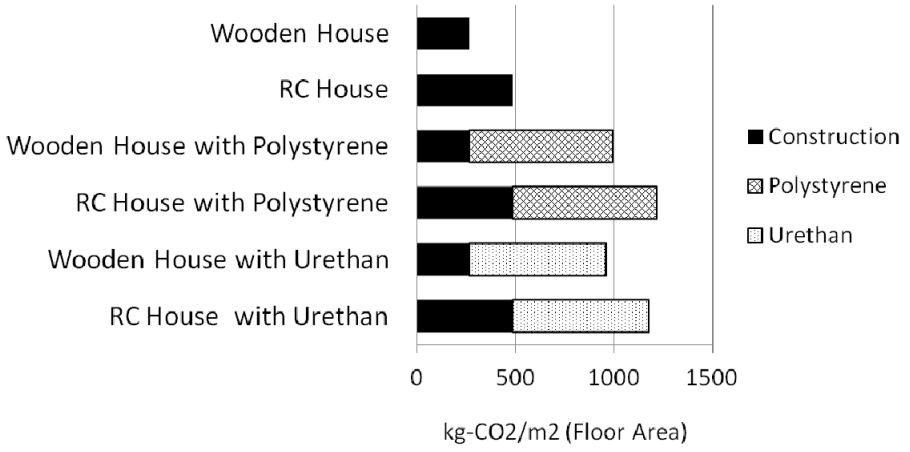
(a) Quantity of waste (Unit: 1000t)

(b) Recycle rate of waste

Fig.3: Recycle rate of building materials in Japan

4.2.3 Greenhouse effect by Freon gases

(1) Insulation material foamed by Freon Gases



For global warming, 60% is due to CO_2 and 14% is due to Freon gases, which are used in insulation boards in some countries and in electric refrigerators. *Fig. 4* shows the impact due to insulation materials using Freon gases. This figure shows that the $CO_{2\ equivalent}$ by Freon gases is enormous.
Embodied CO_2 of wooden house can be derived from Table 1 (Embodied CO_2/m^2: 1707kg-CO_2/6.318m^2=270kg-CO2/m^2). Embodied $CO_{2\ equivalent}$ due to polystyrene insulation foamed by HFC_{134a} can be calculated by: 0.2m^3/m^2x20kg/m^3x0.07kg/kgx1300=364kg-CO_2, where since the durability of insulation is 30 years, life cycle $CO_{2\ equivalent}$ is 364x2=728kg-CO2/m^2 in 60 years. Embodied CO_2 of non-wooden house can also be derived with similar calculation.

(a) Premises of calculation

Floor area of model house	128 m^2	Durability: 60 years
Insulation (Thickness≒0.1m)	0.2m^3(Insulation)/m^2(Floor area)	Durability: 30 years
Polystyrene insulation	Density=20 kg/m^3	Durability: 30 years
Urethan insulation foamed at site	Density=30 kg/m^3	Durability: 30 years

(b) Premises of insulation materials

Polystyrene insulation	HFC134a : GWP=1300	0.07kg-HFC134a/kg-Polystyrene insulation
Urethan insulation foamed at site	HFC245fa : GWP=820	0.07kg-HF245fa-/kg-Urethan insulation

(c) Greenhouse effect

Fig. 4 Greenhouse effect by Freon gases in the insulation materials

(2) Freon gases in refrigerator

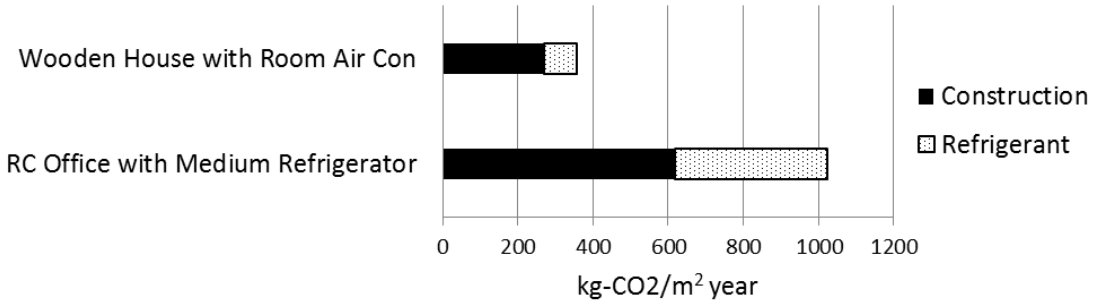


Fig. 5 shows the $CO_{2\ equivalent}$ of refrigerator and air-conditioner in the case that Freon gases are not recovered. The figure verifies that recovery and leak prevention measures are absolutely necessary to reduce embodied CO_2.
Embodied CO_2 of RC office is derived from value in *Table 3*. $CO_{2\ equivalent}$ of refrigerant can be calculated by: 0.045kg/m2x0.06x1300x60 years=211 kg-$CO_{2\ equivalent}$. To design the building which cooling/heating load is as small as possible or to use refrigerator with smaller GWP refrigerant is

effective to reduce embodied CO_2 of the building from the view point of $CO_{2\ equivalent}$ due to leakage of the refrigerant.

Type of building and refrigerator	Embodied CO2 due to construction (kg-CO2)	Refrigerant (kg)	Annual loss of refrigerant (%/year)	Refrigerant released (kg/year)	CO2equivalent of regrigerant in 60 years
Wooden House with Room Air Con	270	0.045	2.5	0.001125	88
RC Office with Medium Refrigerator	619	0.045	6-17	0.0027-0.00765	211-597 (404)

Refrigerant: HFC134a : GWP=1300 0.045kg(HFC134a)/m2

(a) Prerequisition for calculation

(b) Greenhouse effect by Freon gases in refrigerator and air-conditioner

Fig. 5 Greenhouse effect by Freon gases in refrigerators

5. Conclusion

1) The outline of Annex 57 text is described, in which the contents of literature survey, methodologies to calculate embodied energy/CO_2, the measures to reduce embodied energy/CO_2 are also shown.
2) Profile of CO_2 emission in Japan is shown with embodied CO_2 due to building construction and civil engineering as well as CO_2 emission due to building operation. Embodied CO_2 in the countries in the world are also shown as rough calculation result.
3) Energy consumption factors and CO_2 emission factors of the industrial sectors are shown as intensities. The rate of CO_2 emission in the gate factory in the supply chain is investigated.
4) Some measures and the effects to reduce embodied energy/CO_2 are investigated, in which the prolongation of building life, the use of recycled materials and the influences of Freon gases involved in insulation materials and refrigerators are described.
5) Simple prediction method is required to reduce embodied energy/CO_2 since it is the most effective way to use the guideline of embodied energy/CO_2 in the early design stage.

Summary

Identification of key materials which effectively define a building's impact profile have important implications not only on research time and investment, but also on understanding by designers and successful implementation of such concepts in their daily specification practice. Ranking building materials based on embodied energy and CO_{2e} and its disclosure to designers empower the material selection process, enabling more efficient, impact-driven specifications and materials balance. Disclosure of impact profiles to the general public can also provide the grounds for societal pressure for mitigation and technological improvement of the related industries, as well as advise public and sectorial policy-making. However, definition and calculation methodology of these metrics reflect current conceptual vagueness or even divergence, challenging replication, results aggregation and benchmarking. Life cycle assessment (LCA), though still embryonic in Brazil, can scientifically support such calculations. In this paper, cradle to gate LCAs were performed using SimaPro 7.3 software and followed ISO 14040:2006 methodological guidelines. Materials/components production cycle modeling used secondary data collected from national literature or adapted from international literature or from ELCD v.2.0, Ecoinvent v.2.2 and Industry Data v.2.0 databases. Inventory outputs were related to total material quantities (mass or volume) to calculate cradle-to-handover embodied energy and embodied CO_{2e}, normalized per unit of gross floor area (m^2_{GFA}) of four Brazilian case study buildings. For the studied typology, computed embodied energy and embodied CO_{2e} were around, respectively, 1.030 MJ/m^2_{GFA} and 128 kg CO_{2e}/m^2_{GFA}. Top six contributers (Portland cement CP III-32, ceramic brick, steel rebar, sawn timber planks, plywood and PVC tube) respond for over 80% of the total embodied energy computed. Analogously, over 80% of the accounted embodied CO_{2e} was related to cement, steel rebar, ceramic brick and PVC tube and conduit. Also, a core database encompassing twelve building materials and components provides a very accurate (over 97%-coverage) description of the accounted embodied energy and CO_{2e} profiles altogether, which can possibly streamline indicators monitoring scope.

Keywords: embodied energy; embodied CO_{2e}; LCA; building material; indicators; eco-efficiency

1. Introduction

The building sector is responsible for important impacts on the environment. On a global scale, building material manufacture and transportation as well as installation and construction of buildings consume great quantities of energy and emits large amounts of greenhouse gases [1].

The carbon footprint and embodied energy are indicators that, referring to buildings, measure, respectively, the CO_{2e} emitted and the energy used during the manufacture of building materials and components, in transporting these to the site, and during the construction process itself. Given

their life cycle perspective, they further include the measurements of energy and CO_{2e} emission incurred during renovations and replacement of components, as well as those resulting from demolition, waste and reprocessing at the end of the building service life.

Variability within within indicators' definition is observed worldwide, and calculations involved sometimes show clear conceptual conflicts. [2] affirm that in the building industry context, development of embodied carbon and energy accounting methods have been limited and inconsistent. Authors such as [3], for instance, defend that the carbon footprint should measure direct and indirect carbon dioxide emissions accumulated throughout a product's life cycle. Others ([2]; [4]) consider the carbon footprint as the total amount of greenhouse gases emitted – therefore referring to CO_{2e} – during a product or process's life cycle.

Calculation of both indicators can be aided by LCA platforms or, when appropriate, published databases such as [5] and [6]. In Brazil, studies performed by [7] and [8] emphasize the necessity of developing life cycle inventories for the local industry and/or carefuly validating international data before their application in national studies.

This paper presents calculations of life cycle embodied energy and embodied CO_{2e} normalized per unit of gross floor area (m^2_{GFA}) and provides preliminary Brazilian benchmarks based upon four case study buildings.

2. Methodology

The performed cradle-to-gate LCAs followed ISO 14040:2006 methodological guidelines and were supported by SimaPro 7.3 software. Data for modeling the production cycle of materials and components were mostly taken from national literature or adapted from ELCD v.2.0, Ecoinvent v.2.2 and Industry Data v.2.0 databases by switching into the Brazilian energy mix, and other appropriate adjustments. Table 1 indicates the functional unit adopted for each material/component, and the data inputs and sources used for modeling the respective production processes. The exception was the ceramic brick. Given the lack of information on that specific component in both national and international LCI databases, its production cycle modeling used embodied energy figures from [8], who explicitly detailed a methodological approach reasonably close to the one herein proposed; and embodied CO_{2e} data obtained from the University of Bath's Inventory of Carbon and Energy [5]. Even though the difference between the inventory and the Brazilian electricity mixes can impact accuracy, at the time of writing the ICE's methodological thoroughness suggested its use as a proxy.

Embodied CO_{2e} calculations was assisted by *CML 2001 v.2.05* environmental impact analysis, which presents equivalency factors for all greenhouse gases in the global warming impact category, and expresses results in kg of CO_{2e} per functional unit.

The typology investigated here is basically composed by low-rise (up to 3 floors), low window-to-wall ratio, reinforced concrete-framed, masonry façade and partitions, and ceramic or metallic roofing buildings. The four cases comprise one integrated service center (4.975,55 m²); one police-training center (1.511,74 m²); and two school buildings (4.869,23 m² and 2963,08 m²). Total usage of material/components was quantified for all case studies according to the functional unit previously defined, then divided by the total gross floor area and corrected by national estimates for construction waste [9], to configure a cradle-to-handover system boundary.

All case studies used cement type CPIII-32. For reference purposes, Portland cement and ready-mixed concrete are herein expressed considering three amounts of ground granulated blast furnace slag (ggbs) as clinker replacement: 5% in CPI-32, 30% in CPII-E-32, and 66% in CPIII-32, consistent with Brazilian standards [10], [11] and [12].

Table 1: Functional unit and inventory data source for each material and component considered.

Building materials and components	*Data input*	*Functional Unit*	*Data source*
Ready-mixed Concrete (fck 30)	Sand, gravel, water and cement (CP I-S-32, CP II-E-32 or CP III-32[1])	1 m³	[13] (cement) and Ecoinvent, version 2.2 (aggregates and water)
Portland Cement (CP I-S-32, CPII-E-32 and CPIII-32)	Calcium sulfate, clinker and crushed blast furnace slag	1ton	[13]
Steel rebar, Roofing steel structure, Copper wire	ELCD processes, adapted with Brazilian energy mix	1ton	ELCD, version 2.0 and Ecoinvent, version 2.2 (Brazilian energy mix)
PVC (conduit, tube)	Industry Data process, adapted with Brazilian energy mix	1ton	Industry Data, version 2.0 and and Ecoinvent, version 2.2 (Brazilian energy mix)
Wood (plywood; dry plank; dry roundwood)	Ecoinvent processes, adapted with Brazilian energy mix	1 m³	Ecoinvent, version 2.2
Sand, Gravel, Acrylic paint, Hydrated lime, Adhesive mortar, Ceramic tile	Ecoinvent processes, adapted with Brazilian energy mix	1ton	Ecoinvent, version 2.2

In all cases, the studied building had no basement. Ready-mixed concrete, steel rebar and formwork were considered only for the superstructure to isolate the effects of the soil's carrying capacity on the sizing - and consequently on material consumption - of foundation elements. External and urbanization elements were also disregarded. To account for typical reusability cycles, consumption of plywood, sawn planks and raw timber was divided by a factor of three. Consumption of each material/component per unit of gross floor area was then multiplied by its embodied energy/CO_{2e} per functional unit, in order to express these metrics per unit of gross floor area (m^2_{GFA}).

3. Results and Discussion

Figure 1 presents the top ten contributions to embodied energy of building materials and components per m² of gross floor area (median values of the cases studied). In this scenario, Portland cement was used in the production of other cement-based elements, as concrete was delivered ready mixed. As explained, embodied energy and CO_{2e} of Portland cement and concrete are expressed in terms of three clinker replacement possibiities practiced in accordance with Brazilian standards. International studies usually investigate the performance of ordinary Portland cement, which is composed primarily by clinker, with little or no mineral admixtures and would be equivalent to Brazilian CP I-S-32. In Brazil, however, CP II-E-32 (30% ggbs) is the cement type with the broadest commercial coverage, while CP III-32 (66% ggbs) is the top selling cement type in the region of study.

[14] speculated that 30 MPa ready-mixed concrete, steel rebar, cement, ceramic brick and timber are the materials with most embodied energy per square meter of gross floor area. [15] added glass and aluminum to this list. [7] and [16] also highlighted the relevance of concrete, Portland cement and reinforcement steel on the overall energy embodied in building materials.

Results achieved corroborate literature data and also show Portland cement and ready-mixed concrete (site-delivered as a composite) as the main contributors to the building's embodied energy profile.

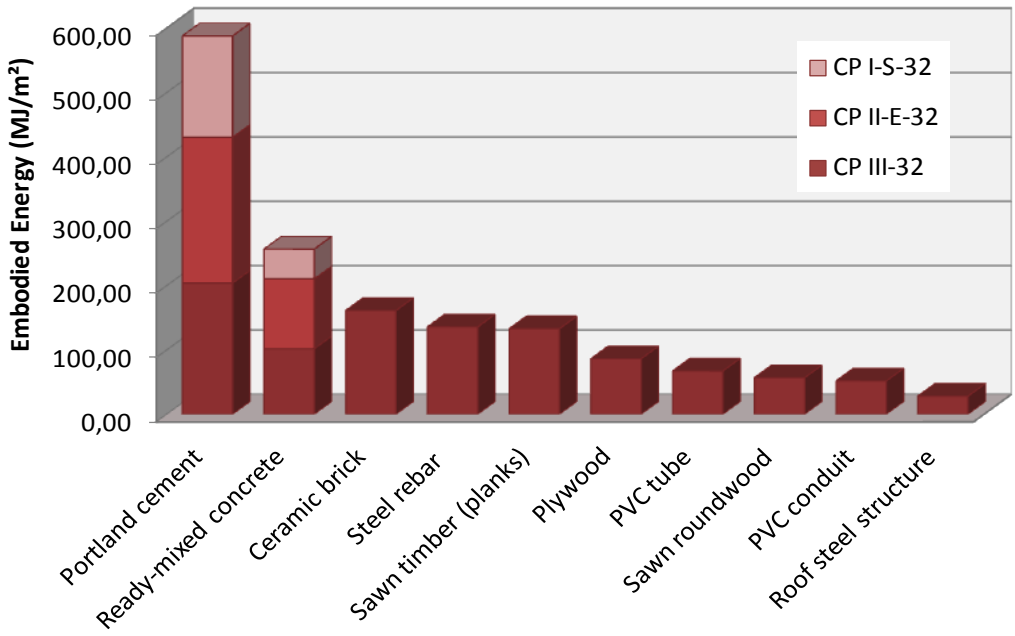

Fig. 1: Embodied energy of materials and components per built m² (median, MJ/m²)

In the scenario shown in Figure 2, concrete was broken down into its constituent elements. Corresponding cement, sand and gravel were added to those used in other construction applications.

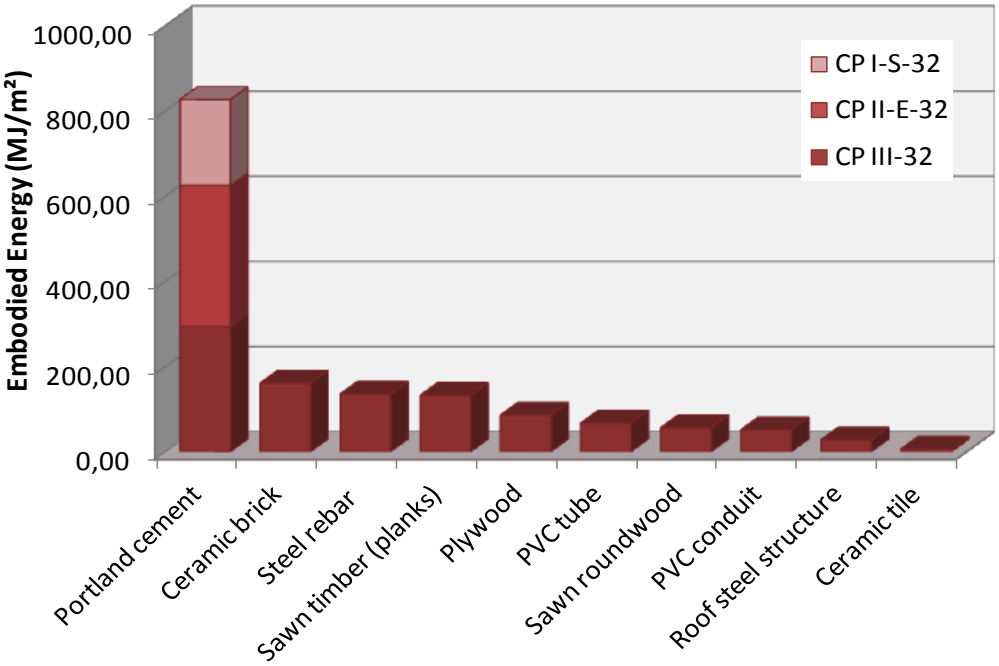

Fig. 2: Embodied energy of materials and components per built m², with concrete broken down into basic elements, which were added to cement, sand and gravel used in other applications (median, MJ/m²)

Table 2 presents embodied CO_{2e} and embodied energy values for the three types of cement with ggbs as clinker replacement, as well as for the corresponding concrete mixes. Both indicators for

cement (and, therefore, for concrete) diminished considerably as the ggbs content increased. Nevertheless, the highest embodied CO_{2e} was still that of cement CP III-E-32 (30% ggbs), followed by steel rebar and ceramic brick. [17] and [18] also reported large contributions from ready-mixed concrete and steel rebar.

Table 2: Embodied CO_{2e} and energy per built m² for different types of cement with ggbs and respective concrete mixes

Materials/components		*Embodied CO_{2e} (kg CO_{2e}/m²)*	*Embodied Energy (MJ/m²)*
Portland cement	CP I-S-32	*125,80*	*827,12*
	CP II-E-32	*94,95*	*625,79*
	CP III-32	44,17	294,13
Ready-mixed concrete (fck30)[1]	CP I-S-32	*39,49*	*256,68*
	CP II-E-32	*32,38*	*210,55*
	CP III-32	15,75	101,86

[1]Indicators for concrete mixes containing CP I-S-32 (5% ggbs, concrete mix 1:2,5:2,9:0,5) and CP II-E-32 (30% ggbs, concrete mix 1:2,2:2,4:0,5) were calculated for reference purposes. All case studies used cement type CP III-32 (66% ggbs, concrete mix 1:2,3:2,5:0,5).

Figure 3 presents the top ten contributions to embodied CO_{2eq} in building materials and components per m² of gross floor area (median values of the cases studied), while Figure 4 shows the same ranking, but with concrete broken down into basic elements, which were added to cement, sand and gravel used in other construction applications.

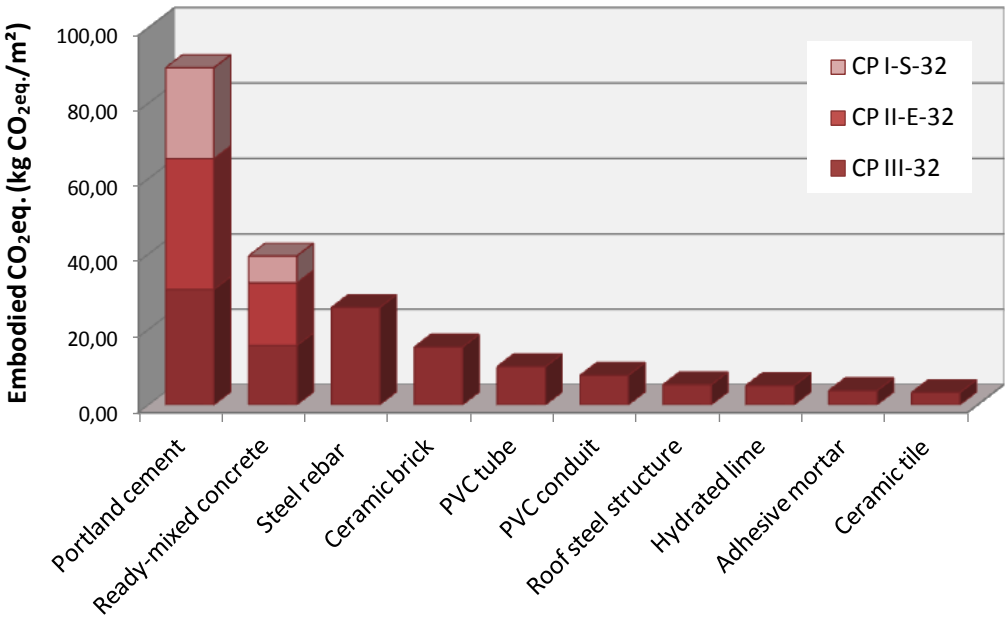

Fig. 3: Embodied CO_{2e} in materials and components per built m² (median, kg CO_{2e}/m²)

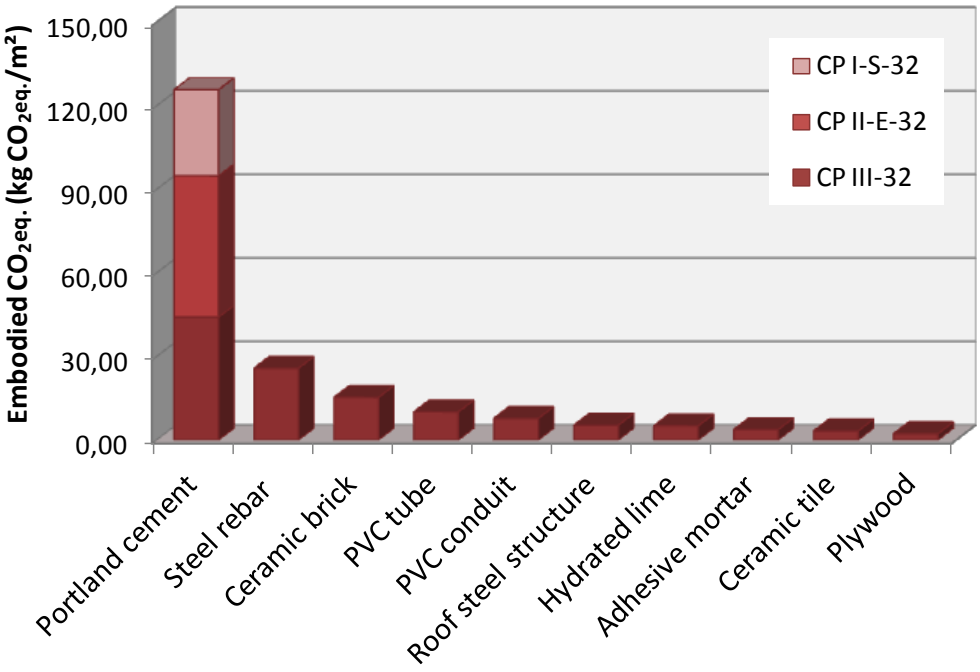

Fig. 4: Embodied CO_{2e} in materials and components per built m², with concrete broken down into basic elements, which were added to cement, sand and gravel used in other applications (median, kg CO_{2e}/m²)

Table 3 gathers data of the building materials/components actually applied in the case studies. Values for ready-mixed concrete were kept for reference purposes. Straightforward Pareto ranking suggests that, for the studied building typology, the top six contributions (Portland cement CP III-32, ceramic brick, steel rebar, sawn timber planks, plywood and PVC tube) respond for 85,2% of the total embodied energy computed. Analogously, 80,9% of the accounted embodied CO_{2e} was related to cement, steel rebar, ceramic brick and PVC tube and conduit. Enlarging this core database to encompass twelve materials and components would therefore provide a very reasonable (over 97%-coverage) description of the embodied energy and CO_{2e} profiles altogether, which can possibly streamline indicators monitoring scope.

For the studied typology, results for embodied energy and embodied CO_{2e} were, respectively, 1.029,58 MJ/m^2_{GFA} and 127,66 kg CO_{2e}/m^2_{GFA}. These figures are much lower than typical data found in literature, which is actually highly variable. Reasons for discrepancies are basically methodology-related and context-related. *Methodology-related variations* are connected to temporal (cradle-to-gate, cradle-to-site; cradle-to-construction…) and functional (whole-building; materials-only; materials and building services; superstructure-only; building typology) system limits as well as in accounting procedures (inference from I-O tables, process LCA, hybrid methods). *Context-related variations* are related to aspects such as energy mix (dependency on fossil fuels); climate (dependency on insulation); construction quality standard and susceptibility to natural disasters, which result in more robust structures. To help standardize evaluation and accounting procedures for estimating embodied energy and carbon dioxide (CO_2) emissions of buildings, the International Energy Agency Energy (IEA) Conservation in Buildings and Community Systems (ECBCS) Programme has created Annex 57 - Evaluation of Embodied Energy & Carbon Dioxide Emissions for Building Construction.

Table 3: Embodied CO_{2e} and energy per built m² for the main building materials/components analyzed in the case studies

Materials/components		*Embodied CO_{2e} (kg CO_{2e}/m²)*	*Embodied Energy (MJ/m²)*
Ready-mixed concrete	CP III-32	15,75	101,86
Portland cement	CP III-32	44,17	294,13
Steel rebar		25,82	135,78
Roof steel structure		5,34	28,08
Ceramic brick		15,33	161,24
Sawn timber (planks)		1,03	132,91
Sawn roundwood		0,32	56,76
Plywood		2,30	86,25
PVC tube		10,15	67,23
PVC Conduit		7,82	51,80
Adhesive mortar		3,78	3,13
Hydrated lime		5,11	1,58
Ceramic tile		3,28	6,85
Copper wire		0,10	1,15
Acrylic paint		1,02	1,12
PVA paint		0,41	0,45
Glass		1,64	1,07
Gravel		0,01	0,03
Sand		0,00	0,01
Ceramic roof tile		0,00	0,01

4. Final remarks

Ranking building materials based on embodied energy and CO_{2e} and the disclosure to designers can empower the material selection process, enabling more efficient, impact-driven specifications and materials balance. Disclosure of impact profiles to the general public can also provide the grounds for societal pressure for mitigation and technological improvement of the related industries, as well as advise public and sectorial policy-making.

For the studied building typology, a core database comprising twelve materials and components - *cement, ceramic brick, steel rebar, sawn timber planks, plywood, PVC tube and conduit, sawn roundwood, roof steel structure, ceramic tile, hydrated lime and adhesive mortar* - provides a very reasonable description of the embodied energy and CO_{2e} profiles altogether, which can possibly streamline indicators monitoring scope. Identification of key materials which effectively define a building's impact profile has important implications not only on research time and investment, but also on understanding by designers and successful implementation of such concepts in their daily specification practice. Results shown in this paper are specific to the construction typology considered, basically low-rise, low window-to-wall ratio, reinforced concrete-framed, masonry façade and partitions, and ceramic or metallic roofing. The case studies represent typical local building construction practices, not only for low-rise buildings but also for most multi-storey apartment buildings. Analysis of other construction typologies (e.g. steel or wood-framed, different wall systems and window-to-wall ratio), standards and cultures may result in other rankings and contributions per material/component.

Next research steps include investigation of additional building materials, components and systems, and of their performance as measured by other indicators; database expansion to include

other building typologies; and comparison of embodied and operational energy in Brazilian buildings, given the differences in industry technology and energy mix in relation to international data. It is also expected that, following a coordinated methodological outline, future works evolve to gradually constitute an LCI database of the most relevant building materials and components, to enable the use of the proposed metrics, as well as of LCA as a whole, as robust decision-making tools.

Summary

This study quantifies the embodied energy and embodied CO2 associated with building construction by using energy intensities and CO2 intensities obtained by process analysis and I/O analysis, and compare with each others in Japan.

The energy intensity and CO2 intensity table is calculated, which is based on 2005 I/O tables in Japan. In the intensity table, intensities of energy consumption and CO2 emission are shown as values of MJ and kg-CO2/million Yen, and each values are shown as based on producer's and purchaser's prices. It can be possible to calculate embodied energy and CO2 emissions due to constructions of various buildings.

The process-based data were referred to existing databases in Japan.

In this study, following comparisons are implemented;

・Comparison on energy intensity and CO2 intensity of building materials of the different databases: Cement, concrete, steel, glass, glass wool and lumber.

・Comparison on embodied energy and embodied CO2 of building by using different databases: a reinforced concrete office building and a steel frame structure office building.

The energy and CO2 emissions associated construction buildings were calculated by using energy intensity and CO2 intensity obtained by the I/O based analysis and the process based analysis. The results showed that many of intensities by obtained I/O analysis are larger than the intensities by obtained process analysis. The embodied energy and CO2 of office buildings by using I/O analysis are approximately 13% larger as the results of process based analysis.

Keywords: Embodied energy; Process based database; I/O based database

1. Introduction

Environmental and energy saving initiatives are becoming important strategies in the building sector today. Most of cases focus on operating stage of buildings. Building sector consume a lot of materials and components. When we look at energy and CO2 emission associated with building construction, embodied energy and CO2 occupy about 11% roughly in Japan, and it suggest that we should consider embodied energy and CO2.

If the energy saving strategies effect and reduce operating energy in near future, importance of embodied energy and embodied CO2 will increase.

Life cycle assessment is the one of the popular tools to assess building environmental loadings.

There are several issues among the life cycle assessment, different data collection measures, various or unclear data boundary condition settings and so on.

This study tries to make clear how different inventory databases influence on embodied energy

and CO2 emissions of buildings by comparing exiting databases.

This study selected three databases, JLCA-LCA Database, EE/EC database based on 2005 IO Table in Japan and Ecoinvent, and compared energy intensities and CO2 intensities of building materials and components. Furthermore, the study conduct analysis of embodied energy and embodied CO2 of a reinforced concrete building and the steel framed building.

2. LCI databases

2.1 Trend of databases

This study reviews LCA tools and LCI databases around the world. Fig.1 shows that LCI databases around the world and clarifies based on the methods of process-based analysis, I/O based analysis or hybrid analysis. This study could find 42 databases and most of the databases are created based on the process based methods.

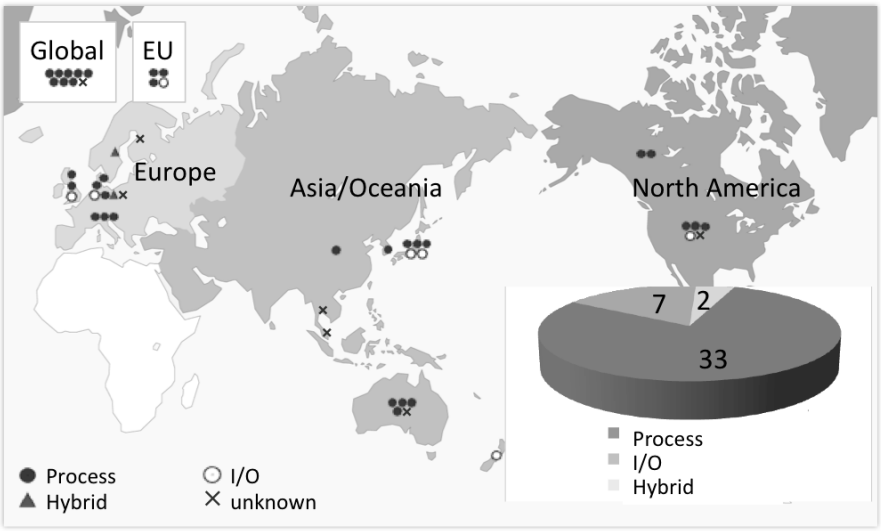

Fig.1 LCI databases in the world

3. Analysis of energy intensity and CO2 intensity of building materials and buildings

3.1 Summary and methods

This study selected three databases, JLCA database, IO database in Japan and Ecoinvent v2.2 compared these databases each other, and the energy intensities and the CO2 intensities of main building materials and components. Furthermore, the study conduct analysis of the embodied energy and the embodied CO2 associated with building construction.

This study conducted two case studies;

- Comparison on energy intensity and CO2 intensity of building materials
- Comparison on embodied energy and embodied CO2 of a steel frame building and a reinforced concrete building.

3.2 Selected databases for the case study

There are several databases in Japan and three database were selected considering characteristics of the process based database and the I/O based database, and the difference by the region.

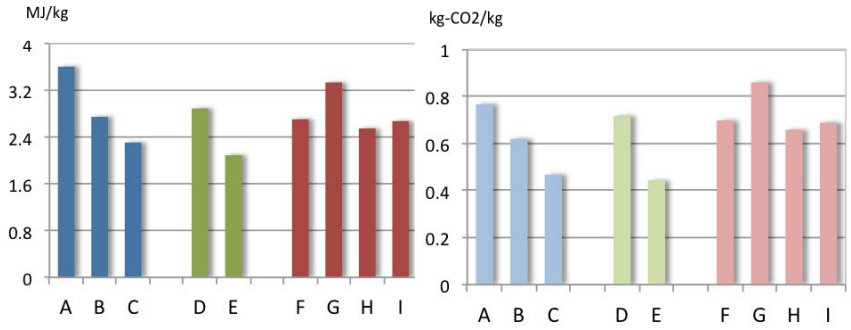
- JLCA database in Japan
- Ecoinvent in Swiss
- EE/EC Database based on 2005 I/O Table in Japan

Table 1 Selected databases

		Total number of data	Number of data relating buildings	Data creation method
DB-1	JLCA	550	71	Process
DB-2	Ecoinvent	4000	39	Process
DB-3	EE/EC database 2005 I/O	401	57	I/O

3.3 Analysis

JLCA-LCA Database and Ecoinvent v2.2 provide energy and other environmental loading data for each items with explanation boundary conditions and the remarks by the data providers. JLCA-LCA 's energy data provide as consumption of electricity, crude oil, kerosene, coal and so on. It needs to convert these data into primary energy by using the primary energy factor.



EE/EC database based on 2005 IO Table provides the energy intensity and CO2 intensity data. The unit of energy intensity and CO2 intensity of the I/O based database express MJ per 1million Yen and kg-CO2 per 1million Yen. This study converted these intensities into the unit uses MJ per kg or MJ per m3 and kg-CO2 per kg or kg-CO2 per m3 by using purchasers' price and quantity data of cost estimation information.

(2) Reinforced Concrete structure Building

Fig.5 shows the embodied energy and the embodied CO2 of the reinforced concrete building by using DB-1, DB2 and DB3. The result of embodied energy of DB-3 is 6.3 % larger as the result of DB-1, and the results of embodied CO2 of DB-3 is about 18% larger as the result of DB-1. Concrete and the reinforced bar occupy about 80% of embodied energy and embodied CO2.

(3) Steel structure buildings

Fig.6 shows the embodied energy and the embodied CO2 of the steel frame building by using DB-1, DB2 and DB3. The result of embodied energy of DB-3 is about 16 % larger as the result

of DB-1, and the results of embodied CO2 of DB-3 is about 28% larger as the result of DB-1. Steel frame occupies about 60% of embodied energy and embodied CO2.

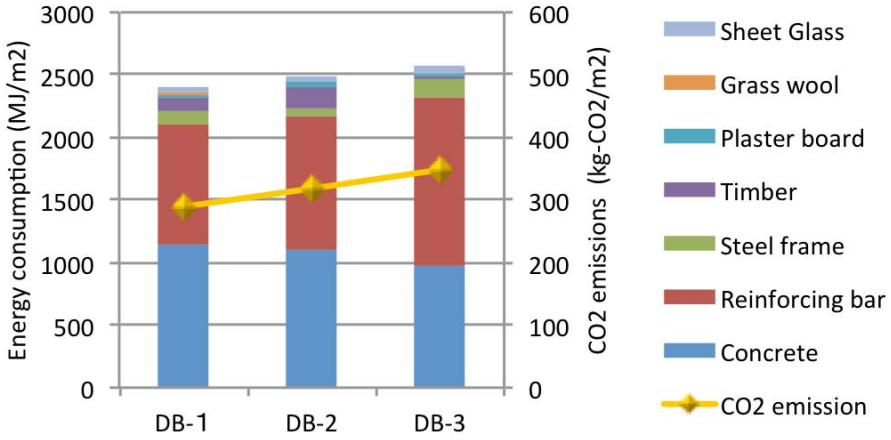

Fig. 5 Embodied energy and Embodied CO2 of Reinforced Concrete Building

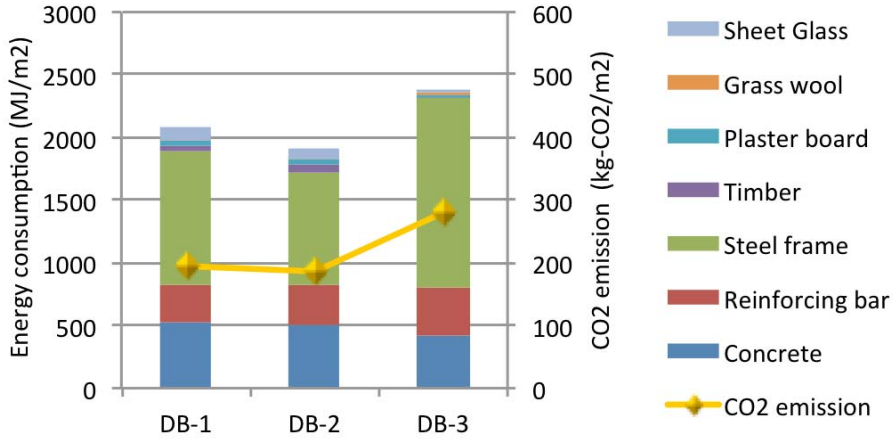

Fig. 6 Embodied energy and Embodied CO2 of Steel frame Building

5. Conclusions

This study conducted reviewing existing LCI databases and comparative case study on energy intensity and CO2 intensity by using different databases. The results show that different databases bring different results of embodied energy and embodied CO2 of buildings, and suggest that it is needed to prepare more accurate databases. This study compared only three databases and the number of building materials was limited to use as comparative study.

Leichtbau 3.0: Material, Structure, Energy

Oliver Englhardt
Prof. Dr.

Graz University of
Technology
englhardt@tugraz.at

Lightweight constructions basically mean the striving to design structures with a minimal weight compared with a full use of the material properties. In future this has to be complemented by a maximum reduction of the cumulative energy demand (amount of energy consumed over the whole lifetime) for structures.
The example of the development of a hybrid building envelope will demonstrate that evolution.

Fig 1. a) Spatial envelope: Zlote Tarasy, Warszaw [Waagner Biro], b) Façade: 1 Angel Square, Manchester [Daniel Hopkinson].

Each component of the structure has to act as a load-bearing member and has to fulfil the functional requirements of a building envelope at the same time. In this respect, the use of the glass elements as surface structures, the load transmission and the boundary conditions become particularly important.
The concepts of lightweight construction are the basic principles of a holistic development and design in building construction. The example shows that facades and building envelopes as part of our infrastructure are offering new development opportunities and innovations in structural engineering and design.

Short Summary

The paper presents an analysis of the influence of various building energy characteristic on the window energy balance in Polish conditions. The analysis is based on the building energy balance with hourly time step calculation in accordance with the methodology described in the ISO 13790 : Energy performance of buildings - Calculation of energy use for space heating and cooling. While the method of windows energy balance calculation is based on ISO 18292 : Energy performance of fenestration systems for residential buildings - Calculation procedure.
In the analysis two different public building types and several energy characteristics have been considered. The results indicate that the building energy characteristic significantly affect the energy balance of windows and thus should be taken into account in the process of setting of the reference data used for widows energy performance calculation.

Keywords:Windows; Fenestration; Certification; Labelling; Energy performance;

1. Introduction

New regulations such as the European Directive 31/2010 Recast impose new demands on the construction industry and investors. New low-energy buildings should be built using advanced technology and design techniques.
Complicated process of more efficient buildings construction can be facilitated by the introduction of energy classes for building elements. If a building is made of high-grade components, it should receive the same high energy class. For this reason, different countries bring in not only energy classes for buildings, but also energy classes for building components.
Windows play an important role in ensuring the comfort of indoor climate conditions. On one hand, they influence to a large extent the heating/cooling demand of buildings, on the other hand they are an irreplaceable source of daylight. This dual role of the windows makes assessment of the

overall energy efficiency of windows very difficult. However, even the assessment of the thermal balance of windows is quite complicated. Commonly used factor for windows thermal efficiency is the heat transfer coefficient U. This factor, however, does not describe the full balance of the window. In fact, windows are also a source of solar heat gains and allow air infiltration. That means that the lowest U-factor does not guarantee the best thermal performance. On the other hand precise calculation of an energy balance of each window would require much data and would be very time consuming. That calls for a simple window rating system that would take into account the most important factors that influence an actual thermal performance of windows.
Existing windows certification systems are based on more or less complex energy balance of windows based on some reference data such as heating/cooling degree hours and utilized solar irradiation. These parameters depend, however, on both climatic conditions and the general building energy characteristic. Therefore two windows with identical properties can have different thermal balance depending on the operating conditions.
In [1] a proposal for a windows certification system has been presented. The system was developed on a basis of an analysis conducted for a representative single family house in Poland. The question is whether the system could be used for certification of windows in different building types (with energy characteristic that differs significantly from residential buildings) .

2. Methodology

2.1 Assumptions

In order to analyse the influence of building energy performance on the energy balance of windows two different building types under various operating conditions have been examined. The analysis includes:

- two reference building types (office building and hospital) with different energy standards (current and from 1970s) with two different thermal masses (light and heavy),
- three climatic zones,
- separate energy balance calculation for both heating and cooling seasons,
- combined heating/cooling energy balance.

The method takes into account that the increase of solar gains (including solar energy utilization factor) during the heating season reduces energy demand for heating while in case of the cooling season, it causes an increase of the energy demand for cooling.

2.2 Calculation method

The general concept of the calculation procedure is presented in fig. 1.

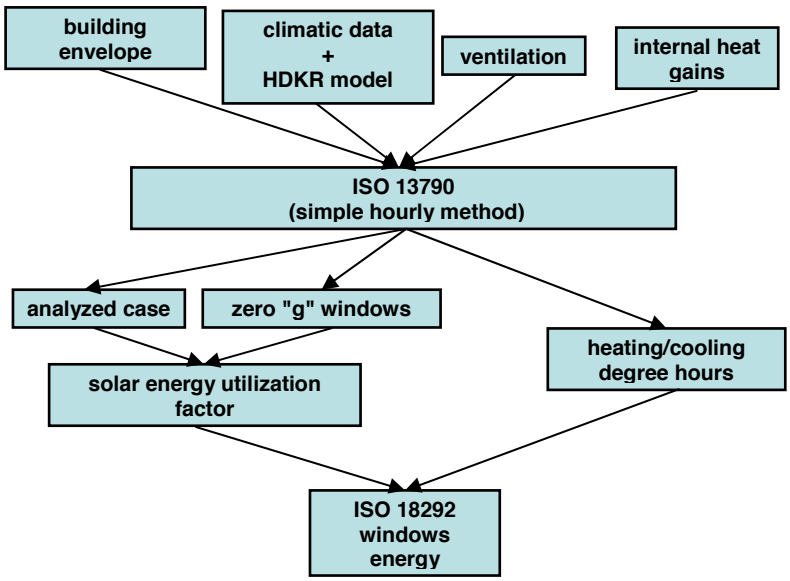

Fig. 1 Calculation algorithm

The assessment procedure in ISO 18292 requires data on both solar heat gains and heat loss through windows. Since both of these parameters depend largely on the climate and the energy characteristic of a building, detailed calculations for each reference building located in the three climate zones in accordance with the procedure proposed in ISO 13790 have been conducted. As not all of the available solar energy can be utilized for heat demand reduction, utilized fraction of the available solar energy is calculated on an hourly basis for the reference house. Solar energy utilization factor is calculated as a ratio of the effective reduction of the heating demand (calculated as a difference of the heating demand of the reference building and the building with windows for which solar energy transmittance equals 0) to the total solar irradiation through windows. Finally the energy performance of windows is calculated as a difference between the utilized transmitted solar energy and the thermal heat losses during the heating and cooling seasons.

$$E_{ref,heating} = I_{heating} \cdot g - D_{heating} \cdot U \quad (1)$$

$$E_{ref,cooling} = I_{cooling} \cdot g - D_{cooling} \cdot U \quad (2)$$

where:

$E_{ref,heating}$ - window energy balance for the heating season [kWh/m^2]
$E_{ref,cooling}$ - window energy balance for the cooling season [kWh/m^2]
$I_{heating}$ - utilizable solar irradiation during the heating season [kWh/m^2]
$I_{cooling}$ - utilizable solar irradiation during the cooling season [kWh/m^2]
g - solar energy transmittance of the window [-]
U - heat transfer coefficient of the window [W/(m^2•K)]
$D_{heating}$ - heating degreehours [kKh]
$D_{cooling}$ - cooling degreehours [kKh]

2.3 The reference buildings

The selection of reference building types is not random, the energy characteristic of office buildings differs significantly from that of hospitals, mostly due to differences in the internal heat gains to heat losses ratio and the windows area to floor area ratio. In order to investigate the influence of the building type on the energy performance of windows, the general building construction for both reference building types was the same:

- heated/cooled space - 4466.17 m^2,
- building volume - 14960 m^3,
- number of floors - 4,
- ground floor/roof area - 1298.30 m^2,
- roof pitch - 0^o.

The windows distribution for the reference building types is presented in table 1.

Table 1: Windows distribution an facades

	Window fraction on a facade [%]	
Orientation	**Office building**	**Hospital**
N	31,3%	17.8%
E	9,2%	7.8%
S	31,3%	17.8%
W	9,2%	7.8%

To investigate the influence for various energy standards of buildings two energy standards have been chosen:

- building WT2008 – building envelope coefficients are taken from present Ordinance of Minister of Infrastructure on the technical requirements for buildings and their location building design. This is an actual standard in Poland used for construction of new buildings.

- building from 70s – building envelope coefficients are taken from Ordinance of Minister of Infrastructure on the technical requirements for buildings and their location building design PN-64/B-03404 and PN-74/B-03404. This is a standard representative for most of existing buildings.

As currently buildings may be constructed in various technologies that may result in various thermal capacities, for new buildings two possible capacities have been considered. As a result three different construction types for both reference buildings have been considered (Table 2).

Table 2: Selected construction types

Construction type	*C [J/(K·m²)]*	*Walls U [W/m²K]*	*Roof U [W/m²K]*	*Ground floor U [W/m²K]*
WT2008 (light)	110 000	0.3	0.25	0.45
WT2008 (heavy)	260 000	0.3	0.25	0.45
70s standard	260 000	1.16	0.5	0.7

The most significant difference in energy characteristic between the reference building types is the ventilation airflow. In case of Office buildings the airflow is set at a level of 4288 m^3/h, while high hygienic demands of the hospital requires an airflow at a level of 50021 m^3/h (over 10 times higher). One of the other differences is the distribution of internal heat gains (Table 3) as different availability of internal heat gains may result in various number of heating/cooling hours and various utilization factor of solar heat gains in winter.

Table 3: Internal heat gains distribution

	Average heat gains [W/m²]	
Hours	**Office bulding**	**Hospital**
workday		
17-23	**15,2**	**9.2**
7-17	**1,6**	**9.4**
17-23	**1,6**	**2.2**
weekend		
17-23	**1,6**	**6.4**
7-17	**1,6**	**9.4**
17-23	**1,6**	**2.2**
average (week)	**5.6**	**6.6**

2.4 The climate data

In Poland, for the purpose of calculating the energy use for heating and cooling, data for 61 cities is given. To select locations that represent warmest and coldest climate a simplified energy balance for all 61 locations has been calculated. The balance has been calculated assuming the same heating and cooling season lengths for all locations. The locations have been arranged from lowest to highest energy balance for both heating and cooling (Fig. 2 and 3).

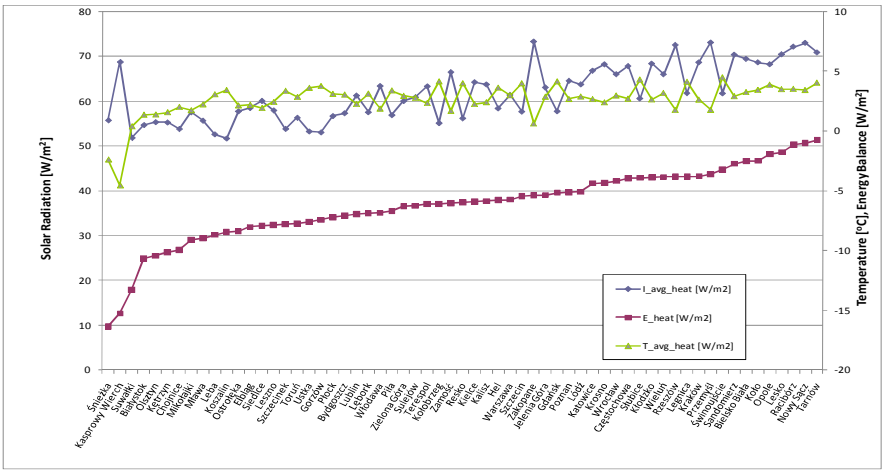

Fig. 2 Main climate data and simplified window energy balance for heating

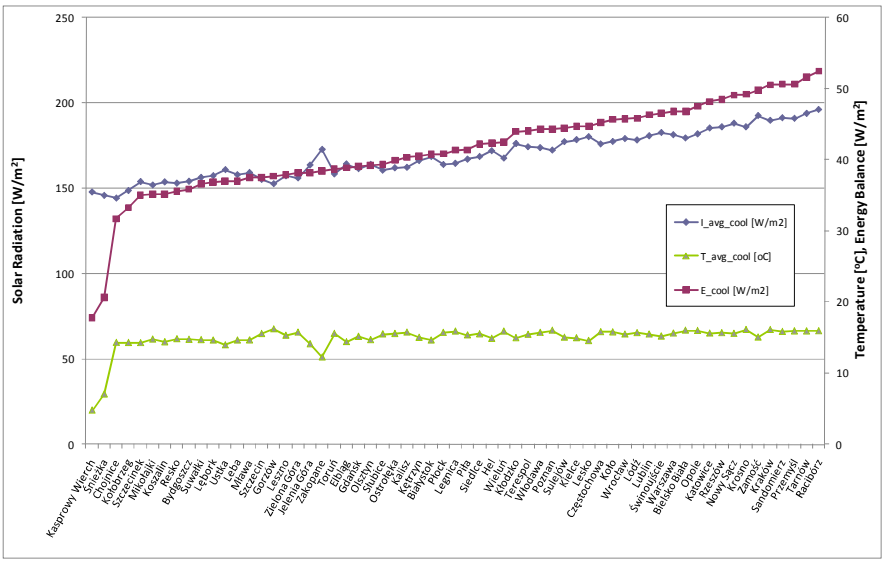

Fig. 3 Main climate data and simplified window energy balance for cooling

The meteorological stations Śnieżka and Kasprowy Wierch have been excluded from analysis as they are located in uninhabited mountain regions. Therefore for further calculations three locations have been selected - Tarnów – the warmest; Suwałki – the coldest and Warszawa as a moderate climate.

2.5 The heating and cooling hours

In order to determine the net energy gain, heating and cooling hours must be known for the specific reference house in an actual location. According to ISO 13790 standard the length of heating and cooling seasons are determined by averaging the cooling or heating demand over the previous 4 weeks. The start and end of the heating and cooling seasons is determined with a threshold value of 1 W/m^2 (related to the floor area). The length of heating and cooling season is needed to know the number of hours of operation of certain systems with auxiliary energy use (e.g. pumps, fans). In case of the energy balance calculations it is important to determine heating and cooling hours rather than seasons as it provides more accurate results. In the used hourly method heating and cooling hours have been determined basing on the calculated specific heat and cold demand with a threshold value of 1 W/m^2.

3. Results

3.1 Degreehours and irradiation

The heating and cooling degreehours and utilizable irradiation have been calculated for both of the reference building types and three construction standards for the three climate zones. The calculations have been made for two different reference building orientations in order to evaluate the influence of orientation on the energy performance. The results of calculations are shown in Tables 3-5. The results indicated a significant difference in the number of degreehours and irradiation for the analysed building types. These differences were mostly a result of lower relation of heat gains to heat losses due to a lower window area and a much higher ventilation heat loss in case of the hospital. As a result for the hospital the heating season was longer and there was almost no need for active cooling as most of heat gains were removed with ventilation air.

Table 4: Calculated number of degreehours and irradiation value for Suwałki

Building type	Orientation	Construction Type	Degreehours		Irradiation	
			D_h	D_c	I_h	I_c

3.2 Windows classification

Windows classification scheme requires an assumption that the net energy ranking for specific windows will be similar for various locations, meaning that a good window in Tarnów will also be a good window in Suwałki or Warszawa. Moreover as the rating may be different for heating and cooling in order to compare windows for both heating and cooling purposes a primary energy consumption factor may be used. Usage of this factor allows estimation of a total environmental impact of windows (3).

$$PE_{ref,total} = -E_{ref,heating} \cdot PRF_{heating} + E_{ref,heating} \cdot PRF_{cooling} \quad (3)$$

where

$PRF_{heating}$ primary resources consumption factor for heating [-]

$PRF_{cooling}$ primary resources consumption factor for cooling [-]

$$PRF_{heating} = \frac{w_{heating}}{\eta_{heating}} \quad (4)$$

$$PRF_{cooling} = \frac{w_{cooling}}{\eta_{cooling}} \quad (5)$$

where

$w_{heating}$ primary energy consumption for the representative fuel used for heating (assumed heat source for Poland – gas boiler; w_{gas}=1.1)

$w_{cooling}$ primary energy consumption for the representative fuel used for cooling (assumed cold source for Poland – electric compressor; w_{el}=3.0)

$\eta_{heating}$ total heating system efficiency (assumed heat source for Poland – central heating system with an atmospheric gas boiler; $\eta_{heating}$=0.78)

$\eta_{cooling}$ total cooling system efficiency (assumed cold source for Poland – split compressor system; $\eta_{cooling}$=2.7)

In the study a set of 12 different windows has been analyzed on the basis of the obtained degreehours and irradiation values (Tables 7-8). Results of calculations indicated that the rating for various locations is similar, which means that the assumption is correct and it is possible to develop a single rating system for all locations in Poland.

Table 7: Windows ratings in the office building for various locations

Window type	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**

Note that windows with a lower U-value are not necessarily the best performing windows as they significantly reduce the amount of obtained solar energy in the heating season, moreover the rating is quite different for the hospital and the office building. As an example, in case of the hospital the energy balance of a low energy triple glazed window (window types 1-2) do not perform as good as a low energy double glazed windows (window types 7-8). In case of the office building the U-value appears to be the most important factor, however in many cases the g-value decides on the rating of a window.

4. Conclusions

U-value of windows cannot be used to compare energy performance of windows. Therefore in order to provide decision makers information on the actual performance of windows it is necessary to develop a windows rating scheme based on an overall energy performance during both heating and cooling seasons. The development of a such system is possible as the performance of windows does not differ significantly for various locations, building envelope standard and orientation. However, different building types are used in a different way, therefore there is a need of a proper set of data depending on the building function, that would allow calculation of the energy balance of windows in buildings with various energy characteristics.
Thermal performance of windows is not the only aspect that should be taken into account, windows are an important source of natural daylight that allows for reduction of electricity consumption for lighting, therefore a method of daylight potential implementation into the windows rating system should be developed. Windows are also providers of natural ventilation, thus improving the indoor thermal climate and reducing cost/energy consumptions for mechanical ventilation. These effects should be considered in future studies

The pitfalls of building integrated photovoltaic.

Dieter Moor
CEO of
ertex solar
Austria
dieter.moor@ertex-solar.at

Short Summary

BIPV the short version for building integrated photovoltaic is one of the possibilities to turn a low or zero energy house into an active energy generating house.
There was a big development in products as well as in projects the last years. Market reports predicted tremendous growth rates which turned out to be wrong [1].
So there was no great breakthrough in the real market. Only few installations were realized in so called lighthouse projects.

Keywords:building integration; photovoltaic; architectural design

1. Introduction

Building codes and rating systems like Leed (US), Breeam (UK), DGNB (Germany) or ÖGNI and ÖGNB (Austria) plead for a direct installation of a PV system into a building.

Fig. 1: "The Peak Building", London with a 35 kW PV installation

In Fig. 1 for example is shown a Breeam rated Office Building in London. The full area also the triangles were covered with PV cells to obtain a maximum output. With this electric output the CO^2 saving is at a level to reach the highest rating according to the Breeam guideline.

From the experience of the author, there is a big demand on the market for similar buildings and projects which is reflected in high number of offers in the recent years. On the other hand the conversation rate is terrifying low. It depends to the project size and location, but averaged its between 1 and 3%. So that means a lot of projects are developed and will not be realized.
The purpose of this paper is to clarify the pitfalls of this lack of breakthrough. It goes into detailed

consideration about the product development and product range. It will consider the question if there is a sufficient range of possibilities to meet the demands of designers and architects. Who is involved in the planning process, are the interfaces clarified between façade-, glass-, electric- and photovoltaic design? Is there an opportunity to standardize the process and the products? Are the highly costs the main impact of the slight market growth?

2. Stages of BIPV projects

2.1 Planning process

At a very early stage all the players in a BIPV project like investors, architects, facade engineers and so on, like to know the exact details about the following topics.

2.1.1 Technical issues

The critical matter at a BIPV project is to solve all the interfaces between facade and glass engineering on the one hand and electric and PV engineering on the other hand. If it´s start whit a simple PV module which is usually standardised by the individual companies, it´s relatively easy to develop a PV plant. The only thing to consider is that every company has its individual design, which is given by the cell dimensions. In the past it was 5 inch (125 x 125 mm) and at the moment 6 inch (156 x 156 mm) which is shown in Fig. 2.

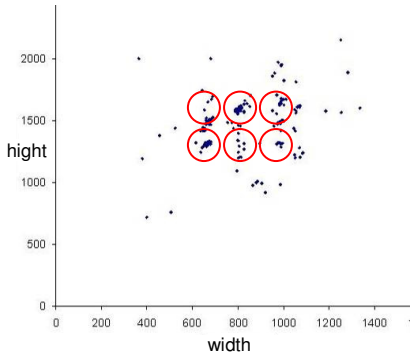

Fig. 2: typical measurement of different “Standard” PV modules

In the construction business especially in the glass facade business it’s unusual to work with fixed dimensions. The flexibility in size, shape and glass thickness is an absolute necessity to fulfil the wishes of the architects.
Therefore the engineering process starts at a very early beginning, at the design of an individual panel restricted by the existing cell technologies.
But this is a big investment in engineering for the BIPV industry, considering the conversation rate which is mentioned above, it´s much too high a risk.

It´s also important from the beginning, that the interfaces between all the four mentioned disciplines (facade, glass, electric, PV) are solved. There is a relationship between phases of error and fault costs, the rule says that the cost will multiplied by 10 at the certain stage if there is an error (planning, development, construction, ...). Therefore it´s indispensable to solve all the questions in the planning process and not at the construction site, which will understandable cost much more then at the end.
Again, from the experience of the Author, a lot of projects are developed too late; problems will be solved in some worst cases at least before delivering the panels on site.

Another lack is the missing information at the tender stage. There are no standardised texts on the market to allow each engineer or architect to prepare the tender documents. So every project has to be planed individual.
Typical for a BIPV tender is a separation in an electrically part and glazing part. This leads in some cases to misunderstanding and misinterpretation of the whole project. The needs of a facade company (weather proofed building) are sometimes contraire to the needs of an electrician (a lot of holes for the cables).
A better solution would be a holistic approach of a BIPV project.

2.1.2 Financial issues

There are two ways to debate this issue. One is about the monetary benefit; the other one is the extreme high cost compared to other standard PV or also building materials.

When we talk about photovoltaic, everybody is asking for a payback time. Therefore the author calls it satirical “The Pavlov Reflex”, because it´s not common for standard building products. That conditioning reflex is caused from the high feed in tariffs for standard photovoltaic installations which intend that individuals can earn money with a PV installation.
For a BIPV installation other benefits are at the foreground. These are the so called multifunctional issues, like weather protection, fall preventing (as a balcony), over head glazing, sun protection and very often the positive marketing effect.

The author has monitored two diploma thesis reg. a theoretically sun protection calculation for individual glazing systems. In the first diploma thesis the technical and theoretical background was figured out for a hypothetically office box with 2,5 x 3,0 x 5,0 m. The simulation was done for four different glazing types, a standard insulate glass, a solar coated glass, a BIPV glass and a brise soleil [2]. In the second diploma thesis an economic calculation where set up on the results from the first study [3]. One of the interesting results was that the supposed very cheap solution with insulated glass turned at the end (after a 20 years cycle) to a more expensive solution compared to the initially very expensive PV installation. This is regarding the high energy cost for cooling down the office with standard insulated glazing. That means if BIPV is considered only from the installing cost, it´s very expensive. If you compare it with other materials including the running cost (in case of PV also savings and earnings) it turns more positive. But projects whit considerations about total cost of ownership are very seldom at the moment.

The second debate is about the general high investment cost for a BIPV installation.
One reason is the above mentioned planning process. A lot of projects will be developed by the industry for free, if they will not be realized the other projects have to carry the load.
Compared to standard PV panels two main issues should be mentioned reg. the gap between the costs.
In a BIPV panel the thickness of the glass is always given by the loads and the clear span of a pane. Due to the fact that the dimensions for glass facades and roofs are getting bigger and bigger the glass is getting thicker. The price increase should not be underestimated.

Another reason is that every project will be calculated, planned and manufactured individual. So there is no serial production which makes the product on and on expensive.

2.1.3 Legal issues

There are a lot of issues to consider which is not possible to explain everything in this paper. In place of all the other topics the necessity of laminated safety glass and fire protection will be shown in detail.

The first topic laminated safety glass is very common in the glass industry, but not in the PV industry. We are talking about horizontal glazing if the facade or installation is declined more than 15° from the vertical. In such cases a laminated safety glass is required, no other products are allowed. Laminated safety glass guarantee, that no splinter fall down and that the entire glass pane

will stay in the construction in case of a breakage. The installation in Fig. 3 is not a typical horizontal (or overhead glazing) but it shows what will happen if a none laminated safety glass in this case a standard PV panel will be integrated into a facade combined with a illegal mounting system.
Because of the thermally toughened glass and its typical breakage structure the glass will collapse because the very slim backsheet which is only a foil is not strong enough to hold the glass pane stable in the structure.

Fig. 3: broken "Standard" PV module in a facade at a shopping mall in Carinthia

The second very important question is about the fire protection. Is there a danger if somebody installs a PV panel for example in a ventilated facade?
With the "Önorm B 3800 Teil 5" a test is established to figure out exact this question. This should be considered in every individual case. That means which type of PV panel will combined with which facade system. In Mai 2013 the Author monitored a fire test at the BVS in Linz Upper Austria. Several PV panels from ertex solar were integrated into a Schüco SCC 60 facade. The engineers found out that no pieces felt down bigger then 0,4 m² and heavier than 5 kg within the 30 minutes of the test procedure. So the system passed the test, but as mentioned above, every combination should be considered individual.

Fig. 4: fire protection test according to Önorm B 3800 Teil 5

2.2 Realization on site

The big critical question is always if the installation of a PV panel is a job for the electrician or for the glazier or facade builder. The answer is, it depends to the situation and to the type of installation. But for special dimensions it is recommended to take an experienced glazing company, if they are not afraid to connect also prefabricated plugs. There are several installation situations shown in Fig. 5 where it´s obvious that no electrician can mount such big panels.

Fig. 5: mounting situations for BIPV panels

A pitfall in BIPV application is, if a none or less experienced company tries to install the very fragile glass product.

2.3 monitoring of existing installations

In some projects monitoring systems are applied to see if the inital output calculation goes conform with the real production. In the best case the PV system is integrated into the building automatisation to see if production and consuption is cungruent. In Fig. 6 an example is shown for the winning project “Canopea” of the Team Rhone-Alpes at the student competition solar decathlon 2012.

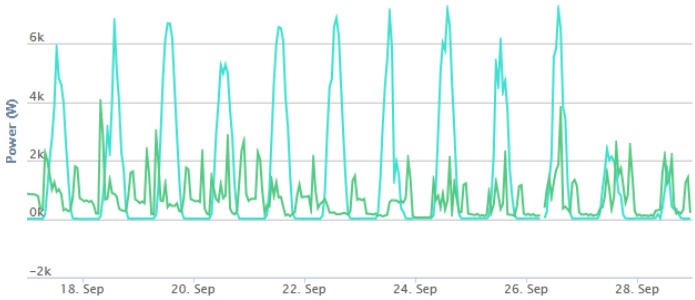

Fig. 6: monitoring between PV production and electricity consumption at the Solar Decathlon Europe 2012, winning project “Canopea” Team Rhone-Alpes www.sdeurope.org

Sad to say but in some projects years past the installation it comes out that no inverter was installed, and nobody take care about the electrically output, this is rare but happens however.

3. Additional considerations

If we are talking about the pitfalls of the BIPV business, there is always a question into two directions.
One direction is to make it more standardized and less flexible for the designers, or is a demand for more flexibilisation.
It seems that the first attempt should go conform to a cost reduction and the second attempt will stay in a niche market with high priced solutions.

3.1 Standardisation

Standardisation in a BIPV context could consider the process itself, for example standardizes the tender phase or electric output or shading calculation. But it could consider also the PV panel as a building material. A possibility could be a standardized PV panel not concerning the electrically standardisation which is more or less a panel with 72 cells easy to handle, it should be more a building product. This building product should be fire resistant, easy to mount and combinable with other processable, cutable, custom tailored materials like fibre cement, melamine board etc.

But is it really possible to create some standards bring it to the designer and finally on the market and hope that the architects will build a building around that existing measurement? It could be possible for some installations, like ventilated facade or very simple facade but not in high sophisticated glass projects.

3.2 Flexibilisation

On the other end of the market some new products are required concerning different colours of the materials, more transparent see through solutions or higher efficiencies. The development cost for such solutions or installations are tremendous high and the generated turn over by such projects will maybe very less. To be an early adopter in such a fragile sector it´s always a risk for the entire industry.

4. Conclusion

In this paper the Author tried to figure out the Pitfalls of individual BIPV projects. In summary it can be said that there is not just one reason.
At a first view it seems that the costs are the main reasons, but if we go into detail we found out, that several “stumbling block” will hinder the participants to use BIPV solutions frequently.

The engineering itself or respectively the establishment of reliable engineering offices is the first to foster BIPV solutions.

Another topic will be the development of PV building products which will follow the building codes, norms and guidelines.

If the BIPV production turns generally into a mass production the prices will getting lower and lower.

Summary

The use of renewable energies in everyday life become more attractive from day to day. Even their use in buildings offer great benefits in terms of fossil fuel reduction as well as green label of those material goods. Particularly, the use of solar thermal systems in architectural integration has a big potential.

Façade solar thermal collectors show double benefits in new architectural goods: integrated functional elements that do not disturb the architectural appearance and there is a high fraction of solar energy as a part of total energy needs of the building. These are the main characteristics of facade solar thermal collectors.

The new model of the window façade collector is described in this work. Namely, it is an ideal way to build-it in the south façade of the building that can be residential / office building or manufacturing plant. With these type of façade collectors/modules, the architectural appearance of the buildings will not be destroyed and at the same time those build-in elements are functional: participate to a great portion of total energy needs of the building. This is a sustainable way of use of solar energy and consequently decrease the CO2 impact to the environment.

Keywords: facade solar thermal collectors, energy-efficiency, solar architecture, building integration, long term stability of collector

1. Architectural integration of new façade window collectors in buildings

Concept of energy efficient buildings does not only mean use of insulating materials to build them and consequently save the energy of the building facility, but also use the energy from renewable source, so they are at the same time declared as eco-friendly objects.

At the moment it is very important that architects and designers should accept a new way of thinking for building designs where beside the architectural appearance, the energy efficiency of building will be also important and valuable component of further decision. Usually, architects are mainly focussed on a good appearance of the building but not on free and renewable energy options that can contribute to eco-friendly aspects of the building. The most ecological and sustainable energy source in this case could be the usage of solar energy. The solar energy could

be used for heating the sanitary water as well as for space heating of buildings that are the main portions of total energy usage.

Solar thermal collectors usually were installed on roofs only but not on facades; nowadays the philosophy is changed. The ratio of available roof space related to the required solar collector area is usually too small, and it is difficult to supply energy from those collectors for the whole building. In this context, if there is enough space on the south facade wall then the solar collectors could be installed there [1-4]. The south facade of the building could be more attractive and better place to accommodate ,,functional,, building elements such as windows solar thermal modules instead their installation on the roofs of buildings.

Another benefit for solar facade collectors is the fact that their appearance could be very similar to the windows glass surfaces. It means that facade windows-like collectors should be free of welding lines, waves and folds and present good replace to a classic windows. They could be mounted on the same windows frames as the window glasses. There is no additional cost because the facade collectors will be integrated in the existing frames.

One of the most important characteristic of these collectors is the fact that water vapour condensation is overcome, otherwise it can destruct the facade appearance and architectural design will be unacceptable if even small amounts of humid exist inside of the collector.
Due to the fact that facade collectors will be mounted under angle of 90 deg. on the façade wall -it means collectors' efficiency will be decreased annually (particularly, more in summer time than in winter due to the fact that Sun has lower position in winter period)- (Figure 1). One way to compensate this decrease in collector's efficiency could be the use of collectors with very high efficiency as much as possible.

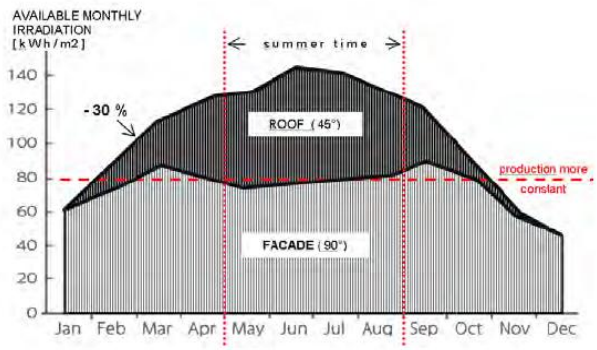

Fig.1. Roof versus facade collector annual yield pattern. [3]

Although, vertical placement of collectors on a building will not maximise the peak yield possible during summer, it makes it easier to scale a system for specific average requirements. As can be seen in figure 1- the yield is much more constant in case of façade placement. Hence, overheating or overproduction can be minimised. In addition, with the right design the shortcomings due to the façade placement can be compensated for by reduced thermal losses. In this context, the use of appropriate insulators options and designs of the facade collectors could help in decrease of thermal losses.

Usually, the insulating options come from the way of mounting of: window module (Fig.2) in the (existing) windows frames or mounting directly to the facade (Fig.3). If the window module is

mounted in the window frames (Fig. 2), then behind the module is insulation that can be also sliding/demounting wall in order to allow in winter time to replace it and the solar module at the same time not only to heat the water in the absorber but also to heat up the space behind the collector module. This is especially important if the back side of collector is made from Al plate that once warms up then by convection will heat up the room space as well.

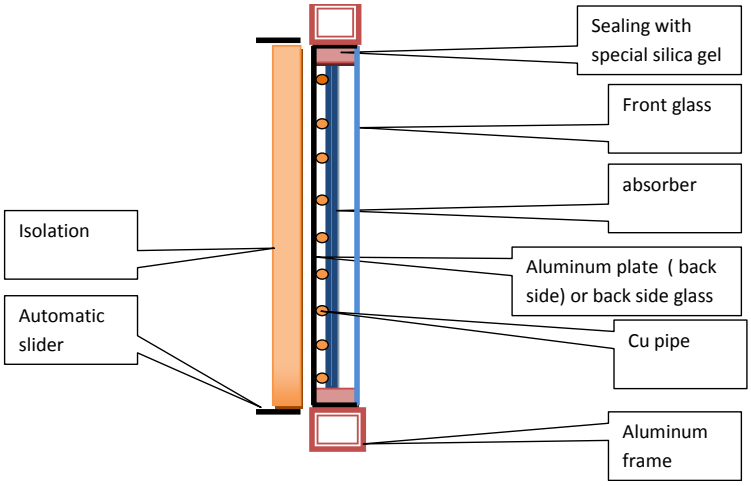

Fig. 2. Window module assembled in window frame. Insulation behind the window module.

If there is a case of mounting of collectors on the space between windows directly on the wall of the facade, then modules are framed in profiles (Fig. 3). Again, behind it is insulation material and they are almost the same as the windows ones. In this case insulation could be thicker than in the standard thermal collectors and the efficiency of the solar thermal collector goes up.

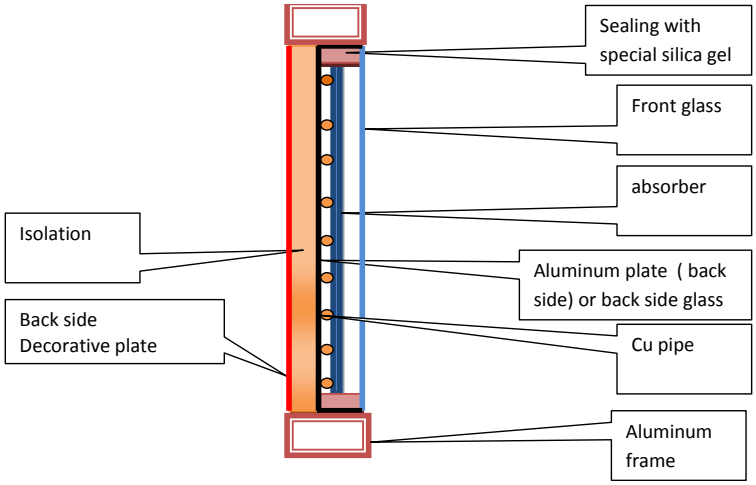

Fig. 3. Window module assembled on the facade wall. Behind is insulation.

2. Long term stability of facade window collector

The long term stability/durability of solar facade collectors is very important. It can be achieved if: the coefficient of efficiency of collector is stable and constant over a long period of time; have a stable colour of the absorber over a longer period of time in order to have optimal and constant optical properties; have a high transmission of the cover glass as much as possible due to the fact that should keep a good facade appearance and consequently have higher values of collector's

efficiency for a long period of time, and of course last but not less important is to overcome the humidity problems.

To solve these issues, it is necessary:

a) ***the selective coating*** of the absorber should be continuous and not damaged. The welding types that exist by now are:
   - ultrasound welding - it removes a part of the selective coating that later becomes a place for initializing of corrosion, water diffusion, oxygen and pollutant penetration and over the time period it causes decrease of optical characteristics of the coating. The emittance value increases that consequently decrease the collector's efficiency.
   - laser welding is the other type of welding that causes point melting of the selective coating that are initial spots of corrosion, water, oxygen penetration and decrease of important optical properties of the absorber.
   - These methods of welding are overcome with the new CS (Camel Solar) type of welding. Namely, the novel type of absorber is named as CS (Fig. 4a) and it is manufactured by the new technology for back-side welding (Fig. 4b).

b) ***humidity issues*** between glass cover and absorber should be solved: no water or vapours are allowed in this space of the collector, that could be achieved with vacuum in this area or with special hygroscopic substances that absorb all initial humidity.

c) the glass should have ***low-soiling or self cleaning coating*** that can stop corrosion as well as soiling or dust collection over the cover surface (glass or polymeric).

a) b)

Fig 4. New CS type of absorber: a) front side, b) back side.

3. Novel type of window facade collectors (modules) – CS type

Solar façade collectors are an elegant and aesthetically units of integrating solar thermal technology in buildings. However, integration currently requires full building refurbishment or in the case of a new building - then at beggining during the designing stage for the building the action for collectors' integration is taken.

During installation of the window modules (Fig. 5) in the existing or the same new window frames of the buildings, there is no need of elevators, protection equipment etc...for their integration. The installation is from the inner side of the building like mounting the windows. If there is a case of their installation during the stage of building, then the same equipment is used for installation of the windows module as well.

The main characteristics of novel CS collector (module) are summarised below:

- the surface area of contact between Cu tubes of the absorber and flat plate (that is Al or Cu) is three times bigger than that one of the standard collector, that means it is a better heat transfer;
- there are no waves on Al or Cu absorber due to the novel welding;
- no melting on the selective coating in spots as it is in laser welding case or ultrasound welding, and no any damage on the selective coating;
- the selective coating is totally undisturbed and there is no diffusion processes of oxygen, water or penetration of other substances that will cause corrosion of absorbers' plate.
- the contact between Cu tubes and Al plate is stable and it is not changed during lifetime of collector's existence and function.
- The module is made of two glasses and between them is the absorber. Behind the absorber is material that absorbs the humidity in the inner space found during the assembling of the collector. (After assembling there is no way to have new quantity of air/humidity, the inner area is totally without any humidity issues). The fact that there is no condensation inside the collector means that there is no any fraction of the collector's energy to be used for evaporation of the water.
- There is a good appearance of these modules on the buildings (Fig. 5) that can be made in different colours to fit the facade colour (Fig 6).
- The efficiency is greater than other flat plate collectors as it is shown in Fig.7.

a) b)

Fig. 5. Window –façade module made with CS absorber: a) single module, b) set of 4 modules.

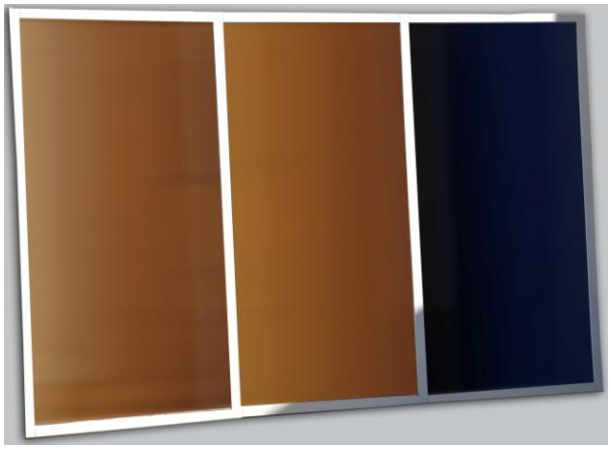

Fig.6. Different colours of window facade collectors.

4. Results and discussion

The Absorber of CS collector consists of 10 copper pipes ultrasonically welded with the aluminium full plate absorber with PVD selective coating with high efficiency. The new type of welding (Fig. 4b) of these absorbers contributes to:

- high coefficient of heat transfer and better performance compared to other types of absorbers.
- Fig 7. show comparison of the efficiency curves of absorbers that are laser welded (blue line) and new type of CS welding technology (red line). (Measurements are performed in independent German laboratory). The novel CS type of welded absorbers are more efficient than other ones.
- there is one of the best appearance of these facade collectors because absorbers are without welding lines and waves; the outer surface of the collector is very similar to window glass surface and therefore is the good choice for implementing in facades as well as to roofs.
- Additionally, the other advantages of these collectors are: smaller stagnation temperature during the summer time due to the fact of angle of installation.

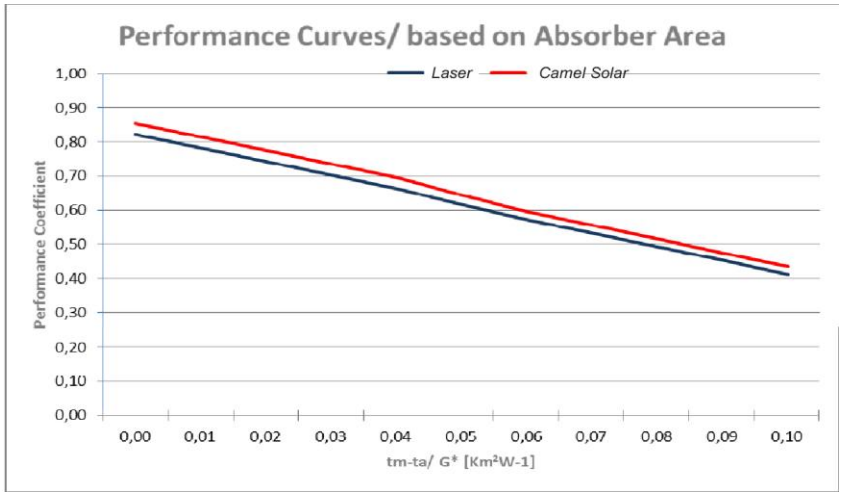

Fig. 7 . Efficiency curves compared for laser welded absorber and new type of CS absorber.

Fig. 8 presents the first demo building where novel CS collectors are installed (in middle vertical column in the existing window frames).

Figure 8. Facade –window collectors installed in south façade in existing Al frames as normal windows. In the middle column of the building are installed the façade window collectors (left and right are normal windows).

5. Conclusion

Novel type of window façade solar thermal collectors are multi-benefitial and functional novel elements integrated in the architecture. The new window module is already installed in several buildings in the last two years and the first results from in-field testing are very satisfying. These field tests are in progress and there will be a continuation of this work.

The main characteristics of window façade collector are summarised as:

a) good architectural appearance that can match the colour of the building façade (Fig. 6 and 8),
b) very high efficiency of these collectors (Fig. 7),
c) long term stability is extended and stable efficiency of the collector over long period of time during their function is shown and expected,
d) no corrosion issues due to the lack of humidity inside the collector (two years experience from installed modules and internal testing's confirmed this statement),
e) no destruction of the selective coating of the absorber is achieved due to the new type of welding of CS absorbers; therefore optical characteristics are kept constant for a longer period of time and no corrosion attacks are envisioned.

The experience with the novel façade-window collectors in demonstration building showed good and acceptable results during the test period, especially in winter time. There are benefits of them in summer time as well, lower stagnation temperature are measured due to the angle of installation on the vertical facades.

Acknowledgment

Data presented in this paper are collected and measured in CS facilities (Macedonia). The work is sponsored by the manufacturing company for window facade collectors- Camel Solar, and by team of collaborators of the authors.

1. Short Summary

The construction sector plays a key role in sustainable development. It is therefore necessary to begin thinking about efficient ways to reduce harmful environmental effects. In this regard the focus should not only be on saving energy during the buildings operation, but also on the environmental performance of construction materials.

In this paper the consequences of sustainable development and sustainability will be discussed with respect to recent standardization activities and building certification systems. The development of innovative building skins in the context of sustainability assessment is presented for the case of a multifunctional plug & play facade (MPPF). Special solutions for energy-efficient operation, active and passive facade components for the use of solar energy will also be presented and evaluated, comparing the MPPF and a standard Façade.

Keywords: Facade; use of natural resources; end of life scenario; energy efficiency

2. Introduction

This paper gives an overview about the standardization activities of CEN and current building certification systems with a special focus on building skins. In the first part of the article there will be explained the latest developments of the standardization work on “Sustainability of Construction Works“[1]. As well as a preview of the future construction regulations, which include the new basic requirement No.7 “Sustainable Use of Natural Resources“ [2].

In the second part of the paper, the consequences of sustainable development in the construction sector will be discussed and the role of building certification systems will also be explained. Using the example of the multifunctional plug & play facade (MPPF) [3], the main measures of the sustainable assessment criteria will be explained. Special solutions for energy-efficient operation, active and passive facade components for the use of solar energy will be presented. Interior comfort and structural issues in production phase, as also for the maintenance works or any changes in use of the façade, will also be considered.

As a result of analyses based on several certification systems the impact of the ecological influence for different certification schemes will be shown. The importance of environmental assessment is one of the optimization tasks for future constructions.

2.1 Green and sustainable building

The construction sector has a great influence on sustainable development since it plays a key role in the consumption of energy and resources as well as in solid waste accumulation [4, 5]. It is therefore importanct to quantify the environmental performance of buildings in order to communicate their potential environmental impacts. [6, 7, 8]

Assessment methods for sustainability have been developed since the early 1990s. The International Standardization Organization (ISO), for example, prepared the first standards to address specific issues and aspects of sustainability relevant to buildings and civil engineering works (e.g. ISO 21930[9]). Already these standards were based on the Life Cycle Assessment methodology (LCA) in ISO 14040 [10].

On the basis of the ISO work, the European Committee for Standardization is working on a set of standards to harmonize the methodology for a sustainability assessment of buildings using the life cycle approach. According to the upcoming European Standards [11, 12, 13, 14, 15] the assessment of the environmental performance of buildings is based on LCA expressed with quantitative categories and Life Cycle Cost Assessment (LCCA).

In the past few years a growing number of building certification systems for green and/or sustainable buildings has been emerging in the market [16, 17, 18] parallel to standardization work to endorse green and sustainable buildings. As several building certification systems involve the assessment of the environmental and/or economic performance, these methodologies are definitely worthwhile looking at more closely [19, 20, 21].

A first evaluation of national and international building certification systems used in Austria shows that most of them do not include the assessment of the environmental performance with the use of LCA and the economic performance with the use of Life Cycle Cost Assessment (LCCA) is currently not fully in line with the upcoming European framework of CEN/TC 350.

2.2 Goal and scope

The aim of the present work is to give an overview about the standardization activities of CEN and current building certification systems with a special focus on building skins. Furthermore, an environmental LCA–based comparison between the Multifunctional Plug and Play Façade (MPPF) and a standard façade will be carried out.

In the conclusion and outlook we show how this might be integrated in the planning process to guarantee a better predictability of sustainability in the development of façades.

3. Standardization and Certification systems

3.1 Integrated performance of buildings according to CEN/TC 350

In the last few years many regulations for the environmental sector have been developed. The Technical Committee 350 is responsible for the development of new standards in the field of sustainability. In this context the two most important standards for the Austrian market, are the ÖNORM EN 15804 [10] and the ÖNORM EN 15978 [12]. These two standards form the basis for sustainable development in the material, building and construction sector.

Another important document of CEN/TC350 is EN 15643-1:2011[8]. Its goal is defined by supplying a common framework methodology that includes the principles, requirements and guidelines for a holistic assessment of the sustainability of buildings concerning their environmental, economic and social performance over the whole life cycle. The item to be assessed is the building including the site on the basis of user requirements in terms of a so-called "functional equivalents". The standardization documents will not include regulations regarding evaluation, quality-levels, or classes (benchmarks).

It is generally assumed that most of the CEN/TC 350-sustainability-standards will be available during 2013. Figure 1 shows the concept of the integrated building performance that incorporates environmental, social and economic performance as well the technical and functional performance that are intrinsically related to each other.

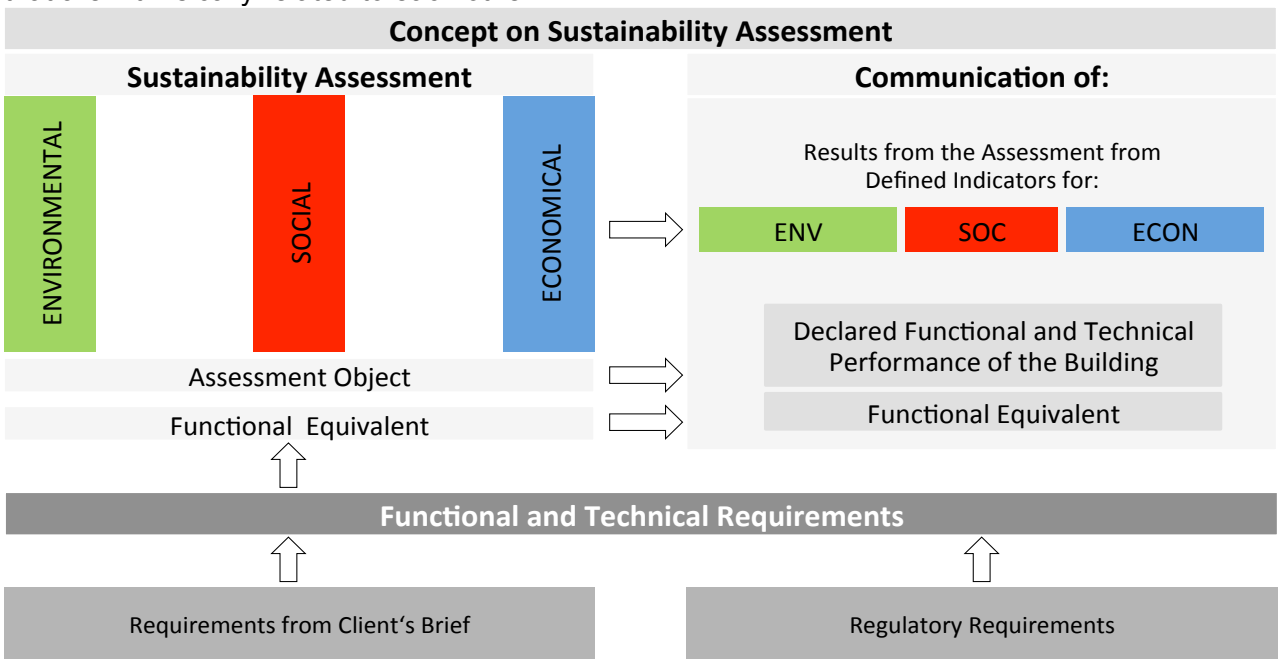

Figure 1: Concept of sustainability assessment of buildings [11]

3.2 The Construction Products Regulation

The Construction Products Regulation (305/2011/EU - CPR[1]) – replacing the Construction Products Directive (89/106/EEC - CPD[2]) is laying down harmonized conditions for the marketing of construction products. The European Parliament and the Council of the European Union adopted the CPR on March 9th 2011. The main parts of its substantial articles have been applied since the 1st of July 2013, at which time it replaced the CPD. The already applicable parts of the CPR focus on the notification and designation processes of the Notified Bodies (NB) and the Technical Assessment Bodies (TAB). The CPR is to ensure reliable information on construction products in relation to their performances, which is achieved by providing a *common technical language*, offering uniform assessment methods of the performance of construction products. These methods have been compiled in harmonized European standards (hEN) and European Assessment Documents (EAD). This common technical language is to be applied by:

- manufacturers when declaring the performance of their products, but also by
- authorities of Member States when specifying requirements for them, and by
- industry users (architects, engineers, constructors…) when choosing the products most suitable for their intended use in construction works.

One the major revisions concerns the basic requirement *hygiene, health and environment* and the addition of a new basic requirement (No. 7) *sustainable use of natural resources*.
This means that construction works must be designed, built and demolished in such a way that the use of natural resources is sustainable and in particular ensure the following:

a) reuse or recyclability of the construction works, their materials and parts after demolition;
b) durability of the construction works;
c) use of environmentally compatible raw and secondary materials in the construction works.

[1] http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:2011:088:0005:0043:EN:PDF
[2] http://eur-lex.europa.eu/LexUriServ/LexUriServ.do?uri=OJ:L:1989:040:0012:0026:EN:PDF

3.3 Building Certification Systems

In addition to the standards and regulations, building certification systems play an important role as voluntary instruments. In these certification systems a set of criteria is defined assessing the individual performance categories of buildings, allowing a comparison of different buildings.
At the international level, there already exist a large number of certification – systems, like BREEAM (BRE Environmental Assessment Method), DGNB (Deutsche Gesellschaft für Nachhaltiges Bauen) or LEED (Leadership in Energy and Environmental Design). In Austria there are currently three systems, to be mentioned. First the ÖGNI (Österreichische Gesellschaft für Nachhaltige Immobilienwirtschaft) – system, which relies on the DGNB - system from Germany. Second the TQB (Total Quality Building) – system of the ÖGNB (Österreichische Gesellschaft für Nachhaltiges Bauen) with its related Klima:aktiv system.

4. Assessment methodologies

In order to identify the main influences of the different types of façade constructions on their environmental performance, a comprehensive analysis of the MPPF in order to an standard facade was carried out over their life cycle using the LCA method. The influence of the construction products is being compared over individual life cycle stages in relation to the building operation. Only this integrated approach allows for correctly quantifying the effective contribution of the façade construction and the different technical modules, which are integrated in the facades.

4.1 Methods for assessment of environmental performance of facades

This work was undertaken according to the European Standards [11] written by CEN/TC 350 that provide a system for the sustainability assessment of buildings using a life cycle approach. In this concept, the sustainability performance incorporates the environmental, social and economic performances as well as the technical and functional ones, and they are all intrinsically related to each other. The assessment quantifies impacts and aspects using quantitative and qualitative indicators. The purpose of this series of standards is to enable comparability of results of assessments without value judgments or setting benchmarks or levels of performance. The assessment of the environmental performance of buildings is based on the methodology of LCA [22] expressed using quantitative assessment categories [12, 15].
In contrast to the above-mentioned approach, this work only focuses on the quantification of the assessment of the environmental performance from two different types of facades. Thus, trying to quantify only parts of the sustainability performance in general does not seem to be sufficient, and a more integrated LCA approach was adopted.

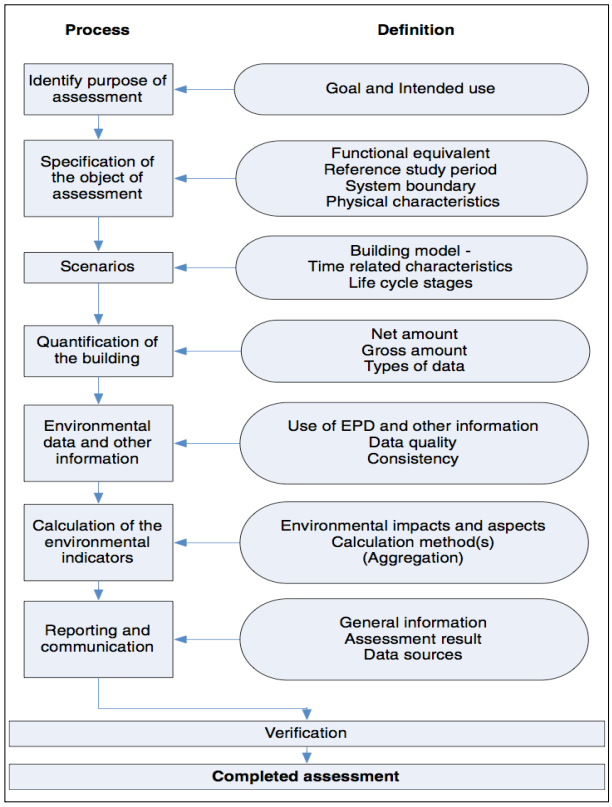

Fig. 2 Main steps within the environmental assessment–workflow according to FprEN 15978 [12]

Figure 2 displays the main steps in the process of assessing the environmental performance according to the FprEN 15978 [15] and gives some examples for required definitions. The scope of the various assessment steps needs to be adjusted to the goal of the assessment. In the various steps. Step number 4 - “quantification of the building” - similar to the LCI in ISO 14040 [10], plays a major role, since the quantification of the environmental performance can be accomplished on this basis.

4.2 Key parameters

For the assessment, the following key parameters, shown in Table 1, were defined. For the reference study period, 50 years was assumed. The functional unit used is an office block, which has been designed by a project partner.

Goal	Complete LCA
Scope	Two different facades life cycle entire facade products
Reference study period (T_{ref})	50 years
Quantification of the operational energy	According to ÖNORM H 5055
Functional unit	Office building (fictitious)
Environmental data	ecoinvent 2.2
Methods	CML 2001, cumulative energy demand
Indicators	AP, EP, GWP, ODP, POCP, CEDr, CEDnr

Table 1 Key assessment parameters

4.3 Inventory analysis

For the LCI based on the bill of quantities for each facade, *ecoinvent*[3] database v2.2 [23, 24] was chosen. This database contains industrial life cycle inventory data for, e.g. energy supply, resource extraction, material supply, metals, waste management services, and transport services.

The life cycle inventory was organized in a matrix. This allowed us to analyze the results for different life cycle stages of the façade constructions as well as for the environmental indicators specific to the construction products and specific to the building operation (use stage). Figure 3 shows the organization of the life cycle inventory and inventoried classes. The building life cycle is therefore divided into the before use, the use, and the end-of-life stage as well as into impacts and aspects specific to the facades and specific to operation.

The boundary conditions of the system determine the processes that are taken into account and are divided into time-related and space-related system boundaries. The time-related boundary covers the before-use stage, the use stage, and the end–of-life stage. The space-related system boundary concerns the whole façade constructions of the fictional office building. This includes all upstream and downstream processes needed to establish and to maintain the functions of the facade, ranging from the acquisition of raw materials to the end-of-life stage.

[3] The ecoinvent Centre, a competence center of ETHZ, EPFL, PSI, Empa, and ART, Switzerland

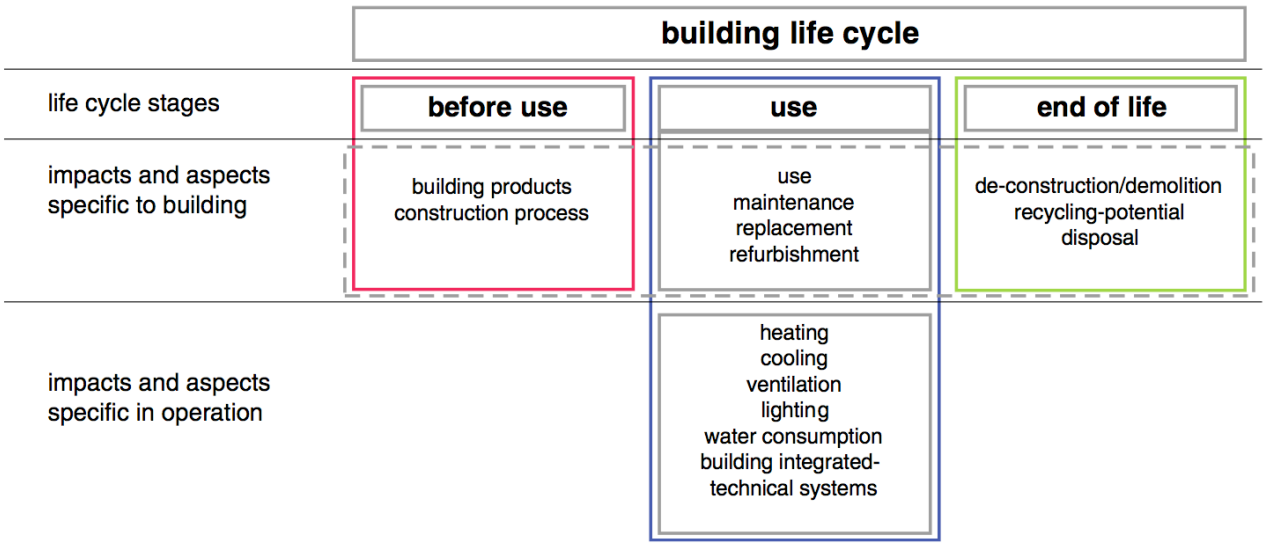

Fig. 3 Organization of the life cycle inventory in accordance with the life cycle stages [25]

4.4 Before-use stage

The before-use stage covers cradle-to-gate processes for construction products (materials/components) and services used for the construction of the facades. The LCI matrix is based on the different construction and support components of the different facades.

In a second step, the items were analyzed for their LCA relevance, which means that construction work without an influence on LCA, e.g., additional charge for special products or work, was ignored. For the LCI of the technical facade equipment, the materials for solar heating systems and PV – installation were taken into account. All technical facade equipment materials were analyzed in detail.

4.5 Use stage

The use stage spans the period from the completion of the construction works to the point when the facade reaches its end of life. The system boundary in the use stage includes the use of construction products (maintenance/replacement) and services for operating the building skin (see Fig. 3). For all construction products (components/materials) that may be replaced, the estimated service life (ESL) was defined in accordance with ISO 15686 parts 1 and 8 [26, 27]. The number of replacement rates for all specific construction products used in the buildings was calculated according FprEN 15978 [15]. Their estimated service life was taken assuming the values by the ESL-Catalogue in Austria [28]. The values given within the ESL are estimates obtained by expert opinions and experience. These values correlate with values in Blom [29] in the case of the technical building equipment.
The Institute of Thermal Engineering has calculated all energetic inputs and outputs for the different types of facades, according to ÖNORM H 5055.

4.6 End-of-life stage

The end-of-life stage of a building begins after the use stage, when the building is decommissioned and is not intended to have any further use. In the presented study, we assumed that the facade would be deconstructed at the end of its life stage and would provide a source of materials to be reused, recycled, recovered, or landfilled, depending on the type of construction product.

4.7 Quantification of the environmental performance

The calculation of the environmental performance is based on indicators according to FprEN15978 [15]. The underlying method is the LCIA according to ISO 14040 [10]. The indicators represent the quantifiable environmental impacts and aspects during the building life cycle. Environmental impacts are expressed with the impact category indicators of LCIA (e.g., global warming potential (GWP)) using characterization factors according to prEN 15804 [13], whereas environmental aspects are based on input flows of the LCI and describe, e.g., the use of renewable and non-renewable primary energy resources (cumulative energy demand (CED)). Out of the 22 indicators listed in the FprEN 15978 [15], [4] seven environmental indicators were selected which are given in Table 2. These seven indicators have been chosen because they are commonly used in practice, e.g., also in building certification systems, and widely accepted calculation methods.

For the calculation of the indicators describing environmental impacts, the characterization methods for the impact assessment according to CML 2001[5] [30, 31] were chosen (see Table 2, “Indicators describing environmental impacts”). For calculation of the indicators describing resource use, the cumulative energy demand (see Table 2, “Indicators describing resource use”), which has been implemented in ecoinvent v2.2, was selected [32].

The environmental indicator values for each indicator were calculated for each product in the different life cycle stages based on a matrix calculation routine (FprEN15978 [15]). This routine consists in multiplying each product and service quantified in the different life cycle stages of the building with its respective value for any environmental indicator. The same calculation routine was applied to all indicators listed in Table 2.

Indicators describing environmental impacts	Code	Unit
Acidification potential of land and water	AP	kg SO2 equiv
Eutrophication potential	EP	kg PO4 equiv
Global warming potential	GWP	kg CO2 equiv
Depletion potential of the stratospheric ozone layer	ODP	kg CFC 11 equiv
Formation potential of tropospheric ozone photochemical oxidants	POCP	kg ethylene equiv
Use of non-renewable primary energy (energy resources)	CEDnr	MJ-equiv
Use of renewable primary energy (energy resources)	CEDr	MJ-equiv

Table 2 Indicators for characterizing environmental impacts and describing resource use

[4] The environmental indicators proposed in the FprEN 15978 (FprEN15978) at the moment consist of seven indicators describing environmental impacts, eight indicators describing resource use, three Indicators describing waste categories, and four indicators describing the output flows leaving the system.

5. Multifunctional Plug & Play Façade (MPPF)

5.1 Goal and Scope of the research project

In the last decades industrial prefabrication has been used mainly for building products and to some extend for building elements. The lack of technical knowledge and the lack of possibilities for individualization of components often led therefore to a monotonous design of elements and buildings, and created a poor image of prefabrication technology.

Recently some things have changed for the better. The rapid growth and availability of computer capacity to perform calculations and newest prefabrication technologies allow for the first time a combination of highly efficient prefabrication technologies with design tools simultaneously allowing a high individualization of products i.e. façades. In practice, this leads to enormous time- and cost savings as well as following possibilities:

- Comprehensive high quality transdisciplinary integral planning
- Efficient high quality prefabrication
- Minimization of installation times with lower error rate
- Mass production of basic elements due to prefabrication
- Expanding design options due to a modular approach
- High potential for enhancement of sustainability performance

Due to this initial position the K-Project, “Multifunctional Plug & Play Façade” (acronym: MPPF), launched in 2008. The research project MPPF aims the development of a multifunctional façade system to be used in modular construction methods with the highest possible level of prefabrication. The approach lies in “the expansion of the functionality of these prefabricated façade elements with building engineering functions (like e.g. heat, cold input, air input, lighting, water, power and IT supply) as well as by solar energy technologies (solar thermal, PV)”[33].

5.2 MPPF design principles

Within the MPPF project a criteria list for requirements for a Multifunctional Plug & Play Façade was developed [34]. These requirements are based on following design principles [acc. to 35]:

1. Adjustment of lifetime of structural components to estimated service life of the façade
2. Promoting of recyclability due to
   a. Simple disassembly
   b. Ease of dismantling and
3. Recyclability of materials. Components shall be
   a. Accessible,
   b. Verifiable,
   c. Repairable and
   d. Replaceable.
4. Reduced cleaning effort due to
   a. Accessibility of the surfaces and
   b. Material surfaces itself.
5. Reduction of transport related environmental impacts due to
   a. Optimization of transport routes (components to prefabrication site and building site),
   b. Optimization of truck capacity utilization (volume and mass goods) and
   c. Fuel-efficient and low-emission vehicles.

6. Requirement of documentation of the façade construction
   a. Materials and components,
   b. Maintenance and inspection schedule.
7. Development of a maintenance strategy
   a. Service schedule,
   b. Inspection plan,
   c. Replacement and improvement strategies
8. Use of components which guarantee following:
   a. Reduced primary energy and low impacts and
   b. Recycling materials or materials with high recycling content.
9. Reduction of the energy demand in the use phase due to
   a. Excellent thermal insulation properties of the façade and
   b. Special attention to technical connection details,
   c. Heat protection during the summer.

In addition to these *MPPF design principles* it could also be shown [36] that the MPPF guarantees best possibilities in terms of dismantling und recyclability. More than 84% of the used materials can be directly used for recycling, if a carefully planned recycling concept is implemented.

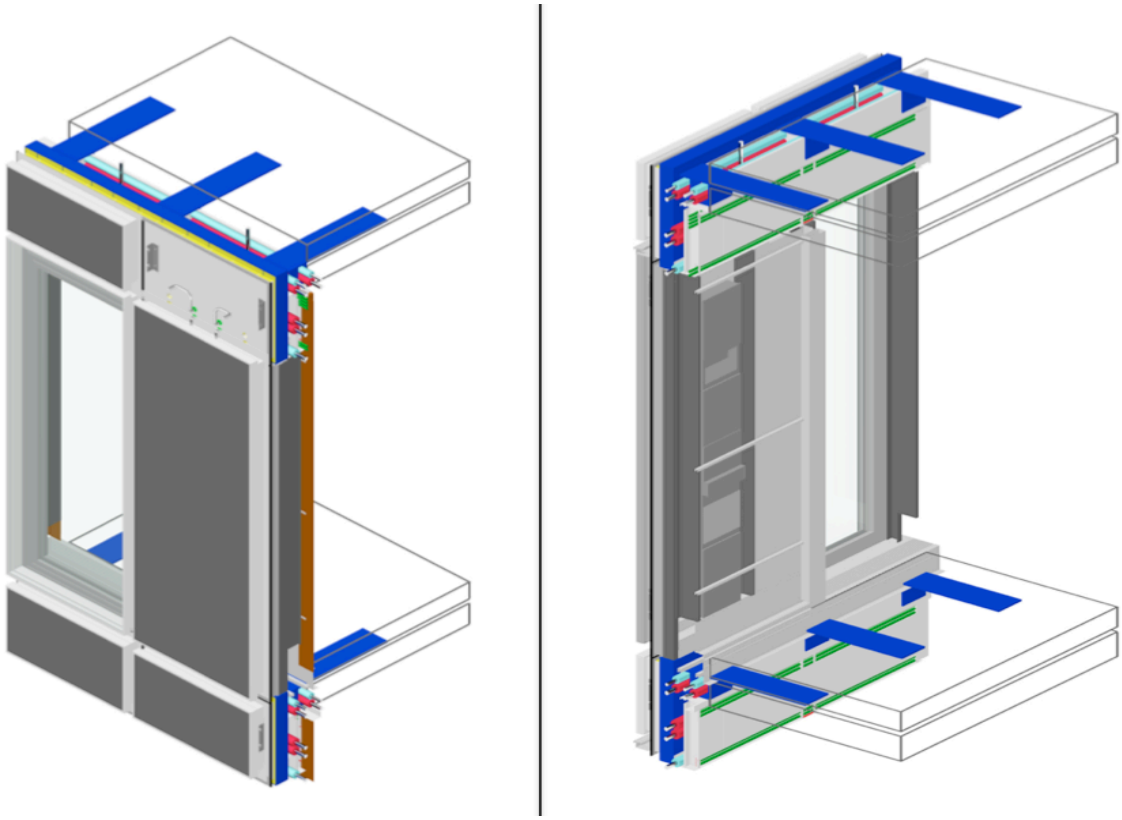

Fig. 4 System sketch of the MPPF [39]

6. Standard Façade

To create a reference to the MPPF it was necessary to design a standard façade, which is based on nearly the same requirements.

The rationale behind the MPPF is a high degree of prefabrication. For that reason it was decided to use an element façade as a basis for the comparison.

6.1 Design principles

An element façade consist, just like the MPPF, of prefabricated modular elements. The individual elements of the unitised façade system are produced in a factory. This means, that all components of the façade, even sun protection and photovoltaic panels get installed in plant.
On site, the finished modules only have to be attached on the building with adjustable anchors.

1. Rational planning of recurring façade elements
2. Specific solutions for different types of buildings
3. Integration of system components like sun protection and photovoltaic panels
4. High performance levels and process safety because of prefabrication
5. Saving time and money by using a prefabricated façade elements

In response to these demands it can be concluded, that an element façade system shows a basis for comparing the MPPF.

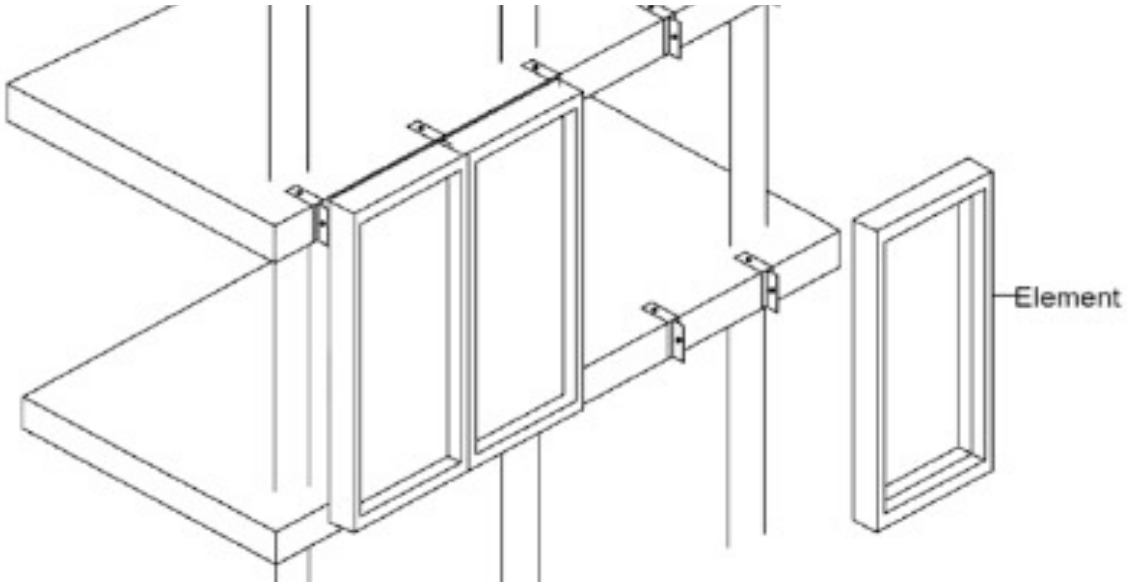

Fig. 5 System sketch of the element façade [40]

7. Comparative results of the different types of facades

The challenge was to show the environmental impacts of the MPPF in order to a conventional facade. Out of that reason the first step was to find a façade, which is constructed by nearly the same basic requirements as the MPPF. This was done by a research and compilation of the characteristics of different types of facades. Investigations revealed that it makes sense, to use an element façade for the comparison.

The next step to realise an LCA for the two different building skins was to obtain certain basic information about the MPPF as well of the element façade too (e.g. power demand, material input,…). In order to this information's it was also necessary to impose the masses of the materials, which were used in the façade constructions.

After collecting all the important basic information's about the materials and characteristics of the two facades the LCA could be done. The results out of the LCA of the different building skins as also the comparison is shown in the following subchapters.

7.1 First comparison, basic structure with passive covering

This first contrasting juxtaposition shows the MPPF basic structure in order to the element façade without any implementation of an active element into the skin of the building.
Figure 6 shows the impacts in order to the different parts of the standard façade. The diagrams of the several indicators clearly show, that the main environmental consequences came out of the finishing elements. For this diagram there also must be mentioned, that active elements like solar thermal panels or photovoltaic panels hasn't been considered in the first step of the investigation. The results for the active building skin will be shown in the next subchapters.

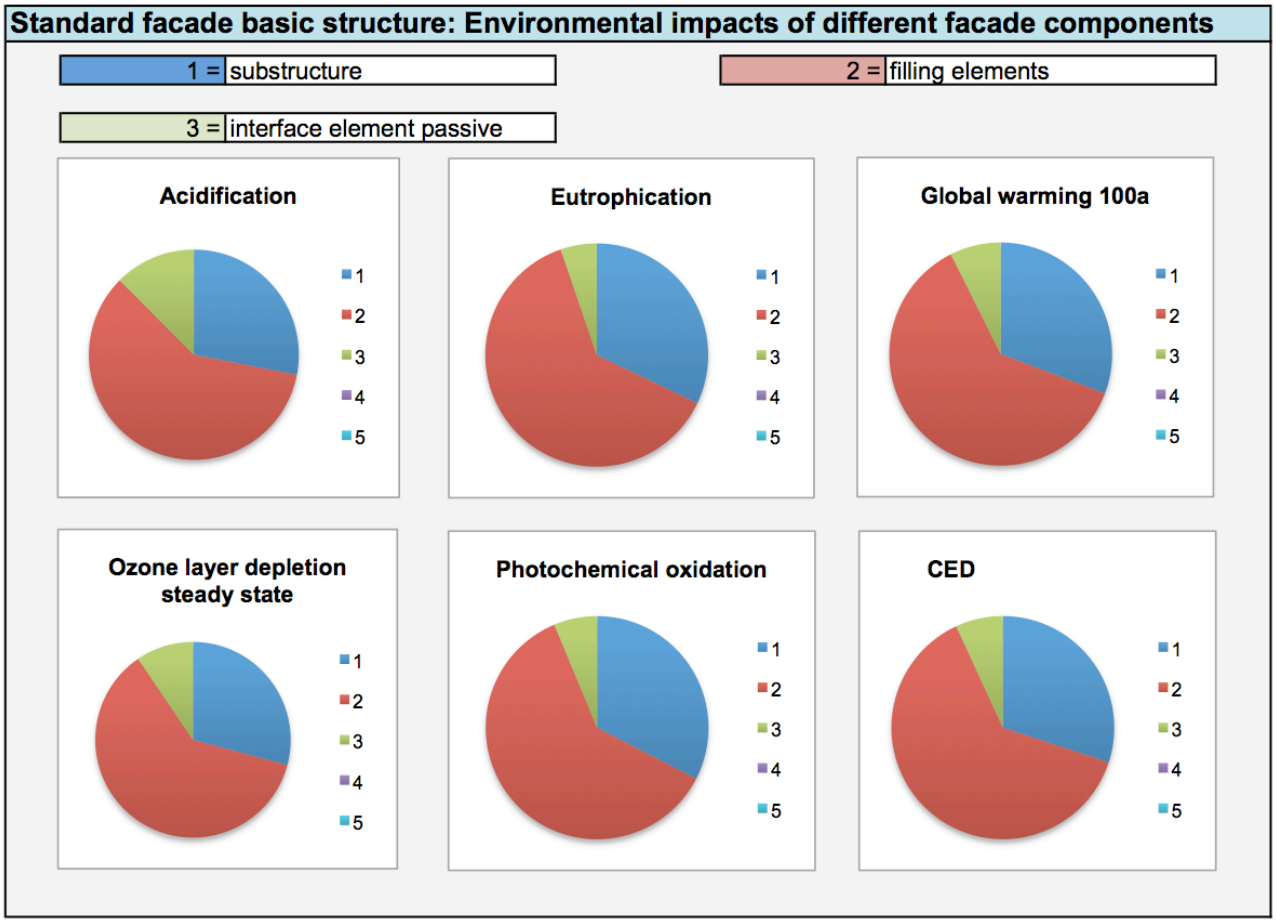

Fig. 6 Environmental impacts of different facade components on the example of the standard façade basic structure

In Figure 7 the issues of the LCA for the MPPF without any active building skin are presented. Out of the pie charts the most environmental relevant components of the MPPF basic structure are shown. Compared with the results of the standard façade (Fig. 6) it is easy to detect, that the majority of the environmental impacts move from the finishing element (standard façade) to the substructure (MPPF basic structure).

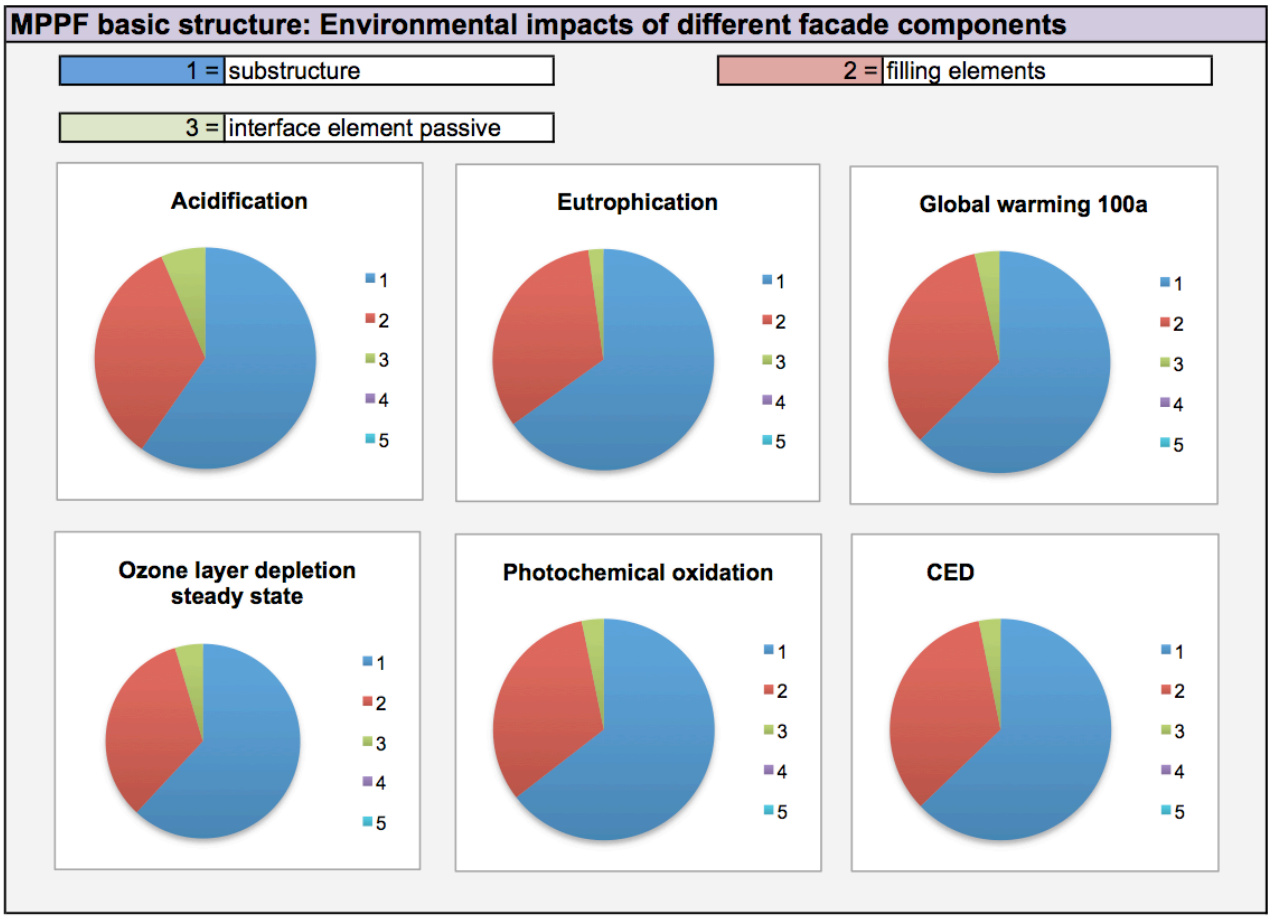

Fig. 7 environmental impacts of different facade components on the example of the MPPF basic structure

The line graph in Figure 8 represent an comparison of the energy demand over a observation period of 50 years. Out of this image (Fig. 8) it is easy to ascertain that a great store of embodied energy is necessary for the production of the facades, especially for the MPPF basic structure because of its substructure, which is necessary because of the requirements described in chapter 5.2. The illustration shows also, that the energy consumption of the building with the MPPF needs less energy over 50 years than the standard façade but the sum of the cumulated energy (embodied and operations energy) of the MPPF is still higher after 50 years of use.
One should bear in mind that in LCA functional and technical performance levels of different Façade systems could not be pictured. This means that the major advantages of MPPF like space for building technical equipment, plug & play capability, dismantling possibilities are not included in the results of Figure 8.

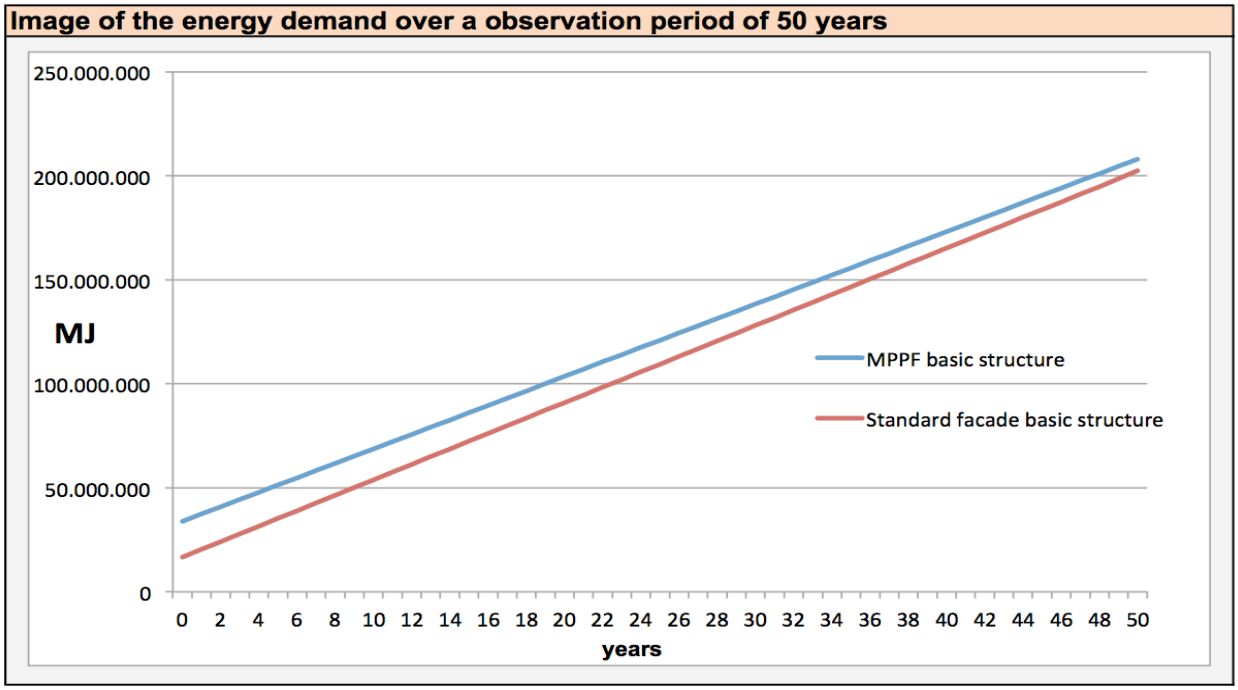

Fig. 8 Image of the energy demand over a observation period of 50 years (basic structure)

7.2 Second comparison, MPPF basic structure and MPPF with active covering (PV)

The second comparison shows the MPPF basic structure in order to an MPPF with implementation of active elements into the building envelope. For this arrangement, photovoltaic panels replaced all the passive items of the facade.
Picture 9 shows the results of the MPPF with an active building skin by the use of PV-Panels (polycrystalline PV - modules). Even though the environmental impacts from the PV-modules are very high, the substructure of the MPPF causes still the most ecological effects.

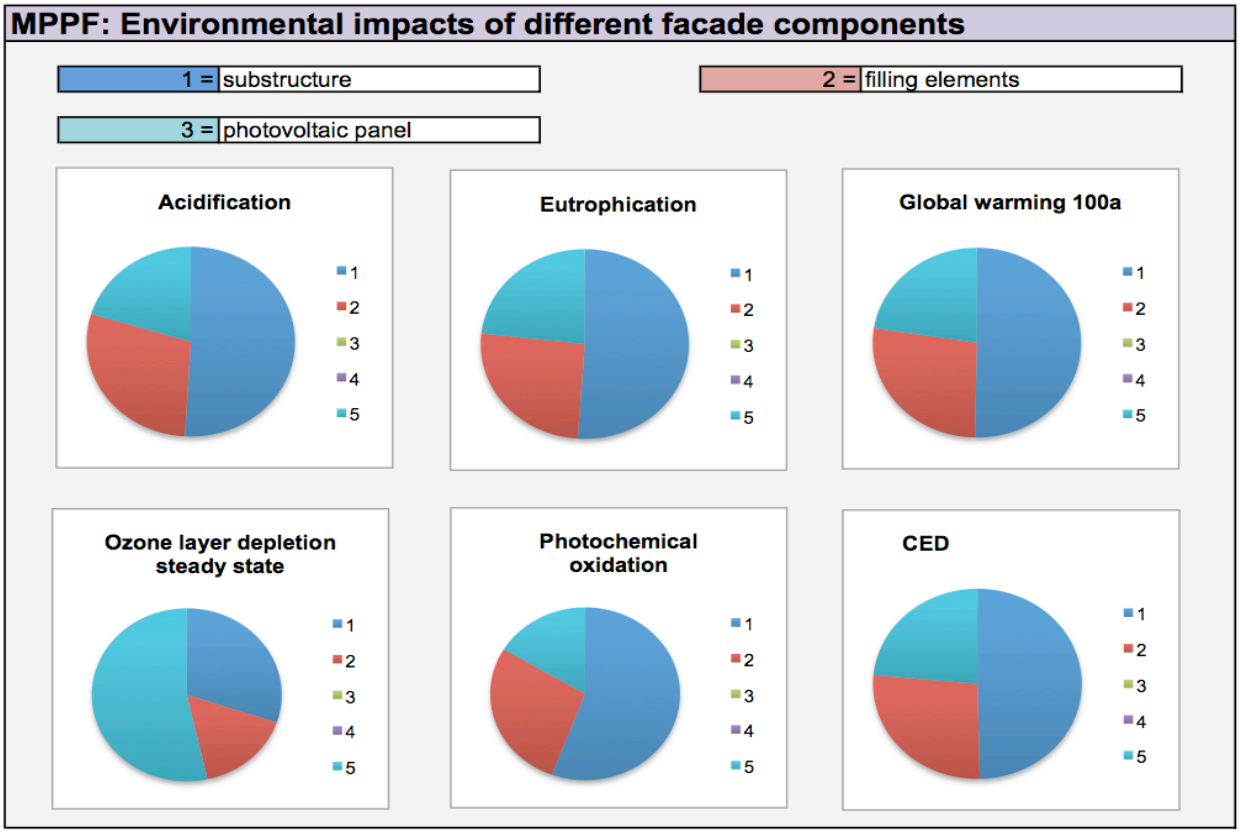

Fig. 9 Environmental impacts of different façade components on the example of the MPPF

Out of the line graphs of figure 10 it can be seen that the MPPF – active needs less energy than the MPPF-passive after a report period of around 4 years. Due to this it can be concluded, that an integration of active modules in the façade is indispensable for an optimization of the energetic building performance.

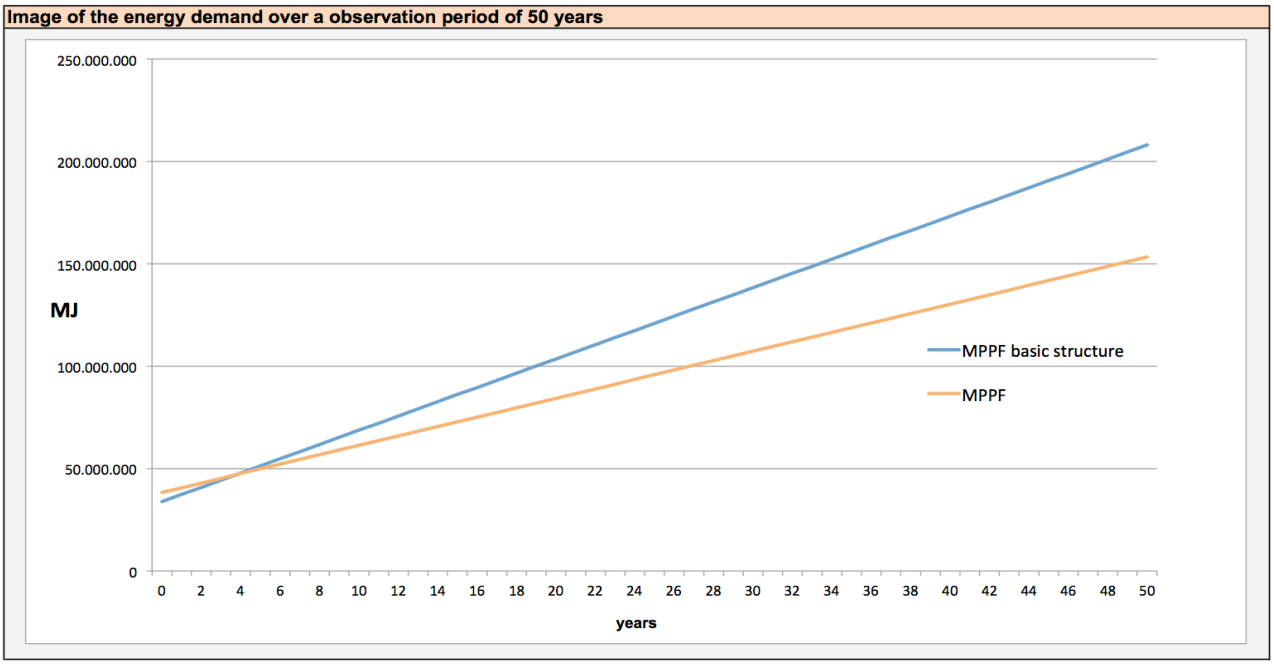

Fig. 10 Image of the energy demand over a observation period of 50 years (MPPF basic structure versus MPPF)

8. Conclusions & Outlook

The demand on buildings, which allow the enhancement of the principles of a sustainable development, will gain more and more importance in the private as well as the public sector. This trend is based not only on marketing demands but also due to the need of better life cycle performance. One of the instruments in proving the performance is building certification, which includes aspects as e.g. LCA and LCCA as well as user comfort (as part of the functional performance) or technical aspects.

For the design of façades this results in increased requirements. This means not only the development of “innovative” building products or elements but also in the “active” provision of adequate product information i.e. EPDs (Environmental Products Declarations) as well as the optimization of processes through out the value chain. A major trend is the assessment of the whole building where every part / component must ensure its contribution to the overall building performance.

For the MPPF project it can be shown that the design of the Façade has a big influence on building LCA results. Additionally the upcoming requirements i.e. sustainable use of natural resources by the new CPR or the assessment criterion “ease of dismantling and recycling” can only be fulfilled by a design process, which considers all these aspects and by façade systems, which integrate building engineering functions as well as solar energy technologies. Prefabrication technology makes it feasible to predict the performance of the façade.

The optimization of the energy performance as well as the optimization of the material choice in the construction (e.g. in terms of LCA or risks to the local environment), functional or technical assessment criteria is one of the most important criteria in the construction sector. It could also be shown that the functionalization of Facades is not only a trend but also environmentally reasonable. As the MPPF allows a broad range on functionalization (e.g. solar thermal, PV and HVAC system) an LCA should be performed on the building level comparing the integration of building functions into the Façade vs. conventional Facades and conventional technical systems.

One should bear in mind that the improvement of building performance is a non-linear approach as different assessment criteria influence each other (i.e. an interdependency of criteria) [37, 38]. Only by ensuring that already the design options are based on a holistic life cycle performance assessment, the demanding challenge of a holistic improvement of building performance can be reached in future [38]. Using a systematic approach could be one way in coping with the complexity of different requirements.

9. Acknowledgements

Part of the research described in the paper is part of the project "Multifunctional Plug & Play Facade" (Project-No.: 815075), supported by funds of the Austrian Research Promotion Agency (FFG), by the federal states of Styria, Carinthia and Lower Austria, as well as by a consortium of scientific institutions and companies, guided by the "Hans Höllwart - Forschungszentrum für integrales Bauwesen AG" (CEO, Mario J. Müller).
Special thanks to the Institute of Thermal Engineering for the calculation of the energy demand for the different types of facades.

Short Summary

The paper presents life cycle analysis (LCA) results of the passive house in Lithuania. For the first approach three the most common and relevant impact categories of the life cycle were chosen – energy consumption, global warming potential and ozone layer depletion. Results of the LCA together with simulations of operational energy demand assert that embodied energy (construction & maintenance) constitutes 1/3 of the whole LCA energy, 1/5 embodied ozone layer depletion, and 2/3 of global warming potential. The environmental impact of various life cycle phases is presented. It is concluded that for different climates, during the life cycle of the energy efficient house, embodied energy is higher than in conventional buildings. Therefore sustainability of the construction materials and different occupation profiles has to be considered very carefully. In addition, influence of the occupants on LCA of the building is illustrated. Results show that it is not always purposeful, when performing dynamic LCA to take into account changes in occupation of the house.

Keywords: LCA; energy efficient house; embodied, occupants, environmental impact, simulation.

1. Introduction

Increase of energy efficiency in buildings sector is a key objective of the European Union's (EU) energy policy. With the adoption of recast Directive 2012/31/EU [1] - the main legislative measure in buildings energy efficiency sector, Member States were obliged by 2020 to move towards new and retrofitted nearly-zero energy buildings. Directive on energy efficiency 2012/27/EU [2] also aims to increase energy efficiency in buildings. But in frames of both directives, energy efficiency is understood as decrease of operational energy consumption of the building. Multiple researches came to the conclusion that the demand for operating energy reduction appears to be the most important aspect for the design of energy efficient buildings [3-7]. But this is correct just for inefficient or standard buildings. With the recent requirements of the above mentioned directives, buildings energy consumption during the operational phase started and will continue decreasing. Improvements made seeking to design more energy efficient building, as a rule, require more materials and as a consequence environmental impact of the building in its construction and demolition phases may significantly increase. The increasing energy demand to build an energy efficient building is already illustrated by some authors. For example, study performed by Blom et al. [8] has shown that improvement of the building equipping it with a heat pump causes the highest environmental burden of all the assessed climate systems. Blengini and Di Carlo [9] conducted a detailed LCA on a low energy family house and found that shell-embedded materials represented the highest relative contribution, but maintenance operations also played a major role. Citherlet and Defaux [10] study has shown that for a family house, it is important to be concerned about the indirect (construction and elimination phases) impact when the final (total) energy demand is lower than about 50 MJ/m^2/y for UCTE electricity mix.

Passer et al. [11] claim that despite many LCA studies were performed, the influence of the construction products used for the technical building equipment of buildings has hardly been described in literature and authors strongly recommend including the technical building equipment for assessments of the environmental performance of buildings. Some authors already have proposed to incorporate LCA approach to building's energy efficiency policy implementation measures. Some authors have already proposed to consider life cycle process in building's energy certification or energy auditing process [12-13]. Hence, an overall judgment on building sustainability should encompass all the life phases and this is emphasized by findings of above mentioned authors [8-10] and a holistic approach is needed, as single improvements might not be effective in a life cycle perspective. There is also a need for solutions adapted to particular climate conditions.

The presented study aims: 1) to assess environmental impact of the energy efficient single-family house, using LCA methodology, involving building's constructions and all engineering systems of the building (energy production, heating, ventilation, water supply, sewage and electrical installation); 2) to identify phases of the life cycle and elements of the building with the highest environmental impact; 3) to apply and evaluate measures to reduce environmental impact of the building during its life cycle; 4) to assess influence of occupants' characteristics (household size and age) and on life cycle of the building.

2. Methodology

Life Cycle Assessment (LCA) is a well-known and internationally identifiable method, properly described and determined by standards. Principles of LCA are also generally applied to environmental assessment of buildings and their constructions. Many studies on the environmental impacts during the operation phase of a building were performed as well as the analysis of life cycle costs, but there are still many questions and uncertainties regarding long-term and combined effects [14]. LCA is usually based on a static life cycle models. However, there are dynamic conditions in every phase of a building's life that could influence the balance of environmental burdens [6]. Dynamics could be expressed by changes in future resources, changes in equipment performance, future occupant behaviours. In some cases, changes during a building's lifetime can influence the LCA results to a greater degree than the material and construction phases. Adapting LCA to a more dynamic approach may increase the usefulness of the method in assessing the performance of buildings and other complex systems in the built environment [15].

Life Cycle Assessment (LCA) is currently used to a very limited extent in the building sector [16]. The recent studies proved that LCA should not be limited to building materials or building components only [17]. Therefore, making an LCA evaluation of a building requires a specific tool to process the large amount of data. The problem of LCA complexity was also analysed by Kellenberger and Althaus [18]. Study authors state that more building components should be studied. Some other examples of LCA studies and new techniques are presented in Table 1.

Despite existing standards, the depth of the methodology is not strictly regulated, therefore, as it was shown above, researchers are still free to choose models, tools and boundaries of the investigation. Main peculiarities and assumptions of the applied LCA method are presented below.

2.1 Life cycle assessment software and functional units

The LCA was undertaken using the computer tool SimaPro 7.2, with the functional unit 1 m^2 of the useful floor area. The single-family house in Lithuania and its subsequent use were calculated over a 100-year period. The key data for inventory analysis were identified by the simulation of the building and the data for impact assessment derived from IMPACT 2002+ V2.10 method SimaPro libraries. For the energy assessment of environmental performance during the operational stage of the building, also dynamic building energy simulation with DesignBuilder was performed.

2.2 System boundaries

The life cycle phases included in the study are: 1) production/construction, 2) operation & maintenance, 3) dismantling and recycling, 4) transportation in all phases. The production and the construction phase include a production of materials for initial constructions and transportation of the materials to their plant. The operation and the maintenance correspond accordingly to a demand of energy for the building usage (heating, ventilation, domestic hot water and lightning) and a renewal of the constructions/systems (a periodic replacement of their elements). The dismantling and the recycling mean a preparation of the embodied materials for their final disposal or recycling. It covers the initial construction materials and the materials replaced during the maintenance. A benefit of the recycling was not counted in the boundaries of the life cycle. The transportation phase amounts all transport facilities throughout the building life cycle (transport of the constructions, elements, materials and fuel). It belongs to the phases mentioned before,but it was separated from.

The elements of the building existence were assorted into two groups – embodied and operational. The first group consists of: walls, windows, doors, roof, foundations, floor, plumbing and sewage, heating system, ventilation equipment, and electrical installation. The second one comprises of heat for space heating (wood pellets), heat for domestic hot water (DHW) (wood pellets) and electricity. All the embodied elements were examined throughout all life cycle phases and the operational elements were evaluated only during the operation & maintenance, and transportation phases (except electricity).

2.3 Indicators

For the first approach the most common and relevant life cycle impact categories were chosen. The focus of this study was on three impact categories: non-renewable energy, global warming and ozone layer depletion. The indicators of the categories are presented in Table 1.

Table 2: Environmental impact categories

Environmental impact category	Indicator	Unit of measurement
Primary energy demand	Non-renewable energy	MJ
Global warming	CO2 eq	kg
Ozone layer depletion	CFC-11 eq	kg

All indicators were assigned for functional unit (the amounts per 1 m^2 of the useful floor area).

2.4 Inventory

Inventory analysis was performed itemizing the building structure. The main components were expressed as volumes of the constitutive materials. Thereby the 35 leading materials were analysed using SimaPro software.

Assumptions:

- The building will be used for over 100 years.
- Calculating the transportation phase, distances were chosen only approximately.
- Examining the materials of which separate elements were produced; a very minor items were not included.
- Domestic electric appliances, their energy demand and furniture were not included in the calculations.
- The operational life span of separate elements (replacement periodicity) was estimated according the national recommendations.

3. Description of the building

To analyse building's energy performance during its operational phase of life cycle, model, described below, was created and simulated in DesignBuilder.

Geometry. One-storey, square-shaped house was selected as an object for the analysis. The total area of the analysed building - 81 m^2. Building is designed for standard family of 4 persons. Other characteristics of the envelope are supplied in Table 3.

Table 3: Characteristics of the building envelope

Building system	Description
Exterior wall	U=0.11 W/m^2K. Materials: Cement plaster, silicate blocks, polystyrene foam, cement mortar.
Foundation wall	U=0.57 W/m^2K. Materials: concrete block, EPS expanded polystyrene, cement mortar.
Internal partitions	U=1.49 W/m^2K. Materials: gypsum plasterboard, air gap, gypsum plasterboard.
Roof	U=0.10 W/m^2K. Materials: bitumen, MW stone wool, EPS expanded polystyrene, aerated concrete roofing slab, cement mortar.
Floor on the ground	U=0.15 W/m^2K. Materials: gravel, EPS expanded polystyrene, concrete, plywood flooring.
Windows	Triple glazed windows: 4-16Ar-4-16Ar-4. U_{glass}=0.72 W/m^2K; U_{frame}=0.94W/m^2K. Materials: Argon, glass, PVC
Doors	Internal door – U=2.5 W/m^2K. Materials: plywood, air gap;
	External door – U=0.75 W/m^2K. Materials: painted stainless steel and foam polyurethane

Lighting and electrical installations. LED lighting with a specific lamp power of 3 W/m^2/100 lx is assumed to be installed. Lighting levels correspond to the requirements of national regulations.

Domestic hot water (DHW). Heat for DHW is produced using solar collectors and biomass boiler. Domestic cold water and wastewater systems were also analysed.

Ventilation. Mechanical constant air flow ventilation system with heat recovery unit was designed in the building. Air flows were selected according to the requirements of national standards. Fresh air was supplied during the hours when building was occupied and one hour before the occupants came back home. During the unoccupied hours the system operated in recirculation mode. The total air change rate in the building of 0.6 h^{-1} was assumed including the infiltration and mechanical

ventilation.

Heating. Energy for heating is produced by wool pellets boiler and floor heating is assumed to be installed. The comfort temperature was maintained just during the occupancy hours. For unoccupied periods heating set back temperature was set 3°C lower than comfort temperatures.

4. Results

4.1 Environmental impact of the whole life cycle of the building

Simulations of the operational energy consumption together with the analysis of the embodied energy (construction and maintenance) have shown that for the building built according to the national passive house requirements (simulated annual heating energy demand - 17.7 kWh/m^2), embodied energy constitutes 31 % of the whole LCA energy and embodied ozone layer depletion – 21 %. Situation is different with the global warming – the highest impact (63 %) is made in construction and maintenance phases.

The environmental impact of various life cycle phases is presented in Fig. 1. As we can see, the phase of operation & maintenance dominates in all impact categories. This phase covers the operational group as well as it includes a part of the embodied group – a renewal of the building elements.

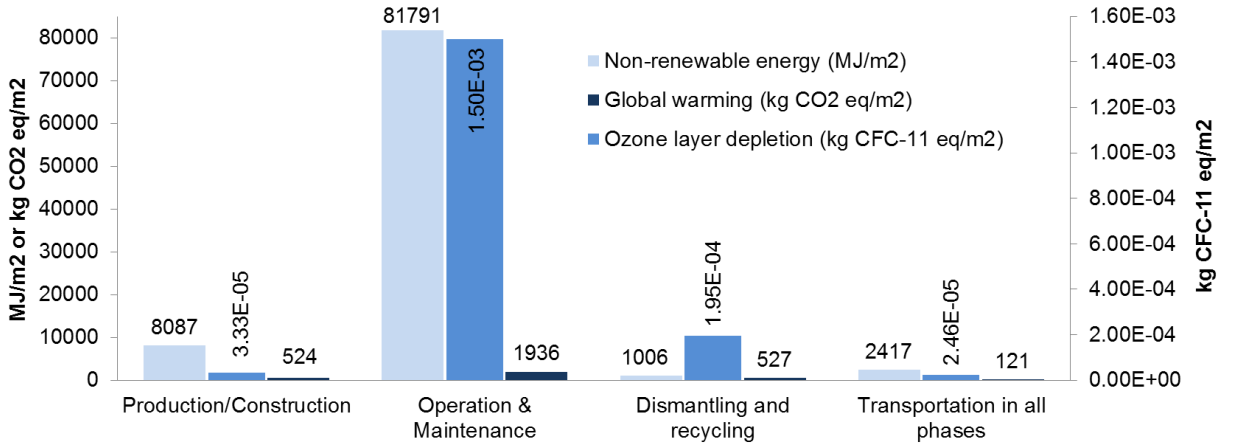

Fig. 1: The environmental impact of various life cycle phases

Results of the study confirm findings of Blengini and Di Carlo [9] for the low energy house in Italy and are very similar to the above mentioned statement of Citherlet and Defaux [10] (house in Switzerland).

4.2 Embodied energy and emissions

Analysis of the embodied energy and emissions of the building has shown that major impact is made by materials used to create building envelope, especially walls, roof and floor. Meanwhile technical installations of the building all together need just 15 % of embodied energy and their embodied CO2 and CFC-11 emissions accordingly are 15 % and 14 %. This might be explained by relatively smaller demand of materials. Seeking to decrease environmental impact of materials used to build and maintain the building; more sustainable solutions for walls, roof and floor should be found. Especially, attention to insulating materials and covering of the floor has to be paid, because of their high impact. Therefore, three embodied alternative improvements were evaluated: 1) new log walls with rock wool insulation; 2) the first alternative plus new steel sheet roof with rock wool insulation; 3) the second alternative plus new ceramic tile floor.

The calculations have shown (Fig. 2) that it is possible to save up to 25 % of embodied energy and

to reduce up to 23 % of embodied CO2 emissions by applying the second alternative. However the greatest reduction of embodied CFC-11 emissions (42 %) could be achieved by applying the third alternative. It is related with disuse of floor lacquer.

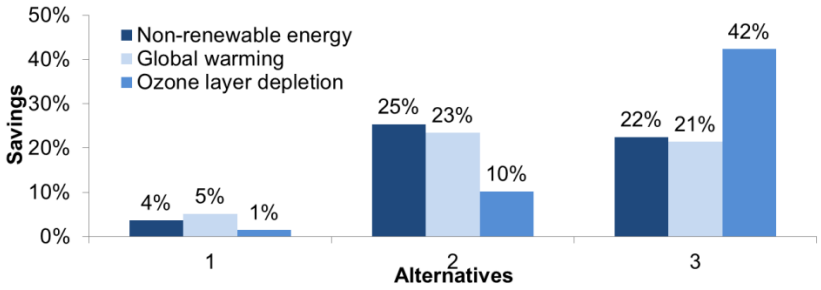

Fig. 2: Savings of embodied energy and reduction of the emissions

Taking into account all environmental impact categories, alternative 3 is considered to be the most efficient one.

Findings of this study together with findings of other studies enable to conclude that for different climates, during the life cycle of the energy efficient house, embodied energy is higher than in conventional buildings. Therefore, not just operational energy is important, but also sustainability of the construction materials has to be considered very carefully.

4.3 Operational energy and emissions - influence of the occupants characteristics

There are many studies proving that operational energy consumption of the building might be significantly influenced by characteristics of occupants (age, size of the household, inhabits etc.). It was also previously assed for the analysed house by Motuziene and Vilutiene [25]. The above mentioned Collinge et al. [13] also have stated that environmental performance of the building is a dynamic process and may change during building's life cycle and one of the reasons of that are changes in occupation. To illustrate how occupants may influence life cycle performance of the building, different occupation alternatives were simulated (Table 3). National specialities of the lifestyle for these different households were taken into account when simulating energy demand of the building.

Table 3: Characteristics of the building envelope

Household type	Description
4 - with children	Household size is 4 people (statistical Lithuanian family is 3.5 people), parent actively working in the city and 2 children stay during the working hours at school or kindergarten; children come back home together with parents.
2 - working couple	Household size is 2 – couple actively working in the city, no children.
2 - retired couple	Household size is 2 – two adult retired people.

Influence of the occupation of the building was assessed for the best alternative 3 (see Fig. 3).

Results show that occupants characteristic, such as family size and age has influence on all environmental impact categories. Compared to the base case (4 family members), total non-renewable energy demand, global warming potential and ozone layer depletion for a 2 working persons household might be accordingly 14 %, 10 and 15 % lower. Meanwhile retired couple, despite that there are twice less occupants, makes the same environmental impact as 4 people's family. Differences in operational energy consumption for analysed households occur because of DHW consumption, which depends mainly on size of household, as well as energy consumed for heating, since different occupation profiles enable to apply different heating system management and electricity for lighting, which depends both on household size and occupation hours.

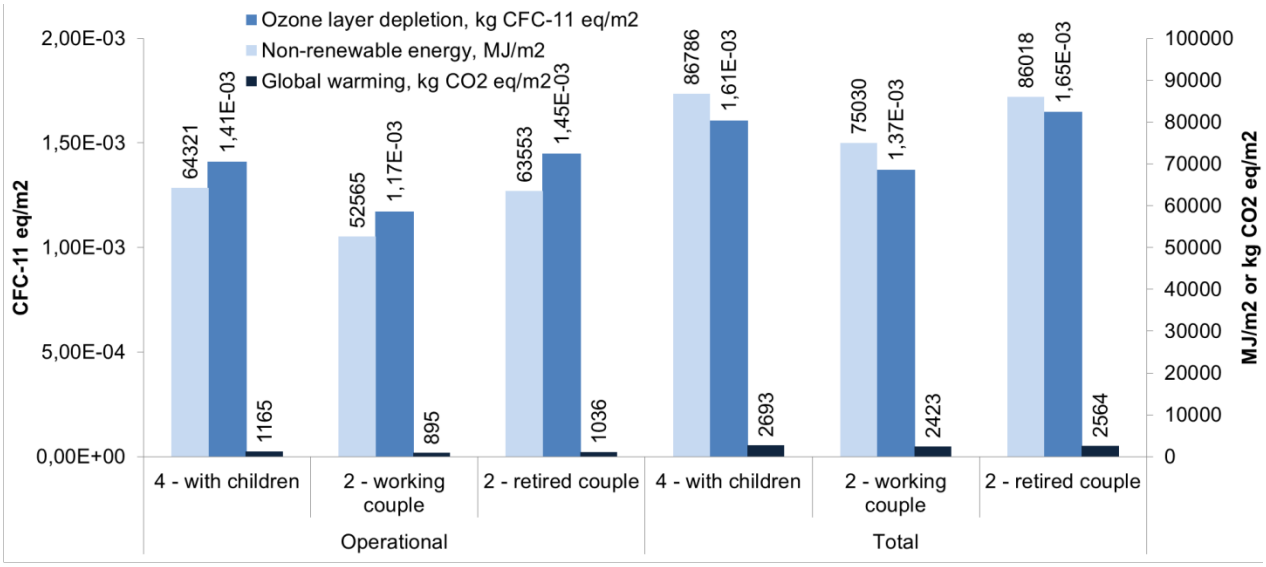

Fig. 3: Influence of different occupation on environmental impact categories

5. Discussion and conclusions

It is defined that for energy efficient houses environmental impact of the operational phase is decreasing, therefore consideration of envelope construction materials becomes a key issue for the design of sustainable building. Technical systems have relatively minor embodied environmental impact and improvement potential. Nevertheless, just complex detailed optimisation of the embodied and operational energy and emissions enables to get the best result.

Household size and age influences environmental impact categories, but it might be considered as insignificant if the size of household and age of occupants is changing during life cycle of the building. Therefore, when performing dynamic LCA, analysis of these factors might be inexpedient. There are still cases, when it might be important to take into account occupant's characteristics, e. g. students' hostels cannot be calculated as standard family houses, because such specific buildings have always the same occupants.

6. Aknowledgement

This research was funded by a grant (No. ATE-03/2012) from the Research Council of Lithuania, Vilnius Gediminas Technical University.

Summary

Within the Austrian research project 'Solares Plus Haus' a plus energy building concept for a brick constructed dwelling is developed, planned and put into operation. The energy performance of the operated building is previously assessed by theoretical analysis of AIT and research partners. Since autumn 2012 a scientific monitoring is operated. This paper documents on the energy performance of the building based on measurement data acquired from January 1st till April 30th 2013. Monthly energy balances were calculated and selected detailed monitoring data of the energy performance of the heat delivering and distribution system are documented and assessed. Key findings are drawn and an outlook about the future research activities is given.

Keywords: Plus annual energy balanced building, energy efficient bricks, solar combisystem, photovoltaics, thermally activated brick wall, monitoring

1. Introduction

According the recast of the EU-Directive [1], future buildings are 'Nearly Zero Energy Buildings' and technically a bright variety of future building concepts exists. Two essential measures lead to such high energy performing buildings: high energy efficiency for both building envelopes and energy systems and use of renewable energy sources on site. Within the Austrian research project 'Solares Plus Haus' a plus energy building concept for a brick constructed dwelling is developed. The energy performance of the operated building is already and will be assessed by the Austrian Institute of Technology (AIT) by means of a scientific monitoring from autumn 2012 to the end of 2014. In particular high solar fractions above 50% for covering the demand for heating and domestic hot water (DHW) preparation contribute significantly to a negative annual primary energy balance (non-renewable part). The research activity focuses intensively on the feasibility of improved use of solar heat by applying the 'Sonnenhaus-Konzept' [2] in combination with thermally activated brick walls. The research project approves the energy performance of the building and thermal indoor comfort with the analysis of measured monitoring data of the operated building and creates advices how to design and control the solar heat activated brick walls.

Preliminary calculation performed by AIT, i.e. energy modelling and building simulation, result into a negative annual primary energy balance (non-renewable part), which could be so far interpreted as a 'plus energy balanced building' [3]. Since December 2012 the brick constructed dwelling is operated and is occupied by the building owner; a four person family. AIT has developed an energy monitoring concept and the required technical equipment of the scientific monitoring over two years is installed and put into operation. This paper essentially documents on first monitoring results related to the energy performance of the building and its subsystems from January 1st till April 30th 2013. Main objectives of the monitoring campaign are:

- Demonstration of the functionality and feasibility of the ‘building concept under real system operation and with the impact of user behaviour
- Quantification of the annual primary energy balance based on measured data
- Quantification of achieved solar fractions beyond 60% in practice
- Identifying measures to optimize the annual energy performance

2. Energy system

The future building as well called ‘e4Ziegelhaus2020’ [4] located in Zwettl, Austria provides 277 m² heated gross floor area and is mainly constructed by using a new generation of energy efficient bricks. The architectural and energy concept of the residential building focuses on a high energy efficiency standard of the building envelope (external walls and windows) and the usage of especially solar energy in order to cover significantly the demand for heat and electricity. The solar thermal system is designed as a solar combisystem, i.e. the solar heat covers the demand for heating and for hot water preparation. Around 50 m² flat-plate collectors south-oriented and titled with 60° provide solar heat to a 9,580 litre hot water tank which is placed centrally within the building. A 40 $kW_{thermal}$ biomass fired boiler serves as thermal back-up system in case of sunless winter days. Figure 1 shows schematically the heat delivering system. Besides a commercially available under floor heating system applied for the living room, the hot water stored in the tank is mechanically circulated also to thermally activated brick walls. Additional 35 photovoltaic modules with a peak power of 6.5 kW_{peak} are mounted on the roof of the garage; the PV system is designed to balance the total electricity consumption by the delivered solar electricity on site.

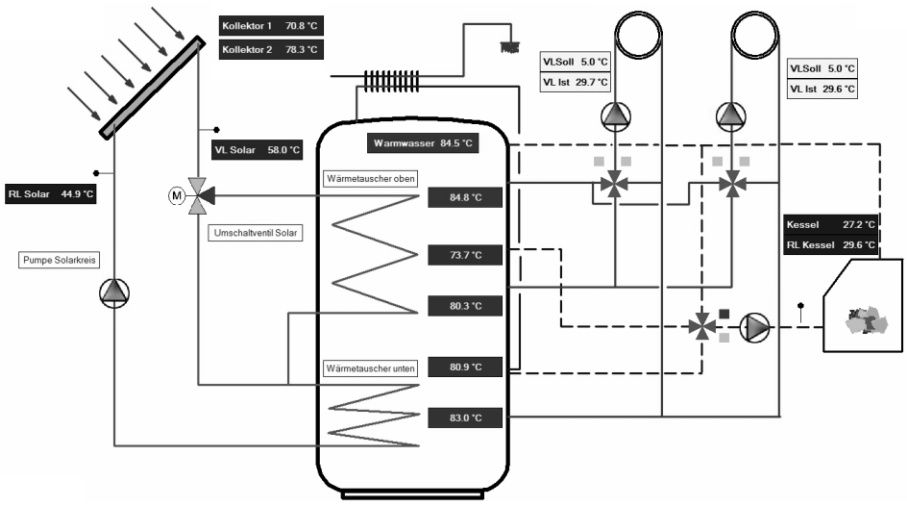

Fig. 1: Scheme of the heat delivering system

3. Monitoring results

All monitoring data presented in this paper are acquired in the period from January 1st till April 30th. In advance AIT did necessary data processing and checks of plausibility. According to statements of experts from ‘Zentralanstalt für Meteorologie und Geodynamik’ in Austria the available sun hours in January and February 2013 were less than 37% in comparison to the multiyear average in Austria [5]. Consequently with such low solar radiation values the applied solar technologies achieved only low solar fraction of both heat and electricity. Within this paper selected monitoring data sets are presented. The following documentation of the measured, post processed and assessed monitoring data addresses a) the total heat and electricity balance of the measurement period, b) energy performance of the heat delivering system and c) energy performance of one selected thermally activated inner brick wall.

3.1 Heat and electricity balance of monitoring period

In 2012 AIT and the research project partners calculated the annual energy balance with regard to heat and electricity demand of the brick made residential building. The specific values of the demand for heat and electricity were taken from Austrian standards except the values for heating demand which is a result of transient building simulation [6]. Table 1 lists the specific and total energy demand values for heat and electricity and additionally contains expected heat delivered by both the solar thermal system and biomass fired boiler. The expected delivered heat has been quantified by applying coupled transient system and building simulation [7]. As well the expected generated solar electricity on site is inserted.

Tab.1: Calculated annual energy balance
*(*Austrian Standard, **transient simulation, ***own calculation)*

	[kWh/m² gross per year]	**[kWh/a]**
Heating demand	39.10**	10,830.7
Demand for hot water preparation	13.00*	3,601.0
Heat losses of heating system	3.40*	936.5
Total heating demand	**55.50**	**15,368.2**
Electricity demand of household	13.00*	3,601.0
Electricity of heating system	2.90***	803.3
Total electricity demand	**15.90**	**4,404.3**
Annual delivered energy on site		
Biomass fired boiler (heat)	22.20**	9,220.9
Solar system (heat)	33.30**	6,147.3
Photovoltaic system (electricity)	18.30***	5,070.0

Figure 2 illustrates monthly heat balances from January till April 2013. For each month the heat delivered to the hot water tank from the solar system or from the biomass boiler is shown and also the heat which was pumped to the brick walls and as well to the under floor heating system. Furthermore the monthly amount of heat is numbered which prepared the hot water for domestic purposes. The thermal balance isn't equalised monthly because there is a water volume of 9.650 litres buffering the hot water provided by both delivering systems the solar and the biomass one. Approximately 630 kWh thermal can be stored potentially in the hot water tank.

Assessing the energy performance of the solar system the solar fraction is one key indicator. Here the monthly solar fraction is calculated by Equation 1.

$$SF_{thermal} = 1 - \frac{Q_{biomass}}{Q_{heating} + Q_{DHW}} \qquad \text{Equ. (1)}$$

with:

$SF_{thermal}$ solar fraction [-]
$Q_{biomass}$ heat delivered by biomass fired boiler [kWh]
$Q_{heating}$ heat delivered to the under floor and thermally activated brick walls [kWh]
Q_{DHW} heat delivered for domestic hot water preparation [kWh]

Equation 2 addresses the amount of electricity used to circulate all hot water of the heat delivering system.

$$EER_{HDS,el} = \frac{Q_{heating} + Q_{DHW}}{E_{HDS,pumps}} \qquad \text{Equ. (2)}$$

with:

$EER_{HDS,el}$ Electrical Energy Efficiency Ratio of the heat delivering system [-]
$E_{HDS,\ pumps}$ Electric consumption of all pumps as part of the heat delivering system [kWh]
$Q_{heating}$ heat delivered to the under floor system and thermally activated brick walls [kWh]
Q_{DHW} heat demand for domestic hot water preparation [kWh]

Figure 3 indicates monthly amounts of consumed electricity and delivered PV electricity from of January, February, March and April 2013. In January 2013 the building user applied an electrical machine for heating and drying the garage what resulted into an extraordinary amount of consumed electricity. The electrical consumption for the monitoring system and pumps of the heat delivering system do have more or less constant monthly values.

One indicator for preliminary assessment of the PV system performance is the ratio of the electricity delivered by PV and the total electrical consumption of the operated building. Additionally the amount of directly used PV electricity on site is from high economic interest in particular when feed in tariffs are below market prices. The monitoring system itself consumes as well electricity and it is necessary to indicate the share of the consumed electricity in contrast to the total amount of consumed electricity. Based on the allocated measurement data the average permanent electrical power of the overall monitoring system is 68 Watt. All monthly values of the introduced key performance indicators are quantified in Table 2.

Tab. 2: Calculated key performance indicators

		January	**February**	**March**	**April**
Electricity consumed, total	[kWh]	602.4	418.5	420.4	350.8
Heat transfered to heating systems and DHW, total	[kWh]	2,911.0	2,633.0	2,627.4	1,557.2

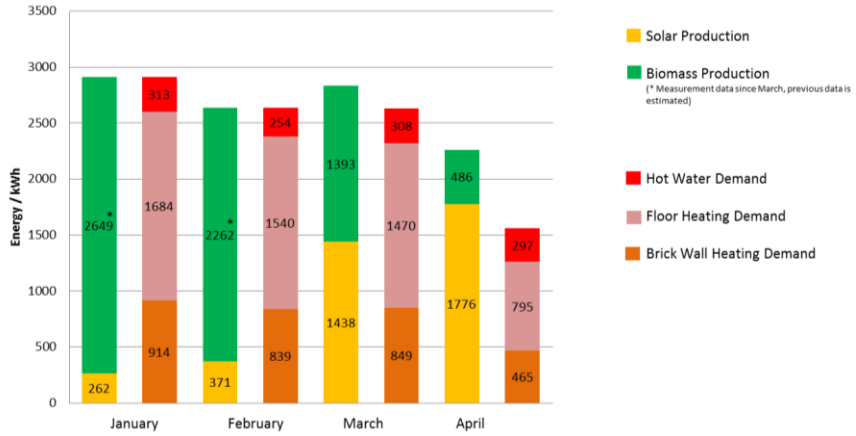

Fig. 2: Monthly energy balances from Jan 1st till April 30th (heat)

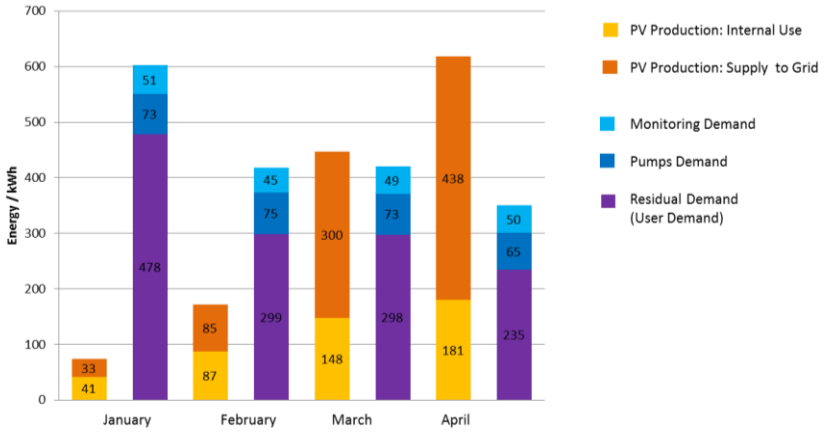

Fig. 3: Monthly energy balances from Jan 1st till April 30th (electricity)

3.2 Performance of the heat delivering system

A crucial part of the reality check is the performance of the heat delivering system – see Figure 1. In the previous section monthly energy balances were introduced and illustrated. For more detailed analysis daily performance data of the heat delivering system in terms of heat capacity and temperature profiles are addressed. Based on the acquired monitoring data of March 2nd 2013 the system performance is documented and evaluated. Figure 4 - right placed - illustrates profiles of thermal power from the solar collector system, the biomass fired boiler, the heat delivered to the under floor heating system and thermal activated brick walls and the heat taken from the tank for hot water purposes. The ambient temperature of that day was approximately in between 0 and 5 degree Celsius. In the evening of March 1st the biomass fired boiler is manually loaded with wooden split logs. The heat delivered to the hot water tank achieved a capacity of around 35 $kW_{thermal}$ (nominal 40 $kW_{thermal}$). Due the high level supply temperature (approx.. 70 to 75 degree Celsius) of the biomass boiler and the designed fixed inlet positions of the hot water just the upper one-third of the tank (95%, 88% and 74% of total highness of 5.5 m) is thermally effected. At around 6 a.m. the control unit operates the heating pumps, i.e. the under floor system and the brick walls are immediately provided with hot water. In the initial operation phase of both heat distribution systems were thermally loaded with high power values which decreased slowly to zero. The under floor heating system was thermally activated more powerful. Figure 4 left display the temperature profiles of the heat delivering system of March 2nd. The flat-plate collector system lifts the outlet collector temperature by approx. 20 Kelvin up to around 50 degree Celsius and generates a maximal heating power of around 27 $kW_{thermal}$. The temperature stratification of the 9.650 litre hot water tank functioned properly with regard to the creation and the continuance of low temperatures in the lower tank section, what allows generally an increased use of solar heat.

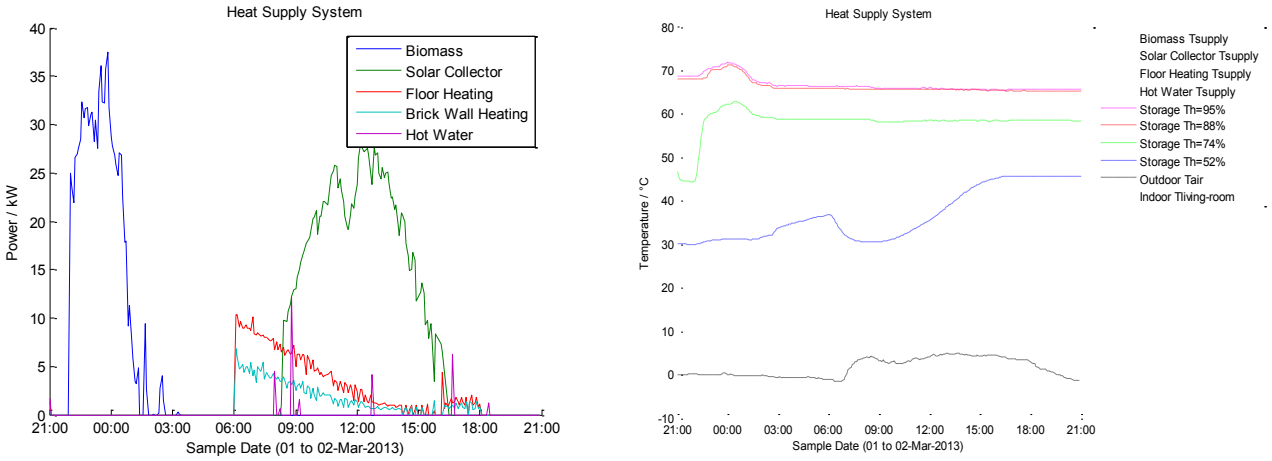

Fig. 4: Energy performance of the heat delivering system on March 2nd '13

Left:
Biomass – thermal power of the delivered hot water from the biomass fired boiler
Solar collector – thermal power of solar collector in the primary solar circuit
Floor heating – thermal power of the hot water which is delivered to the under floor system
Brick wall heat - thermal power of the hot water which is delivered to all activated brick walls
Hot water – thermal power which is delivered to the domestic hot water system

Right:
Biomass Tsupply – outlet water temperature of the biomass fired boiler
Solar Collector – outlet water/glycol temperature of the solar collector field
Hot water – outlet water temperature of the heat exchanger to prepare domestic hot water
Storage Th=95% - hot water tank temperature (level 95% of the total highness, i.e. 5.23 m)
Storage Th=88% - hot water tank temperature (level 88% of the total highness, i.e. 4.84 m)
Storage Th=74% - hot water tank temperature (level 74% of the total highness, i.e. 4.07 m)
Storage Th=52% - hot water tank temperature (level 52% of the total highness, i.e. 2,86 m)
Outdoor Tair – Ambient air temperature
Indoor Tliving-room – Indoor air temperature of the living room

3.3 Performance of the thermally activated brick walls

In the earlier project phase the research partners did theoretical calculation and analysis of the energy performance of the novel thermally activated brick wall. Herewith a 1D-model was developed in order to predict the thermal system performance by using coupled transient building and system simulation [7]. This paper addresses a reality check by presenting selected daily system performance of the thermally activated building element based on measured data of March 2nd 2013. Figure 5 illustrates the profiles of measured temperatures and thermal power provided to one specific brick wall, which is positioned close to the staircase facing the living room. Additionally Figure 5 displays a sketch illustrating the positions of the applied temperature sensors and the volume flow meter. On March 2nd the thermally activated part of the considered brick wall was supplied by water temperatures in the range of approx. 29.2 and 33.6 degree Celsius. In the initial operation phase the heat transferred from the circulated water to the colder thermal mass of brick wall achieves a peak power of approx. 0.4 $kW_{thermal}$ and ends with approx. 0.1 $kW_{thermal}$ at 6 p.m. Figure 5 plots as well selected surface temperature profiles, which represent the temperatures of the gypsum layer put on the thermally activated brick wall. There is an average temperature lift of all five displayed surface temperatures of 1.9 Kelvin. With regard to the monitored temperatures following findings are detected; a) the indoor air temperature is quite high (between 23.3 till 25.3 degree Celsius) in comparison to the standard set temperatures of 20 degree Celsius and b) manually opened windows provided fresh air for the living room and caused a temperature decrease for both indoor air temperature and surface temperature of the thermally activated brick wall.

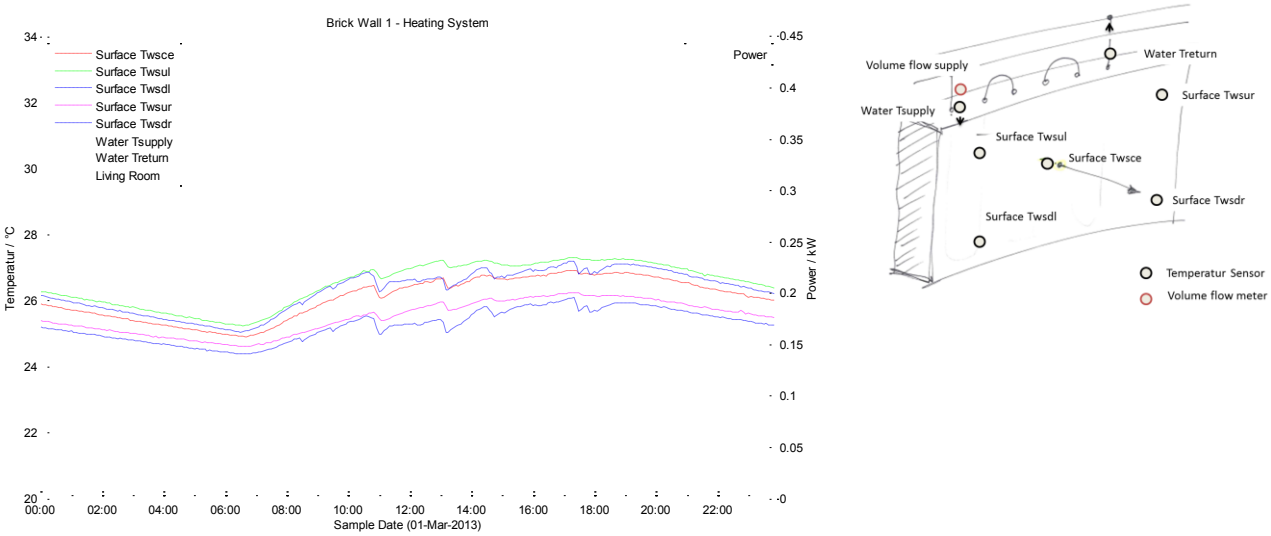

Fig. 5: Energy performance of the thermally activated brick wall on March 2nd '13

4. Findings and outlook

Based on measurement data acquired from January 1st till April 30th 2013 a first documentation and assessment of the energy building and system performance of the 'e4Ziegelhaus2020' is submitted. Monthly energy balances were calculated and the daily energy performance of the heat delivering and heat distribution system were analysed based on monitoring data of March 2nd. With the analysis of the selected monitoring data some conclusions are drawn. Key findings are:

- In comparison to preliminary theoretically generated annual energy balances it is most probable that the building operation will exceed the expected heating demand. During the first four month of 2013 the heat delivered to the under floor system and the thermally activated brick walls already cover 72% of the preliminary predicted 11,770 kWh heating demand including heating system losses. It is obvious that higher indoor temperatures of around and above 24 degree Celsius lead to higher amounts of delivered heat.
- Especially due to marginal sun hours in January and February the amount of heat delivered by the flat-plate collector system wasn't significant. In January the solar fraction was only SF_{Jan} = 9% and in February SF_{Feb} = 14.1%.
- The hot water tank operated with reasonable and stable stratification.
- The thermally activated brick wall operated with low supply temperatures, but the major heat was delivered via the under floor heating system – see Figure 4 right.
- The solar electricity delivered on site by the photovoltaic modules in March already equalises the total electrical consumption – see Figure 2. The percentage of directly used solar electricity in the building was between 29.2% and 49.4% - see Table 2.
- The scientific monitoring system operated with an average permanent electrical power of 68 Watt and that implies means a share of 8.5% up to 14.3% of the total electricity consumption – see Table 2.

Future research work will focus on:

- Continuation of the scientific monitoring till the end of 2014
- Acquisition of one complete monitoring data set from January 1st till December 31st in order to provide the annual energy balance based on measured data
- Comparison of theoretical models with measurement data (especially heat delivering system)
- Analysis of both the thermal building performance and the heat delivering system in summer (e.g. risk of overheating, risk of stagnation of the collector field)

Short Summary

We have performed a life cycle assessment of an office building of the planned Technology Park in Bolzano, Italy. The analysis takes into account embodied, operational and transport energy, carbon emissions and other environmental impact factors. Further, we have created two virtual scenarios that show how green choices during building design and operation can potentially reduce total life cycle energy and carbon emissions by 60%. Assessments of this kind are still missing in most design and tendering procedures, and even if they are done, they usually focus only on one single aspect at a time. Such an approach may result in a considerable waste of resources and increase in environmental impact. We have estimated that for Net Zero Energy Buildings embodied energy and transport energy may account for more than 90% of the total life cycle energy. Therefore, we strongly recommend integrating these factors in building design.

Keywords: office building; embodied energy; operational energy; transport energy; green insulation; emissions reduction; sustainable mobility; Net Zero Energy Building

1. Introduction

It is reported that conventional office buildings consume in the range of 250-550 kWh/m^2 per year and that Operational Energy (OE) for these buildings amounts to 80-90% [1]. Therefore, it seems natural to focus on OE. However, in highly efficient buildings such as Net Zero Energy Buildings (NZEB), OE is expected to be low. Therefore, Transport Energy (TE) and Embodied Energy (EE) of such buildings grow in importance. EE is even more important in office buildings that contain large amounts of steel, reinforced concrete and glass. TE can be reduced designing an efficient transport system that connects the building with the surroundings. Also, the building location affects the commuters' habits and therefore the TE.
A comprehensive Life Cycle Assessment (LCA) that includes EE, OE and TE is still rare in procurement, design and tendering procedures for new buildings. A study on residential buildings in line with such an approach has shown that EE and TE together can amount to almost 50% of the total life cycle energy demand in passive houses [2]. Office buildings are a much more complicated system from a construction and technological point of view. In this work we would like to analyse how the impact of different building life stages is transforming in a vision of very low energy demand office buildings.
Our case study is a new office building in the industrial zone of Bolzano, northern Italy. The building has been designed by Claudio Lucchin & Architetti Associati and Chapman Taylor and

denominated “Black Monolith”. Building owner and design teams aspire to reach the targets of total primary energy (PE) consumption less than 60 kWh per square meter per year and net zero energy balance. To reach these targets, a set of energy efficiency solutions has been selected during the integrated design process with the aid of dynamic simulation results. To reduce environmental impact, passive solutions, in particular natural ventilation and daylighting, have been preferred over active solutions. Apart from PV and solar-thermal renewable energy integration, otherwise wasted energy such as heated-up ground water in series with an industrial cooling process has been exploited. The building has been selected as a pilot for the European FP7 project DIRECTION dedicated to the demonstration of innovative, cost-effective and replicable energy efficiency solutions for low energy new buildings [3]. The results obtained in this study are useful to the project and to the building owners to a) better assess the sustainability of the DIRECTION pilots, b) identify the most impacting parts of them, and c) eventually unleash the potential of green alternatives.

2. Methodology

We have taken into account Operational Energy, Embodied Energy and Transport Energy in order to develop three main scenarios of the expected total life cycle energy (LCE) and emissions of the building. The method is replicable in other designs of office buildings.
The LCE is the life cycle energy demand of a building and its users and is therefore the sum of the requirements at building scale (embodied and operational) and at city scale (infrastructure and transport) [2].

2.1 Embodied Energy

We have evaluated the EE of the construction materials with the online tool “SBS Building Sustainability” (SBS) developed at the Fraunhofer Institute for Building Physics [4]. The tool integrates the European Sustainable Construction Database (ESUCO) and GaBi data [5] for less common materials.
As reported by the SBS online tool, the life cycle inventory is based on data collections from industry and on a literature research. A deviation margin of 10% is added to the results since they have not undergone independent review. The environmental profile contains the expenditures from "cradle to gate".
We have inserted the following constructive elements into SBS:

- Building envelope: major contributory elements and materials of façade and roof
- Load-bearing structure: concrete beams, pilasters, main walls, stairs and ramps
- Main party walls for services and technical rooms
- Floor slabs

For each material, the Life Cycle Inventory (LCI) of SBS takes into account the following impact factors: Primary Energy (PE), Global Warming Potential (GWP), Abiotic Depletion Potential (ADP), Acidification Potential (AP), Photochemical Ozone Creation Potential (POCP), Eutrophication Potential (EP) and Ozone Depletion Potential (ODP).
The load-bearing structure has an important impact on environment due to the considerable bulk of material. The subdivision of the indoor spaces of the Black Monolith has been kept flexible by request of building owner and future tenants. Nevertheless, main party walls have been considered as they are a common part of office buildings.
At the time of writing, bids have not been reviewed completely. Only the tendering documents with minimum equipment performance requirements have been available to us, but no information on specific brands or products. As the materials and their production chain may vary completely from one product to another, we have decided to exclude HVAC&R, lighting and renewable energy production systems from the analysis.
We have considered the following life cycle phases: production, operation, reuse/replacement and recycling/disposal taking into account a suitable lifespan for each material and a 50 years lifespan for the whole building. We haven’t considered a longer lifespan as construction materials and building system technologies change rapidly. However, the emissions distribution in the atmos-

phere changes considerably over much longer time periods [6,7]. Therefore, we have chosen a lifespan of 100 years for the emissions estimation.
SBS computes the maintenance and replacement cycles automatically according to the lifetime of the building.
First, we have performed a LCA of the actual building design as specified in the tendering documents. The building structure is of reinforced concrete. The EPS- and XPS-insulated envelope is a combination of glazed curtain walls and aluminium panels.
Next, we have chosen five claimed as greener insulation materials in order to reduce the EE and environmental impact of the façade: cotton fleece, expanded cork, hemp fibre fleece, natural rubber foam and mineral wool. We have varied the insulation thickness in order to keep the thermal transmittance of the building envelope constant. Finally, we have substituted the aluminium envelope with a wooden construction.
Based on the results, we have chosen the following three envelope variants:

- XPS- and EPS-insulated aluminium envelope
- XPS- and EPS-insulated wooden envelope
- Hemp fibre-insulated wooden envelope

2.2 Operational Energy

In SBS, the user can choose from generic equipment such as different kinds of heat pumps, boilers, chillers, etc. As the equipment and energy efficiency measures for the Black Monolith cannot be mapped in sufficient detail to the types available in SBS, we have computed the OE with a dynamic simulation model developed in TRNSYS. In the OE calculation, the PV field energy production has been subtracted from the thermal and electrical loads for HVAC&R and lighting.
We have calculated the OE for two cases. In the first case we have considered only the PV field on the roof of the Black Monolith (estimated MWh/year: 264). In the second case we have considered also the planned PV field on the roof of an adjacent historical industrial building (estimated MWh/year: 450) located on the same lot.

2.3 Transport Energy

Life cycle transport energy of a building is the energy demand associated with commuting and is mainly determined by the annual travel distances and energy intensities (energy consumed per unit of distance) of the transport modes used by the commuters [2,8].
We have compared three transport configurations: the as it is case, a case based on expected changes in Bolzano in the 20 years and a case going beyond.
The first strategy corresponds to the actual transport situation. We have combined the commuting behaviour of the roughly 40 employees at the Institute for Renewable Energy of EURAC research, Bolzano, Italy in 2013 with statistical data on transport modalities in the municipality of Bolzano shown in Table 1 [9]. We expect the near-future commuting behaviour of the roughly 300 employees working at the Black Monolith to be very similar as our offices are only 1 km away from the construction site and the future tenants will be involved mainly in RTD activities.

Table 1: Current commuting modality in Bolzano

Commuting type	Average commuting distance	Means of transport	Use percentage
Urban 65%	8 km/day	Bike Car Train Bus Motorcycle Foot	37% 29% 13% 10% 7% 4%
Extra urban 20%	50 km/day	Train Car Bus	75% 23% 2%
Extra provincial 15%	120 km/day	Train Car	75% 25%

The second strategy follows the Urban Mobility Plan 2020 for the municipality of Bolzano [10]. Compared to the previous as is solution, the bus transfers and 14% of the car transfers are substituted with tram transfers.
The third strategy envisages a transport based purely on electric vehicles: 71% train, 25% shared electric cars and 4% tram.
We have computed the TE for all three strategies using the following formula:

$$LCTE = \sum_{tm=1}^{TM} TD_{tm} \cdot DEI_{tm} \quad (1)$$

In Equation 1, LCTE denotes the life cycle transport energy demand of the building tenants. TD_{tm} denotes the total yearly travel distance of all users that use the transport mode tm and DEI_{tm} denotes the yearly direct energy intensity (energy dedicated only to propulsion per unit of distance) of the travel mode tm. We have taken the DEI_{tm} values from the literature [11].
Finally, we have calculated carbon emissions for all three strategies with the same formula where we have substituted energy intensity with carbon intensity (CO_2-equivalent emissions per unit of distance) [12].

2.4 Comprehensive scenarios

From the EE, OE and TE reduction strategies detailed above, we have developed three comprehensive scenarios listed in Table 2 that consist of meaningful combinations of the considered design factors: a) envelope construction, b) integration of RE production into the calculation of OE, and c) transport strategy. We have compared these scenarios with respect to total life cycle energy demand (LCE).

Table 2: Comprehensive scenarios for the LCE analysis

Scenario	EE	OE	TE
1 (as it is)	XPS- and EPS-insulated aluminium envelope	PV field on the roof of the Black Monolith only	As it is
2	XPS- and EPS-insulated wooden envelope	PV field on the roofs of the Black Monolith and the adjacent historical industrial building	Urban Mobility Plan for Bolzano (PUM 2020)
3	Hemp fibre-insulated wooden envelope	PV field on the roofs of the Black Monolith and the adjacent historical industrial building	Only electric vehicles

3. Results

In order to be able to compare the impact of OE, EE and TE, we have normalized the energy figures to kWh per year and the CO_2-equivalent emissions to kg/tons per year. Tables 3 and 4 report the overall energy and carbon demands for the three scenarios.

Table 3: Shares of OE, EE and TE in the total LCE for the three scenarios

Scenario no.	EE [kWh/year]	OE [kWh/year]	TE [kWh/year]	Total PE [kWh/year]
1	303,000	482,000	330,000	1,110,000
2	275,000	41,300	332,000	649,000
3	245,000	41,300	208,000	495,000

Scenario 1 is the as it is situation. The OE amounts to 38.5 kWh/(m^2 year). The PV field on the roof of the Black Monolith is estimated to produce 49.7 kWh/(m^2 year). Therefore, without renewable energy production, the OE would amount to 88.2 kWh/(m^2 year). OE, EE and TE share 43%, 27% and 30% of the total LCE, respectively. If TE is not considered, OE amounts to 61% and EE to 39% of the total LCE. 50% of the CO_2-eq. emissions are due to transport ("transport carbon"), 36% are due to building operation and 14% are due to "embodied carbon", that is, CO_2-eq. emissions caused by raw materials extraction, production processes and recycling.

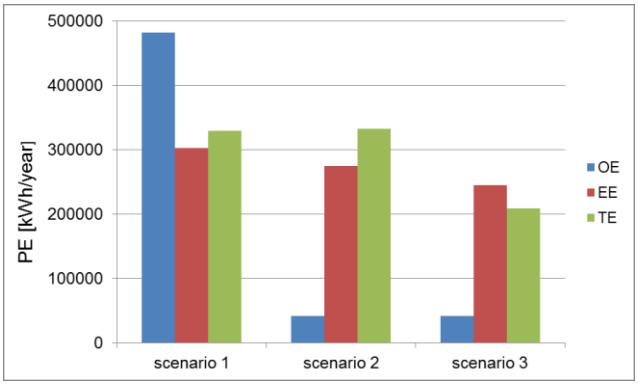

Fig. 1: OE, EE and TE shares in LCE for the three scenarios listed in Table 2

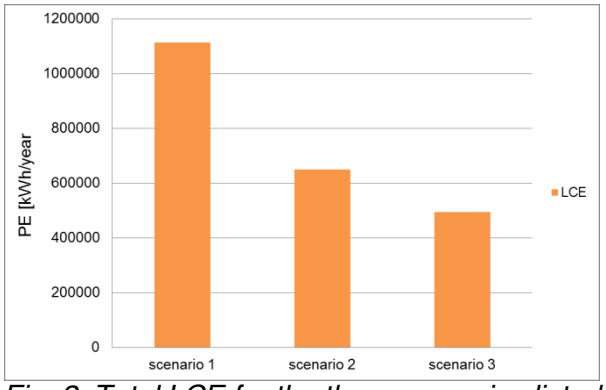

Fig. 2: Total LCE for the three scenarios listed in Table 2

Scenario 2 represents an intermediate solution. OE, EE and TE share 6%, 43% and 51% of the total LCE, respectively. The high shares of TE and EE are due to the use of cars and EPS and XPS as envelope insulation materials. If TE is not considered, EE amounts to 87% and OE to 13% of the total LCE.
Although the PE consumption due to transport is different from that in Scenario 1 by less than 1%, the CO_2-eq. emissions are reduced by 38% thanks to the Urban Mobility Plan for Bolzano. Transport is mainly responsible for carbon emissions (72% of the total carbon emissions), while embodied carbon amounts to 28%. The carbon emissions during the operational phase are lower than 1% as the electricity produced by the PV field enters the OE calculation as avoided carbon emissions. In practice, the electricity produced will be auto-consumed or fed to the grid.
The very low figures for OE in scenarios 2 and 3 are due to the applied conversion factors that profusely rewards the avoided emissions. That is, it is more a calculation effect than an actual zero emission phase.

Table 4: Shares of embodied, operational and transport emissions in tons CO_2-eq. for the scenarios listed in Table 2

Scenario no.	Embodied carbon	Operational carbon	Transport carbon	Tot.CO_2-eq
1	48,000	126,000	177,000	351,000
2	42,000	Less than 1, see text	109,000	152,000
3	38,000	Less than 1, see text	104,000	142,000

In Scenario 3, EE amounts to 50%, OE to 8% and TE to 42% of the total LCE. If TE is not considered, EE amounts to 86% and OE to 14% of the total LCE.
The CO_2-eq. emissions are 73% caused by transport ("transport carbon"). "Embodied carbon" amounts to 27%. For the same reason as in Scenario 2, the CO_2-eq. emissions during the operational phase are lower than 1%.

All other environmental impact factors assessed are listed in Table 5.

Table 5: Values of the other environmental impact factors on EE assessed for the scenarios listed in Table 2

Scenario no.	PE [kWh/m^2 year]	GWP [kg CO_2-eq]	ADP [kg Sb-eq]	AP [kg SO_2-eq]	POCP [kg ethene-eq]	EP [kg phosphate -eq]	ODP [kg R11-eq]
1	24.0	3.87	0.0286	0.0258	0.00255	0.00153	2.27 E-7
2	22.0	3.39	0.0262	0.0241	0.00243	0.00144	1.80 E-7
3	19.6	3.04	0.0225	0.0230	0.00192	0.00134	1.71 E-7
DGNB benchmark values	41.9	9.40		0.037	0.0042	0.0047	5.30 E-7

The results listed in Table 5 show that substituting the aluminium envelope with a wooden envelope reduces environmental impact by 5-12% in almost all impact categories except for the ODP which decreases by 21%.
In changing synthetic polymer insulation (XPS and EPS) with hemp fibre insulation, the highest decrease is in POCP (21%) followed by ADP (14%), whereas the other impact categories decrease by 5-10%.
The values relative to the main impact categories listed in Table 5 are all lower than the benchmark values reported by the Deutsche Gesellschaft für Nachhaltiges Bauen (German Sustainable Building Council, DGNB) [13]. The values – reported in Table 6 for the convenience of the reader – are taken from a German national research project [14] in which "typical" buildings in Germany have been evaluated in order to derive benchmarks on the basis of mean values and develop an understanding of the relations between a building and its environmental impacts. The values are referred to educational, office, hotel and residential buildings in a reference study period of 50 years.

3.1 Conclusions and discussion

We have performed a LCA of a planned office building located in the industrial zone of Bolzano, Italy. In addition, we have created two virtual scenarios that show how primary energy and emissions could be reduced by 60%. We have put emphasis on a holistic approach that takes into account the primary energy consumed and produced during each life cycle phase of the building, from extraction of raw materials to deconstruction and recycling. We have also estimated the transport energy and shown that it may account for 50% of the total LCE. By substituting the current transport network with a network based on electric vehicles (shared cars, buses, trams and trains) supplied by renewable energy sources such as PV, PE savings due to transport of up to 60% may be achieved.
The shares of EE and OE reported for Scenario 1 are typical for efficient new office buildings. Good Net Zero Energy Buildings are able to reduce OE to a minimum and may have EE and OE shares similar to those reported for Scenario 2 or 3.
We conclude that, once a complete and accurate building materials, components and systems inventory will be available, a comprehensive LCA that takes into account OE, EE, TE, carbon emissions and environmental impact factors such as GWP, AP, ADP, etc. should be part of every integrated design and tendering procedure for highly energy efficient and sustainable new office buildings. It may even make sense to request a report of the LCA from bidders and to review it carefully during the bids evaluation process. Scenarios 2 and 3 demonstrate the potential and the importance of mobility plans tailored to the commuters' needs. In Bolzano, a number of cycling

lanes cross the industrial zone. A comprehensive cycling network connecting the building with other hot spots of the city promotes sustainable mobility and improves the quality of life of the workers.

3.2 Limits of the analysis

We have considered only the main building components. Fasteners, screws, cables, etc. have not been included in the assessment. We have had to leave out lighting and building equipment of the EE assessment due to lack of detailed information on the production chains, types and amounts of materials, but we have considered the thermal and electrical loads of these systems in the TRNSYS model and hence in the calculation of OE and carbon emissions. However, we do think that the active building systems play a role in EE assessment. We are awaiting the start of the construction works to be able to integrate reliable information on these systems in the EE evaluation.
We have selected all materials from the ESUCO database without editing their predefined impact factors. Therefore, production, maintenance and recycling processes are in line with the European average. We have made this design choice not only due to lack of information on how materials will be procured during construction, but also to ensure comparability with the LCAs of the other building demonstrators chosen for the DIRECTION project.
The SBS tool does not include transportation in the process cycles assessment. Transportation of materials may lead to a 10% increase in emissions [13] [15]. The tool hasn't any option to recycle the glazing. It is supposed that the glass is simply crushed and thrown into a landfill.
We have focused ourselves on the optimization of insulation and envelope only, without working on the building structure. We have made this choice mainly because the design of the Black Monolith was already at an advanced stage when we started with the LCA, and an analysis of more substantial interventions would have been of no practical use. However, although it may be a good idea to choose green insulation materials in most cases, the insulation is probably not the main element to focus on. The LCA optimization potential of the insulation may be marginal against an optimization of the building structure and the fenestration-wall ratio.
The assessment is based exclusively on an environmental point of view. For example, from an economic point of view, green insulation may be discouraged or prohibitive.
In the assessment of the TE, we haven't considered indirect transport energy intensities. Direct transport energy denotes only the energy used for the propulsion of a vehicle. Indirect energy includes: construction, operation, maintenance and demolition of infrastructure for transport; manufacturing, service and scrapping of vehicles; fuel production for the transport sector. Indirect transport energy may amount to 10-30% of total transport energy [11].

Extended Abstract

In the year 2004 the Medical University of Graz (Med Uni Graz) was founded as an autonomous university and currently operates from several locations scattered across the city of Graz. The MED CAMPUS will combine the university with the existing university hospital in one unified location[1]. Physical contiguity will do more than solve the difficulties of the current situation; it will enable teaching, research & development and patient care to reach an international level of excellence.

The project area consists of two construction sites where twelve institutes are combined in four centres. These will include teaching facilities, administration offices, a library, a canteen, an assembly hall, and space for start-up companies operating in related fields. The building complex as a modern university, research and communication centre will have space for around 1700 employees and 4300 students.

From the project's inception, the office of the university's rector managed its development as a sustainable and healthy property in the broadest sense, and this resulted in sustainability quality targets being included in the public competition requirements. The project is currently being certified with a DGNB/ÖGNI Certification of Lab Buildings [2].

The present contribution describes the approach chosen by the university as customer and user, and key milestones for implementing sustainability targets in the planning of the campus. The effects of this strategy on the results of the project are presented.

In summary, it can be said that as far as can be judged at present, the very ambitious goals of the Med Uni Graz for the sustainability of the buildings will be reached. The extra effort of the design process is therefore worthwhile from the point of view of the Med Uni Graz.
The future will reveal how far this extra design and organizational effort can be reduced by developing standardized instruments and procedures. However, it does appear that the best solutions will always be highly specific to the location and the planned uses of the buildings. If we consider that diversity often seems to be one of the best survival plans, then this finding can be seen in a positive light.

Acknowledgments

This described work in the paper was carried out in the project MED CAMPUS Graz by Medical University of Graz and Bundesimmobiliengesellschaft m.b.H. with the generalplaner Riegler-Riewe Architects ZT GmbH (architects, commissioned by BIG) and Team TU Graz (Prof. Maydl, commissioned by Med Uni Graz). We would like to thank all partners for their support and their inputs.

Keywords
Sustainability; DGNB/ÖGNI Certification of lab building; planning process; design consequences;

1. Introduction:

1.1 What is the MED CAMPUS?

In the year 2004 the Medical University of Graz (Med Uni Graz) was founded as an autonomous university and currently operates from several locations scattered across the city of Graz (Fig. 1).
The realization of the MED CAMPUS will gather the entire operation of the medical university onto one site immediately adjoining the LKH University Hospital (Fig. 2). This is intended to improve the levels of communication and interaction between the clinical and nonclinical sections of the university; to simplify the organisation and improve the quality of research and teaching activities; and to simplify the organisation of the administrative activities. Thus the new campus is meant to provide:

- a location that will encourage teaching and research to cross existing structural boundaries, forming new areas of excellence and a stronger overall profile
- space for communication between teachers, researchers, students and employees of the Med Uni Graz.

The move to the new campus will be accompanied by a reorganization of teaching and research. The overall goal of the project is to achieve a large step forward in the quality of the core activities of teaching and research.
To reach the defined goals, the Med Uni Graz, with the support of the Bundesimmobiliengesellschaft (BIG, Austrian holding & management company for federally-owned buildings), conducted a competition for the overall design, beginning in 2010, which was won by the office of Riegler-Riewe Architects in Graz (Fig. 3,4).
In the summer of 2013, construction work on the main building Module 1 of the MED CAMPUS will begin

Fig. 1: Departments being gathered to the MEC CAMPUS (MUG)

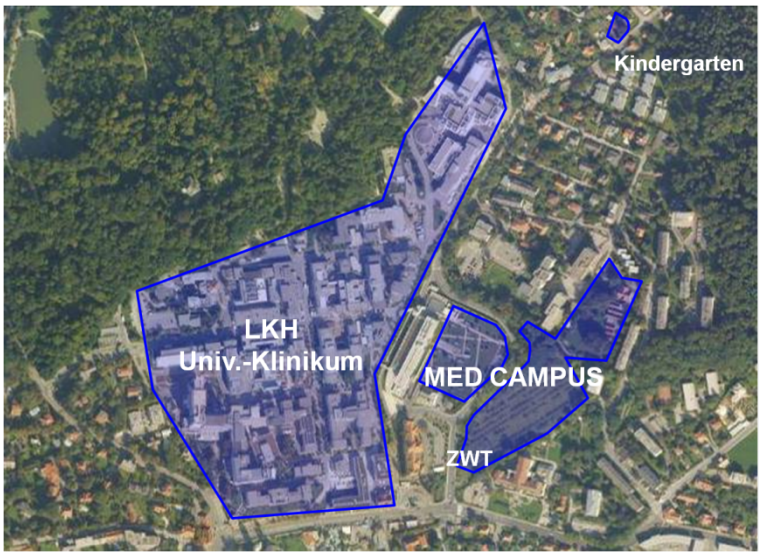

Fig. 2: Site plan of LKH University Hospital and MED CAMPUS (MUG)

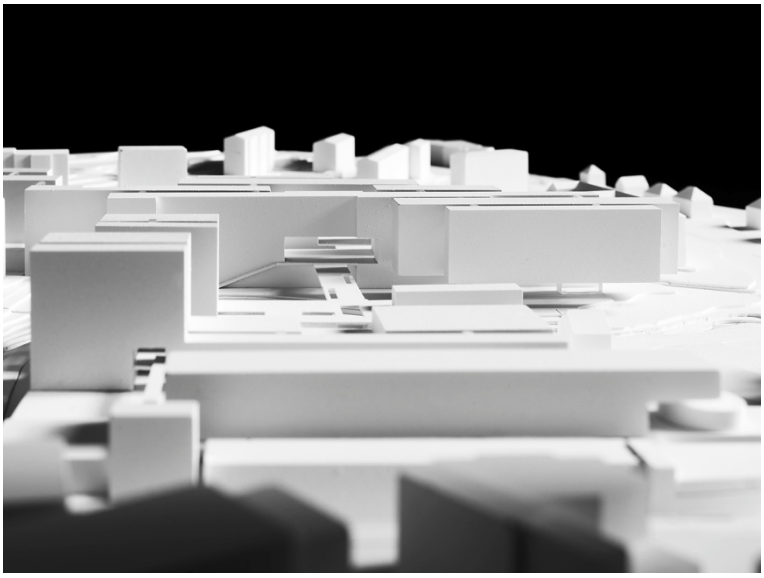

Fig. 3: Architectural model view MUG)

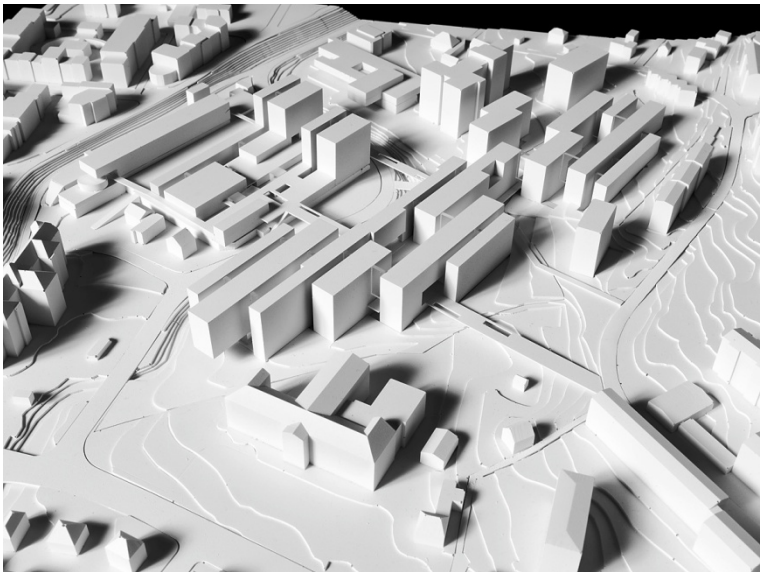

Fig. 4: Architectural model view (MUG)

1.2 MED CAMPUS key facts:

The MED CAMPUS will include space for research, teaching, administrative and for generell infrastructure.

Usable spaces to be created in main building modules 1 and 2 (Fig. 5):

- Research spaces for researchers and students
- Teaching spaces for 1200 students (medicine, dentistry and nursing science)
- General infrastructure for 4300 students (canteen, event spaces, open space)
- Administrative space for all together 840 employees of the Med Uni Graz

Total areas to be realized in main building module:

- Useful area MED CAMPUS Module 1: approx. 20,000 m² (total useful area 38,000 m²)
- Gross floor area MED CAMPUS: approx. 44,000 m² (total gross floor area 74,000 m²)
- Site area 43,000 m²

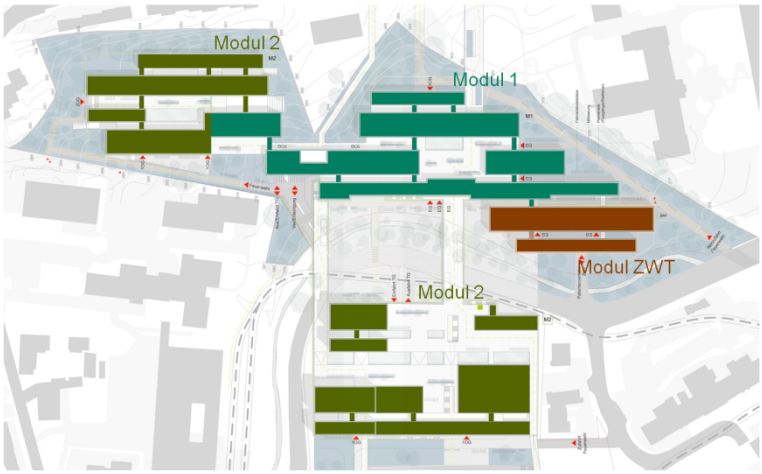

Fig. 5: Construction phases (RRA)

Current Status of the Project:

The project is now at the stage of tendering for the main building trades. Construction work began at the end of July 2013 (Fig. 6). At the same time, the preparatory work for the certification of the buildings by ÖGNI were completed.

Fig.6: Time schedule of MED CAMPUS main buildings, Module 1 (MUG)

1.3 Motivation of the Med Uni Graz for building a sustainable MED CAMPUS:

The Med Uni Graz has a strong interest in creating sustainable campus buildings for the following reasons:

- A fundamental commitment of the Medical University of Graz to sustainability in research and teaching
- The improvement of the usage of the buildings that can be achieved by creating a high-quality built environment
- The wish for an innovative building
- Flexibility and adaptability of the built spaces for changing uses
- The need to keep future operating costs low, particulary in view of foreseeable rises in energy prices

1.4 Sustainability goals for the MED CAMPUS project:

The purpose of the MED CAMPUS is not just to create new buildings for existing organizational entities, but to accompany the reorganization of the non-clinical research and teaching activities and the administrative departments of the Med Uni Graz. Thus the MED CAMPUS is not a pure building project but the implementation of a new organizational concept.
As well as this overall project aim, the MED CAMPUS project has been designed to be sustainable in a broad sense of the term.

Extract from the competition text: the combination of the measures in the MED CAMPUS (buildings and organization) should serve the goal of achieving a quantum leap in the quality of the core activities of teaching and research. Besides this, networking of the MED CAMPUS with the clinical institutes of the LKH University Hospital Graz is expeczed to have beneficial effects on patient care.

In this context, the usual meaning of sustainability of buildings was deliberately expanded to include the sustainability of the functionality and of the added value of use of the buildings. This decision was taken in view of the complexity and scope of the requirements placed on the project and to ensure their integration into a holistic overall concept.

In the preparation of the call for the architectural design competition, two groups of sustainability goals were defined. In the contract negotiations with the chosen architecture firm, these were further developed, culminating in an agreed list of sustainability objectives.

1. General sustainability goals (hard and soft factors)
2. Sustainability goals based on ÖGNI criteria

Economics	Functionality	Added value of use	Ecology
Affordability	Open use conzept	Identity foundation	Human health
Life cycle costs	Use synergies	Image formation	Commodities, climate protection
Energy efficiency	Flexibility, adaptability, change of use	Integration of the urban space	Renewable energy
Maintenance costs	Operation optimization of the building	Quality of stay	Urban Ecology
Other operating expenses	Accessibility	Communicative qualities	Microclimate
Safety		Comfort of use	
Lifespan		Building Culture	
		Art and construction	

Fig. 7: Dimensions of sustainability in the MED CAMPUS project (MUG)

2. Main Challenges in the Design Process, and their Solutions:

Incorporating sustainability considerations into building design is not completely new. In fact, the long-term optimization of buildings, at least in some respects, has always been part of the building-design and construction processes.

What is new is the approach of creating a comprehensive evaluation and optimization of the buildings over a long time period, covering the dimensions of functional, economic, and environmental sustainability and also the added value of use (as an expansion of the concept of sustainability).

These requirements gave rise to the following challenges in the design process:

2.1 Implementing of Sustainability-targets makes the design process more complex, because it cuts across specialties

The sustainability perspective, and especially the evaluation according to ÖGNI, is one that cuts across all the usual design specialties.

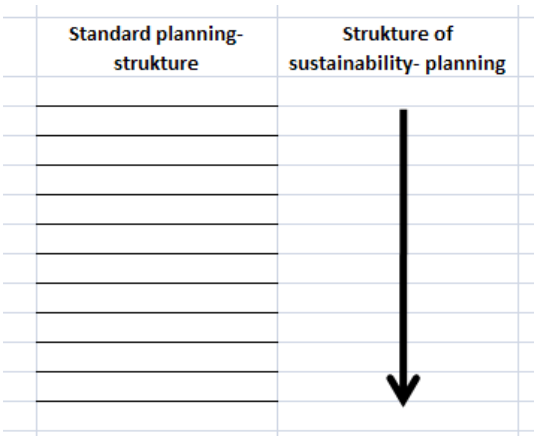

Fig 8: Structure of sustainability concept compared to conventional design process (MUG)

Furthermore an on going estination of the various aspects of sustainability is necessary.

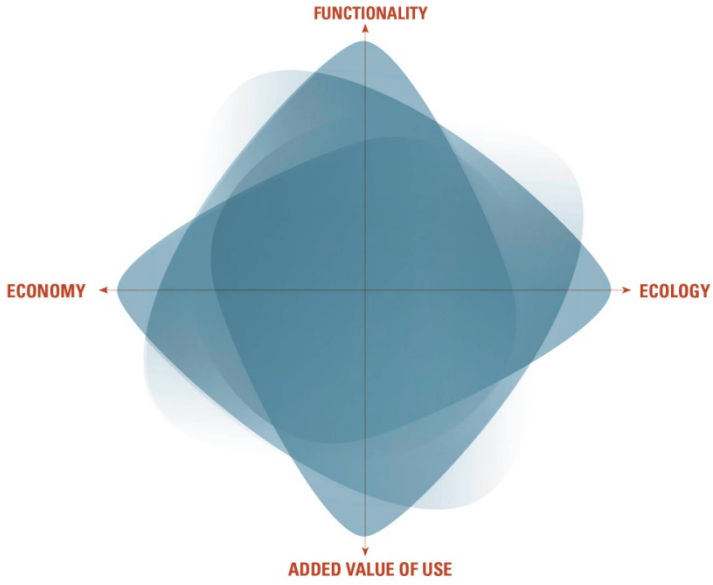

Fig. 9: Estination fo the various aspects of sustainability (MUG)

To keep the resulting complexity within practicable limits and to ensure a structured approach, the following measures were implemented:

- Kick-off workshops with all the specialist design/engineering staff
- Regular pre-checks to evaluate current status and track progress towards targets
- Interim reports on sustainability as a steering instrument
- Ongoing definition of thematic areas of focus
- Regular sustainability meetings
- Appointment of one sustainability coordinator in each of the organizations Med Uni Graz, BIG and Riegler-Riewe architects

2.2 Lack of standards for design of sustainable buildings

This challenge in the design process lay in the fact that in many areas, for the planned uses of the building, new standards had to be developed from scratch, for example:

- Definition of goals:
  The need to work out a consensus on the definition of sustainability

- Design activities:
  Structures and tools had to be developed to guide the implementation of sustainability in the design process

- Lack of task descriptions for the specialist designers:
  task descriptions had to be drawn up for various specialties and partly revised during the design process

- Certification procedures in accordance with ÖGNI:
  Process needed to be developed, especially for the laboratory areas, for which ÖGNI did not have any mandatory sets of targets at the beginning of the design process.

- Sustainable technical system solutions:
  Required the sustainability evaluation of all technical systems

- Choice of sustainable building materials and components:
  Required the sustainability evaluation of a large number of materials and components

2.3 Complexity of the building project itself

The building project is highly complex even before taking into account the sustainability goals (Fig. 10). The shape of the site, the large number of participating institutions, the spatial program the range of spaces needed and the functional requirements all contributed to this complexity. The floors at the base of the buildings will house different areas for teaching, the assembly hall, the large lecture theatres and the administrative infrastructure. The floor above these will contain highly-equipped laboratories and their dedicated office areas. Spaces for the university administration are planned in separate towers.
The MED CAMPUS will host the following functions:

- 39 organizational units
- 14 instituts
- 4 centers
- 9 core facilities
- 10 lecture halls
- 46 seminar rooms
- 345 laboratories
- 532 offices

- IT- rooms
- workshops
- communication space, Social rooms, meetings points, cafes, canteen, assembly hall
- supply rooms
- storage rooms

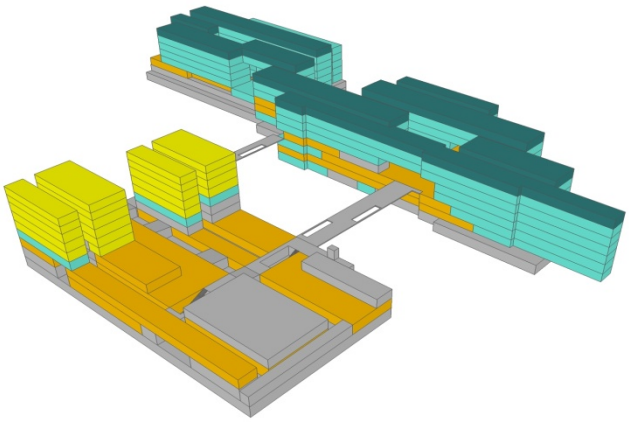

Fig. 10: Map of functions (RRA)

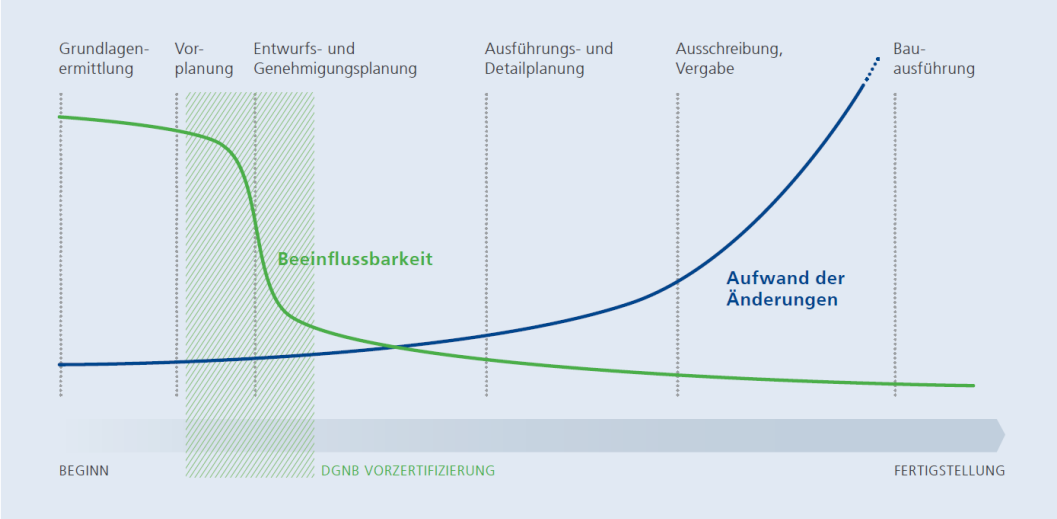
3. Methods and Tools used to reach the substainability goals

3.1 Definition of sustainability for the project MED CAMPUS:



Sustainability is subject to a variety of different definitions. For the MED CAMPUS project, the following definition was adopted:

Sustainable development:
A development is sustainable if it "meets the needs of the present without compromising the ability of future generations to meet their own needs." Quoted from "Lexikon der Nachhaltigkeit", www.wirtschaftslexikon.gabler.de

3.2 Organizational *measures* to reach the sustainability goals:

Implementation of the defined tasks in a project of this size and complexity gave rise to the following organizational requirements:

- Integration of the sustainability topics in the early project development, in drawing up the usage concept, and in setting parameters for the architectural competition (Fig. 11). This to ensure the largest possible influenceability to reach the sustainability goals. To reach the sustainability targets numerous activities where set in the different planning phases – shown in Fig. 12.

Influenceability of the planning in the planning process
Outlay for modifications

Fig. 11: Influenceability of the planning in the planning process (aus: ÖGNI-systembroschüre 2013)

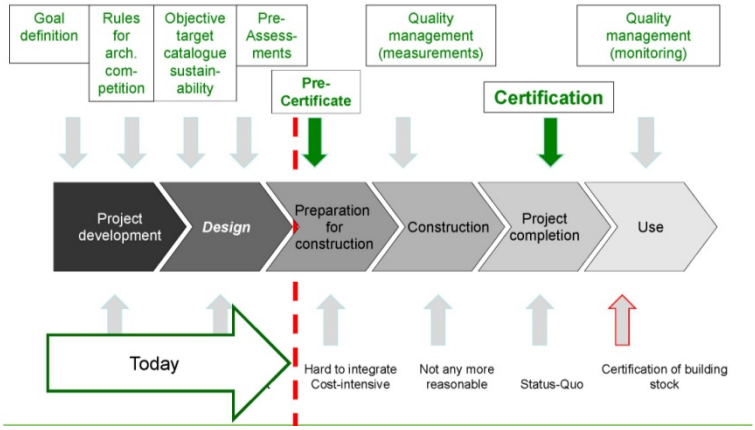


Fig.. 12: timing of integration of sustainability targets into the planning process (TTUG)

- Standardized definitions of targets, measures to ensure that the goals are understood and supported at all levels of decisions making and by all the people / organizations involded
- Selection of reference projects to support the definition of targets
- Establishment of an integrated planning team by BIG, integration of specialist design staff into the overall design team (energy design, LCC calculation etc.) as shown in Fig. 13.

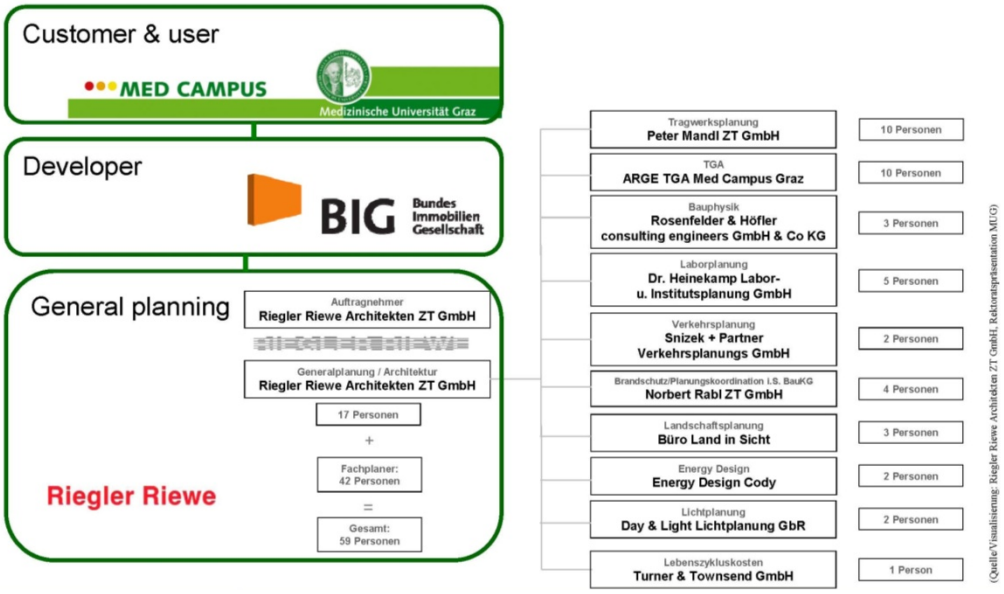

Fig. 13: Schematic representation of design organization (MUG)

- Ongoing dialogue between different areas of detailed design (continuous consideration of sustainability trade-offs in all decisions of specialist disciplines)
- Commitment and openness of all people involved to innovative practices
- Use of special control tools
- Operation of a separate sustainability budget to guide the project towards the goals

3.3 Planning and design tools used to reach the sustainability targets:

To reach the sustainability targets the following planning and design tools where applied in the project.

Evaluation of variants:
Variant studies were done for all the main components of the technical systems, beginning, in a simple form, with the earliest draft design.

Compilation and evaluation of detailed decision-making dossiers:
for decisions on individual system components, data were collected systematically on standardized forms, covering factors such as payback calculations, etc.

Design & development of an integrated energy concept, elaboration of comprehensive strategies & recommendations for energy optimization:
The buildings energy concept includes the areas of indoor climate, building shape, building envelope, building services and energy supply/distribution. It was drawn up in consultation with the relevant specialist design staff (building services, electrical engineering, facade) as a design task in its own right, and at the draft design stage it was passed to the specialist designers as a binding document.

In addition, the following design instruments were used:
Whole building simulations
Assessment of individual measures including economic feasibility calculations
Design and evaluation of energetic parameters & internal loads
Thermal building simulation
Daylight simulation
Life cycle costs analyses (LCCA)
Life cycle assessment (LCA)
Sustainability report

Use of the ÖGNI certification system as a tool to measure fulfilment of targets and thus as a control instrument on the client side (Med Uni Graz)

4. Planing Reasons

Generally there have been implemented sustainable solutions in each of the four dimensions of sustainability:

- Economy
- Functionality
- Added value of use
- Ecology

4.1 Specific sustainability measures to be implemented within the project (excerpt list):

The MED CAMPUS main building Module 1 will incorporate the following sustainability measures:

1. Usage Concept:

- The structure of the usage concept fosters flexibility and synergies during the operation (concept with centres, Medical Research Centre II (ZMF II), connections with ZWT (Fig. 14, 15).

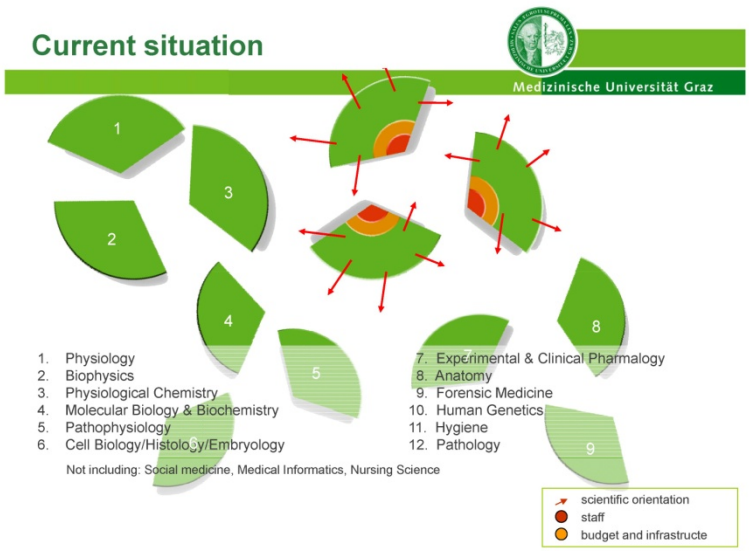

Fig. 14: Concept of centres (MUG)

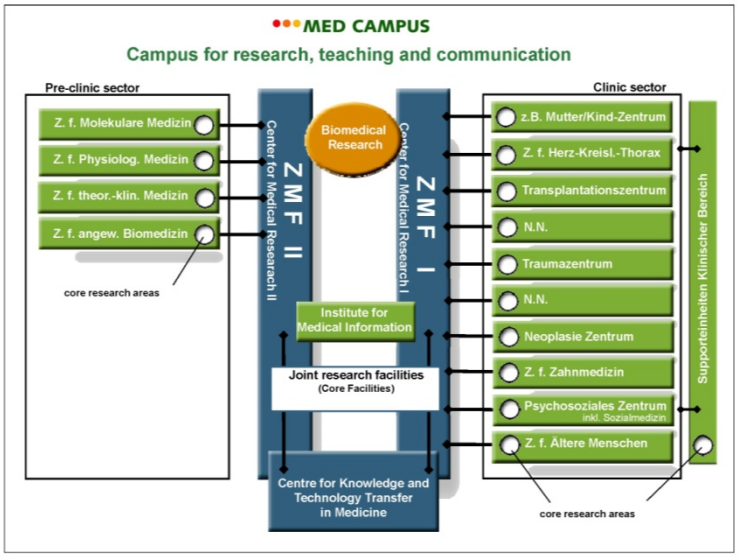

Fig. 15: Overall usage concept (MUG)

2. Sustainable traffic plan and implementation of a mobility plan: A mobility agreement with the city of Graz, the regional government of Styria and the hospitals corporation KAGEs, covers construction of new infrastructure and organizational measures. The plan includes measures on limiting the number of car

parking spaces, walking and cycling, public transport, motor traffic and mobility management.

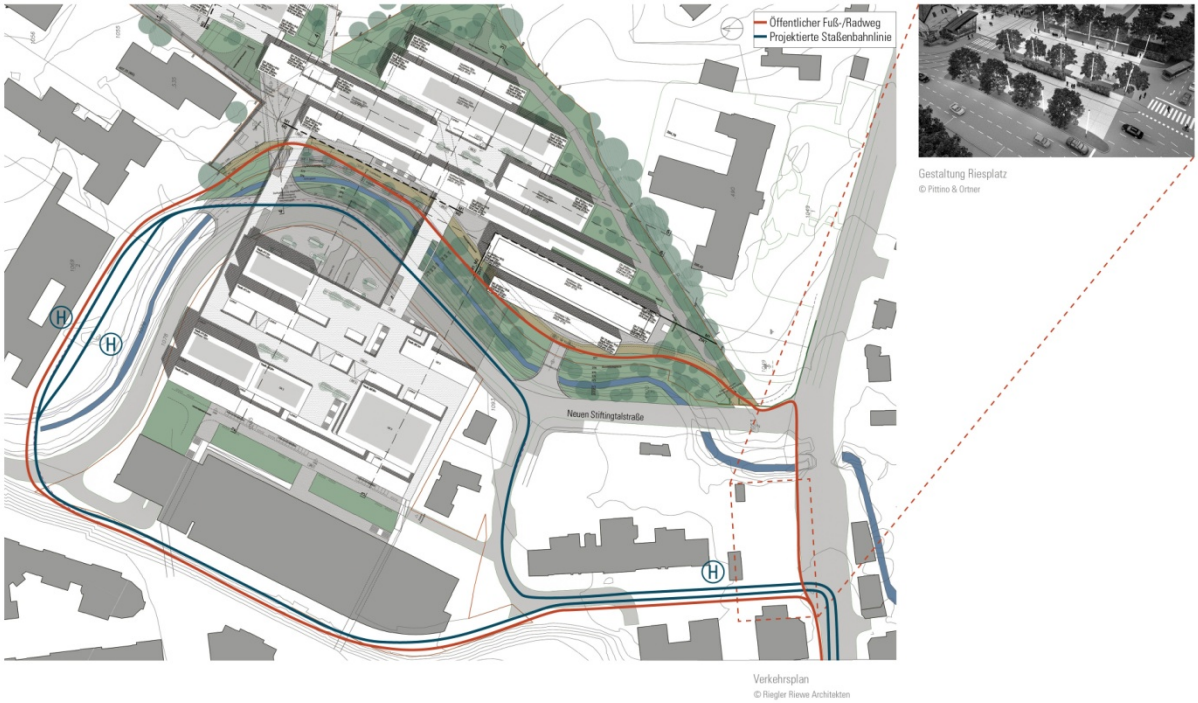

Fig. 16: Extension of tram line, reorganization of green spaces, rebuilding of Riesplatz (RRA)

3. Urban planning:

- High-density building:
- respecting the fresh air corridor for the city.
- The buildings are specially aligned and dimensioned so that they do not adversely affect the flow of fresh air from the Stiftingtal (river valley) into the city (Fig. 16)
- Integration of the MED CAMPUS into the urban space

Fig. 16: Fresh air corridor, orientation of buildings (RRA)

4. Design of floor plans:

- Interconnection of all building sections with bridges on all levels (Fig. 17)
- Standardized floor plans that are adaptable for different uses

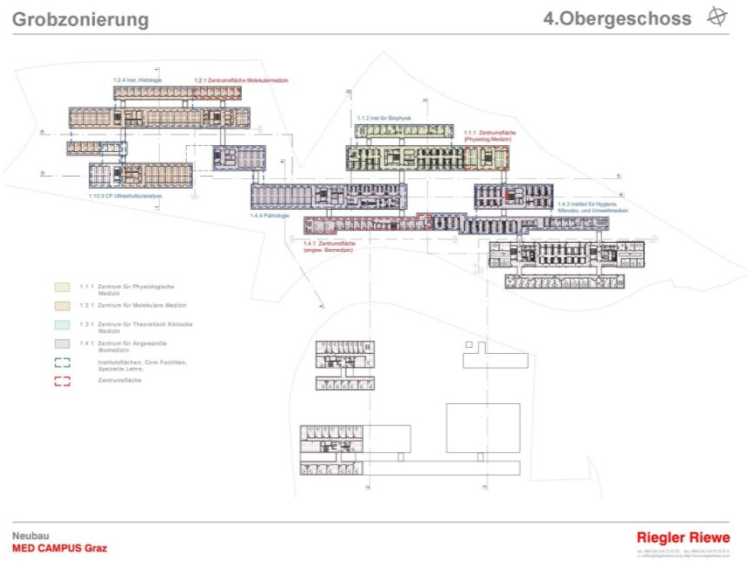

Fig. 17: Floor layout with bridges (RRA)

- Communicative qualities of the building and the outdoor spaces (Fig. 18)

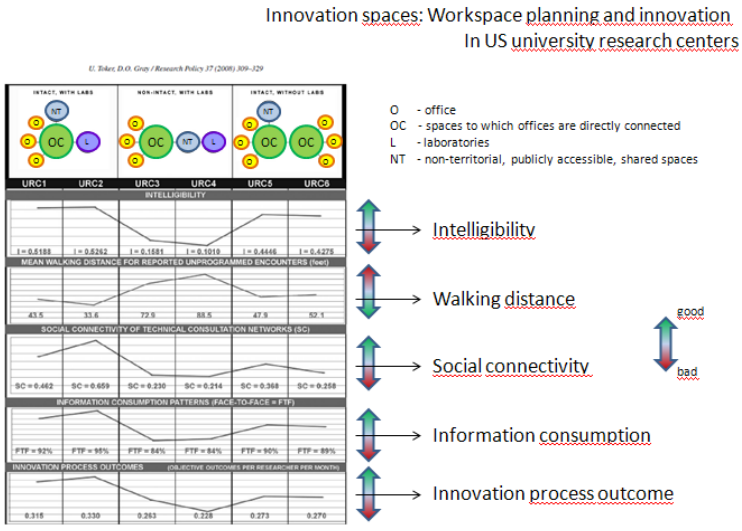

Fig. 18: Effect of communicative spaces on the research output (MUG)

5. Facade (Fig. 19)

- Automatic exterior shade elements
- Strategic use of different window sizes and positions according to functional requirements AWD lighting-situations

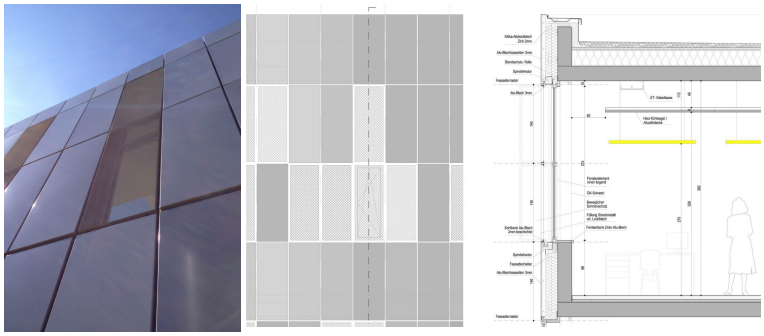

Fig. 19: Facade design (RRA)

6. Building technology:

- Thermal insulation of walls, roofs and floors to a higher level than in the reference buildings
- Triple glazing
- Use of ventilation systems with heat recovery systems in laboratory areas, including fume cupboards
- High-efficiency energy recovery systems in the lecture theatre areas (rotary heat exchangers instead of plate heat exchangers, η=0.8 instead of 0.65)
- High-efficiency energy recovery systems in the seminar room areas (rotary heat exchangers instead of plate heat exchangers)
- Control of ventilation in the lecture theatre areas using CO2 sensors.
- Utilization of waste heat from the cooling plant by means of water-based heat transfer to the central heating system
- Control of lighting in the office areas, corridors and laboratory office areas depending on natural light and occupancy
- Energy supply: use of energy piles (coupled to heat pumps) in the building foundations (approx. 300 structural piles needed).

7. Materials and surfaces:

- Use of environmentally friendly materials

5. Estimated fullfilment of goals – effects of the measures taken on the quality of the buildings and their future use

Thanks to the intensive collaboration of everyone involved, we succeeded in incorporating all of the defined sustainability goals into the design. The process of doing so placed extraordinary demands on the whole project staff, but the extra effort has paid off.

The result is a complex of buildings that fully meets the stringent requirements on:

- economy
- functionality
- added value of use
- and ecology

Concerning the costs there is:

- approx. 40 % saving of energy costs so that approx. 20% saving of operating costs, this with a amortization time of 7 to 17 years for those sustainability measurements, that have been examined concerning to amortization.
- added to this cost savings there is a cost saving that hardly can be measured, but that is in long terme probably even more important: the cost save resulting on the aspects of the factors of sustainability concerning functionality, added value of use (building quality) and ecology

In addition, the project was final awarded with a precertifcate in gold according to the ÖGNI system (Fig. 20). This would be the first gold award for a laboratory building in Austria. The single building qualities and the fulfilment of target values are shown in Fig. 21.

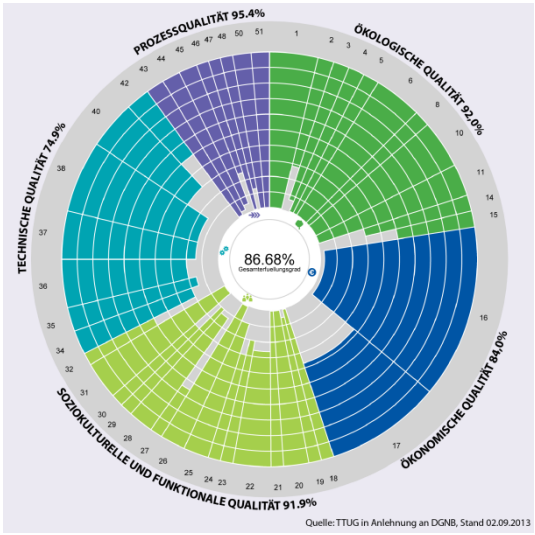

Fig. 20: Current status of evaluation according to ÖGNI criteria (TTUG)

Fig. 21: Precertificate of ÖGNI (ÖGNI)

6. Conclusion and Outlook

In summary, it can be said that as far as can be judged at present, the very ambitious goals of the Med Uni Graz for the sustainability of the buildings will be reached. The extra effort of the design process is therefore worthwhile from the point of view of the Med Uni Graz.
The future will reveal how far this extra design and organizational effort can be reduced by developing standardized instruments and procedures. However, it does appear that the best solutions will always be highly specific to the location and the planned uses of the buildings. If we consider that diversity often seems to be one of the best survival plans, then this finding can be seen in a positive light.

7. Acknowledgments

This described work in the paper was carried out in the project MED CAMPUS Graz by Medical University of Graz and Bundesimmobiliengesellschaft m.b.H. with the generalplaner Riegler-Riewe Architects ZT GmbH (architects, commissioned by BIG) and Team TU Graz (Prof. Maydl, commissioned by Med Uni Graz). We would like to thank all partners for their support and their inputs.

Short Summery

The building uses the Passive House concept for a Nordic country and serves as a model for Passive and Plus Energy Buildings in northern latitudes. The building is housing a typical Estonian family with 5 members and demonstrates that a Passive House concept combined with active solar technologies can produce same amount energy than is needed over the year – even in northern countries.

Keywords: Plus Energy House, Passive House, Solar heat gains, Solar Active House

1. Climatic conditions

As a typical country bordering the Baltic Sea, Estonia is divided to two climatic zones – e.g. coastal area and inland area where conditions differ due to influence of nearby sea. The more detailed spatial division and climatic differences are given in [Kalamees and Vinha 2004]. The building described in this article is located in the town of Põlva at the South-East part of Estonia where more continental climatic conditions occur along with lower temperatures, deeper and longer lasting snow cover compared to coastal areas [Raik 1967 *cited in* Kalamees and Vinha 2004]. Compared to Central European climate where the use of passive and active solar techniques is more widely used the winters are cold in Estonia. Based on national Test Reference Year for energy calculations the long-term average dry bulb temperature for inland part of Estonia in December is -2,5°C, in January -3,0°C and in February -5,2°C [Kalamees and Kurnitski 2006], however long-term average daily minimum values for each month from November to March are below -10,0 °C reaching -14,3 °C for January [Kalamees 2006]. In more extreme years the air temperature falls below -30 °C occasionally, staying frequently below -15 °C for several days [Estonian Meteorological and Hydrological Institute 2002]. Despite the low temperatures there is also a lot of solar radiation available on Southern elevations on cold days (especially in February and March) due to lower solar altitudes and long lasting snow cover compared to Central European locations. Though the monthly sums of direct and indirect solar radiation on vertical surfaces strongly depend on the yearly variation of snow and cloud conditions [Estonian Meteorological and Hydrological Institute 2003], the nearly perpendicular sun-angles in heating period make the solar use strategy in this latitude (58°N, 27°E) interesting.

2. Project description

2.1 Architectural solution

The building site is a rectangular plot with two different levels. The new building is positioned within the given slope connecting those levels leaving the south and east façade of basement floor exposed to winter sun. The main glazed façade is oriented directly to south maximising the use of passive solar gain during the heating season. On southern façade terraces and balconies are partly reaching out over the slope to give shade and protect against the overheating during the summer period.

Figure 1 rendered view, cross sections, south fassade, winter and summer, etc.

The building has three stories, total net floor area of 305 m^2, external envelope surface area of 864 m^2 and enclosed volume of 1586 m^3, which corresponds to compactness factor A/V of 0,55 m^{-1} for the building. For the energy calculations a reduced “treated floor area” of 280,6 m^2 was used (40% of rooms with no windows and corridor in the basement was excluded).

The ground level consists of an entrance area, the big living room, the kitchen, the master bedroom and the corresponding auxiliary rooms. The living room is two stories high. In the upper floor you find a gallery, which is open to the living room and gives access to three children's bedrooms and a working area. In the basement there is a sauna and a steam bath (both very important in the daily day live of the inhabitants) connected with an area for shower and a big room for recreation (fully served with day light). There are also a technical room, a room for the kids and some storage rooms.

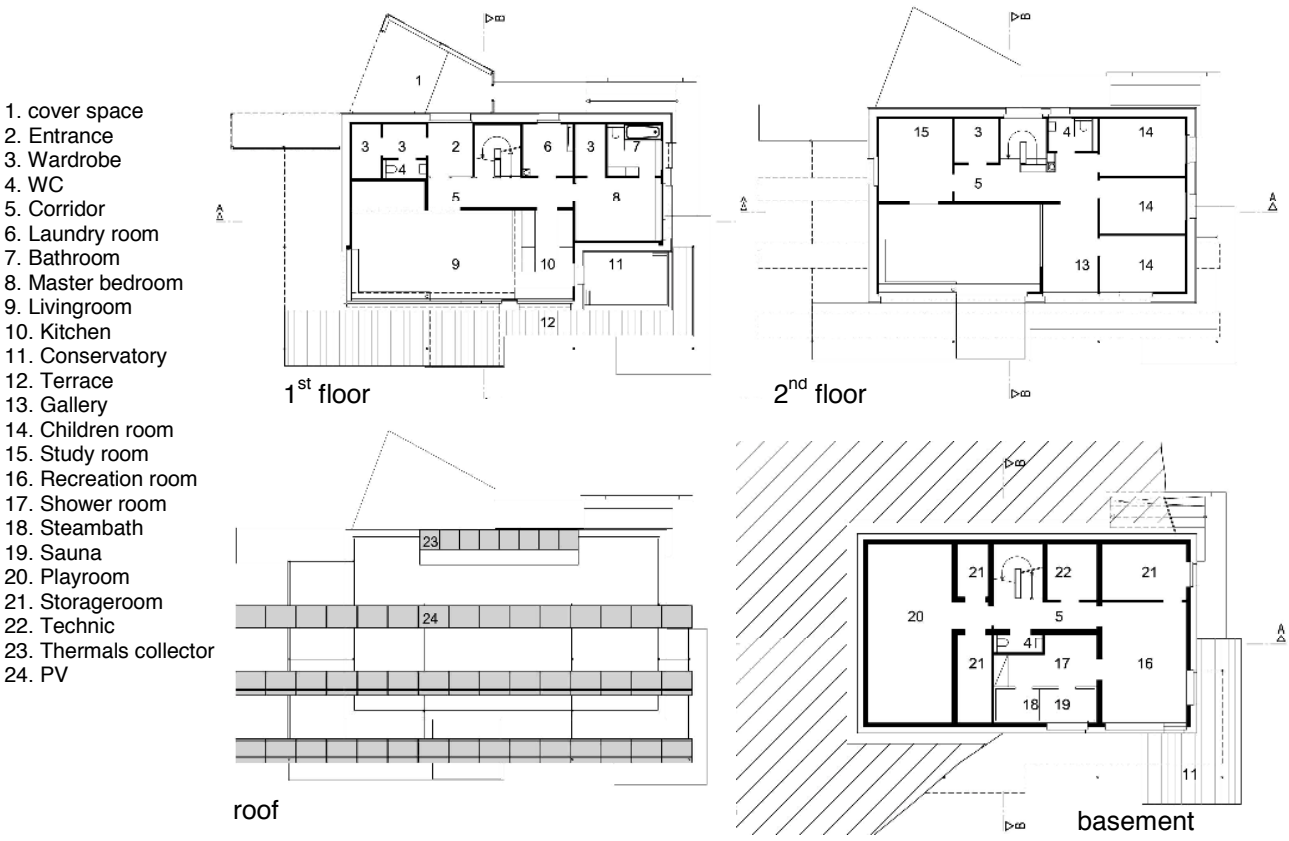

Figure 2 Floor plans and roof

Since the winter sun has to contribute a big part of the heating of the house, the south side of it is opened with big windows. This goes back to the fact that just in the south façade passive house quality windows can give a positive balance over the heating season (and not windows at other orientations).

Separate lightweight construction is built over the building to support the large array of photovoltaic panels (90 m^2), which provide a source for renewable energy and at the same time provide additional shading for the roof and southern façade.

Special slanted extension of the roof construction on the northern side is created to allow additional night cooling through natural ventilation. The extension also gives support and thermal resistance for roof integrated solar thermal collectors (11,6 m^2 active surface area). Those roof collectors are optimized for the summer sun (warm water production). Additionally, a separate array of solar thermal collectors (13,1 m^2 active surface area for

heating and warm water) are integrated to southern façade and optimized for the winter operation. Those vertical collectors gain special profit from the deep inclination of the winter sun and from the permanent snow reflection at this time.

2.2 Thermal envelope

The house is built with mixed construction system – the basement (partly in ground and partly open to the sloping hillside) is casted concrete construction with thick layer of XPS/EPS insulation depending on the wall/floor type. The aboveground perimeter walls have 300 mm of EPS insulation and belowground perimeter walls have 500 mm of EPS insulation. The floor slab configuration features 300 mm of XPS insulation and 100 mm of EPS insulation.

Ground floor and upper floor have a 94 mm thick cross-laminated timber block elements (KLH) as the static layer and 400 mm of cellulose insulation with custom made C-joists made out of timber and OSB sheets. The roof panel is insulated with wedge shaped EPS insulation (380 mm - 550 mm). The walls of the upper floors have façade solution with ventilated cavities mainly covered with rendering boards and partly covered by vertical solar collectors.

Special construction was applied to unheated (but inside building's rectangular form) conservatory floor, which needed 80 mm of vacuum insulation panels (Vacupor Vacuspeed) to achieve the needed thermal resistance and also lower the thermal bridges in surrounding junctions.

The glazed areas feature krypton filled triple glazing with different low-emissivity coatings depending on the orientation of the windows and glazed doors. The declared Ug values of the glazing units are 0,60 W/(m^2K) for the southern façade and 0,49 W/(m2K) for other orientations, the SHGC values for these glazing units are accordingly 0,59…0,62 for southern façade and 0,36…0,37 for other facades depending on the glazing thickness. The glazing properties are differentiated to maximize the solar gain during the heating season. The wooden window frames with thermal separation (SmartWin) have very low thermal conductivity (average Uf value for open able windows 0,75 W/(m^2K) and 0,59 W/(m^2K) for fixed windows) to minimize the heat losses.

Additionally all possible measures were taken to lower the heat losses including the optimization of thermal bridges. The thermal bridging in main junction types were avoided by the selection of construction type with uniform outside insulation. However, the bulk amount of different window connection details were calculated with LBNL Therm software to achieve as good as possible solutions for regular installation, but also for fixing the shading rolls on southern façade. Almost all possible junctions were assessed with 2D finite element calculation in order to gain all possible reductions in heat balance calculation. An overall reduction by 1,9 kWh/(m^2yr) to annual net heat demand was achieved compared to situation with no thermal bridge input using external dimensions.

In total the average thermal conductivity of the whole building envelope (including windows, doors and linear thermal bridges) is 0,146 W/(m^2K).

2.3 Ventilation system

The building has balanced mechanical ventilation system with PHI certified passive house ventilation unit (Paul Novus 300 with exhaust side heat recovery efficiency 93% according to PHI certification system) [Passivhaus Inst 2009]. Fresh air with no additional heating is supplied to living-room and bedrooms and then exhausted from kitchen, bathrooms. The airflows have been reduced to limit the risk of overly dry air during the winter season. The average airflow rate measured during the start-up of the ventilation system is 280 m^3/h, which corresponds to average air change rate of 0,4 h^{-1}. Preliminary measurements show that CO_2 levels are low enough to further lower the airflows if necessary.

The frost protection of the ventilation unit is solely by sub-soil brine heat-exchanger. The system features 226 m (with 40 mm diameter) of plastic pipe buried horizontally in the depth of approx. 1,0 to 1,2 m and connected to Paul Sole Defroster unit SD-550, which controls the fluid flow speed of the system according to air-temperature before the ventilation unit. Preliminary measurement results show stable air temperatures around 1°C after the defrosting unit for the first heating period.

The infiltration and exfiltration of the air through the building envelope is reduced radically through the use of special airtightness products and careful planning and execution. Measured average airtightness at the 50 Pa pressure difference (average air change rate n_{50} of the under- and over pressurization test) is 0,36 h^{-1}.

2.4 Heating system

The heating system is based on ground source heat pump combined with split solar thermal system. Wiessmann “Vitocal 300 G BWC” ground source (two 80 m deep vertical boreholes) heat pump unit with 5,9 kW heating power output and declared (EN 14511) COP of 4,51 (for B0W35 conditions at flow/return difference of 5K) is combined with Sonnenkraft roof-mounted (11,6 m^2 active area) and vertical wall-mounted (13,1 m^2 active area) solar thermal panels and 2 x 1000 l storage tanks (PSC1000E). The panels are oriented directly to south. The storage tanks are covered with 200 mm insulation to reduce the stand-by heat losses and lower the overheating of the rooms on the basement floor.

A very short DHW circulation system with connected distribution pipes as well as piping from storage tanks to wall- and floor-heating collectors are insulated with 40 mm mineral wool or 13 mm Armaflex technical insulation depending on the placement of the piping.

The heat is distributed through water based wall- and floor-heating system with supply and return temperatures of 39/33 °C. The wall-heating system was chosen to lower the fluid temperatures and provide more uniform temperature distribution for greater indoor comfort.

2.5 Grid-connected PV system

The system consists of 66 panels SolarWorld Sunmodule Plus SW 196 Vario poly with unit dimensions 1001 x 1357 mm. The total panel area is 89, 8 m^2. Maximum power P_{max} under standard test conditions (STC) is 196 Wp. The panels are located in 3 rows, 22 units in each row (figure 4). Tilt angle from horizontal is 38°.

Figure 3 Roof with mounted PVs. Solar thermal collectors on the left.

Inverter is Solutronic Solplus 100, 11 kW, 98% efficiency. The system has Solutronic Loger with LAN output. Maximum output AC is 11000 W. According to PVGIS calculation (Photovoltaic Geographical Information System for Europe) [ECJRC Institute for Environment and Sustainability 2013], the annual production of the system is 10120 kWh (setting 5% losses).

2.6 Heat balance of the building

The heat balance and subsequent net energy demand for space heating was calculated using PHPP2007 software (ISO 13790 monthly method). A detailed energy model was generated carefully describing all different envelope areas, lengths of the linear thermal bridges (calculated separately with finite element calculations) the shading situation etc.

Average climate data for Southern part of Estonia was selected from the default database in calculation software. The description of the usage (number of people, use of household appliances, energy demand for technical appliances etc) and internal gains was carefully estimated, which corresponded well with the conservative standard usage defined by Passivhaus Institute (average internal heat gains 2,1 W/m2) [Passivhaus Inst 2012]. Consumption of DHW (25 l/(d pers)) and heating setpoint temperature (20 °C) for Passive House certification were also defined according to standard usage.

Throughout the projecting phase and also in building process the heat balance of the house and its several configurations was iteratively calculated to optimize the room layout, insulation thicknesses, required efficiencies of the technical equipment and especially the

configuration of glazed areas regarding their size, fragmentation and thermal and solar transmittances in order to fulfil the passive house requirements defined internationally. The final (as built) heat balance of the building for the heating period is given in the figure 4. The estimated annual net space heat demand of the building is 4043,8 kWh/a, which corresponds to specific net space heat demand of 14,4 kWh/(m^2a).

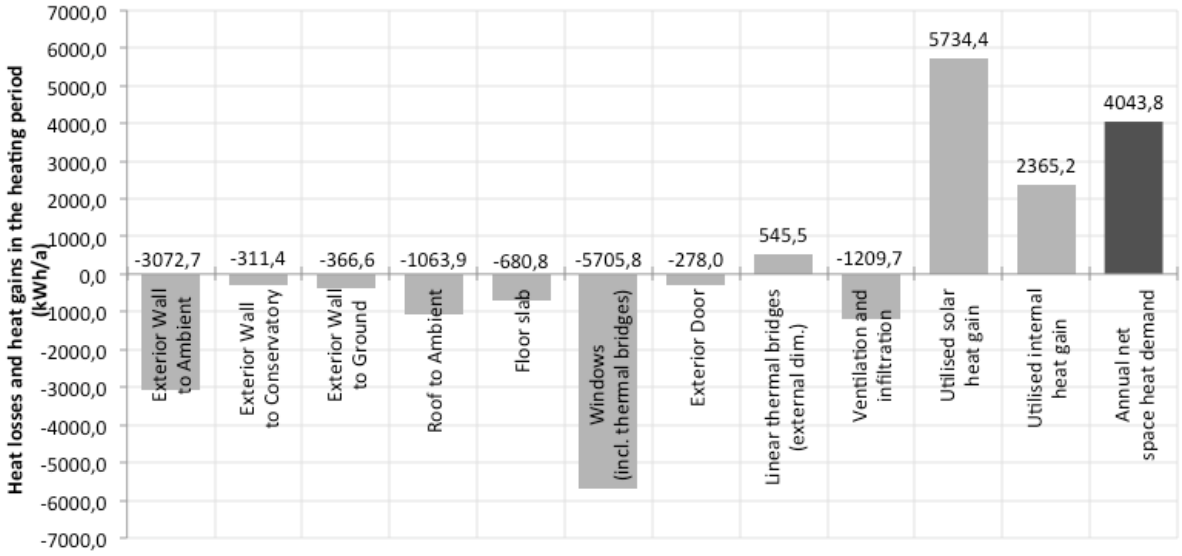

Figure 4 Heat balance of the building (as built) for the heating period.

From the Figure 4 it can be seen that heat loss through ventilation and air leakages is very small, which is achieved through the use of very efficient ventilation heat recovery system combined with ground-coupled brine preheating unit and good airtightness of the building envelope.

The heat loss through the highly insulated roof and floor construction is also quite small. The remaining heat loss through external wall (to ambient and also to unheated conservatory) has a lot more influence on heat balance. Although the thermal transmittance of the glazing units and also window frames are radically reduced, the windows are still the largest source of heat loss through the building envelope. The heat losses through windows and doors are more than all other sources of transmission heat losses altogether. This can be attributed to extensive glazing area on the south façade and also to few larger windows on eastern and western façade. Nevertheless, the large areas of glazing are a result of project optimization towards the energy efficiency. The losses through transparent envelope areas can be largely compensated by solar heat gains during the heating period even in the cold climate of Estonia. The separate heat balance of window areas for heating period (i.e. for the months that have calculated heat demand in this building) is given in the figure 5.

The calculations showed that using windows with high solar transmittance and very good thermal resistance resulted to overall heat gain in the heating period. The balance of heat gains and losses for the eastern and western windows showed that although a large part of combined heat losses can be compensated by the solar gains, the configuration still results

in total loss because of the high latitude and low sunshine duration during the heating period.

The monthly figures of total heat loss compared to utilize and non-utilized solar and internal heat gains are shown in the figure 5. It can be seen that for the deepest winter months (November, December and January) the solar gains are low in such high latitude and cold Estonian climate, but already in February the solar gains surpass the remaining heat demand. For all other months in a typical (average) year all heat losses are compensated by internal and solar heat gains so no remaining space heat demand occurs. The extensive part of non-utilised solar heat gains in spring and summer period reduced by using external shading blinds on southern façade and night cooling through automatically induced natural ventilation (the shading and night cooling effect is not included in calculation results shown in figure 5).

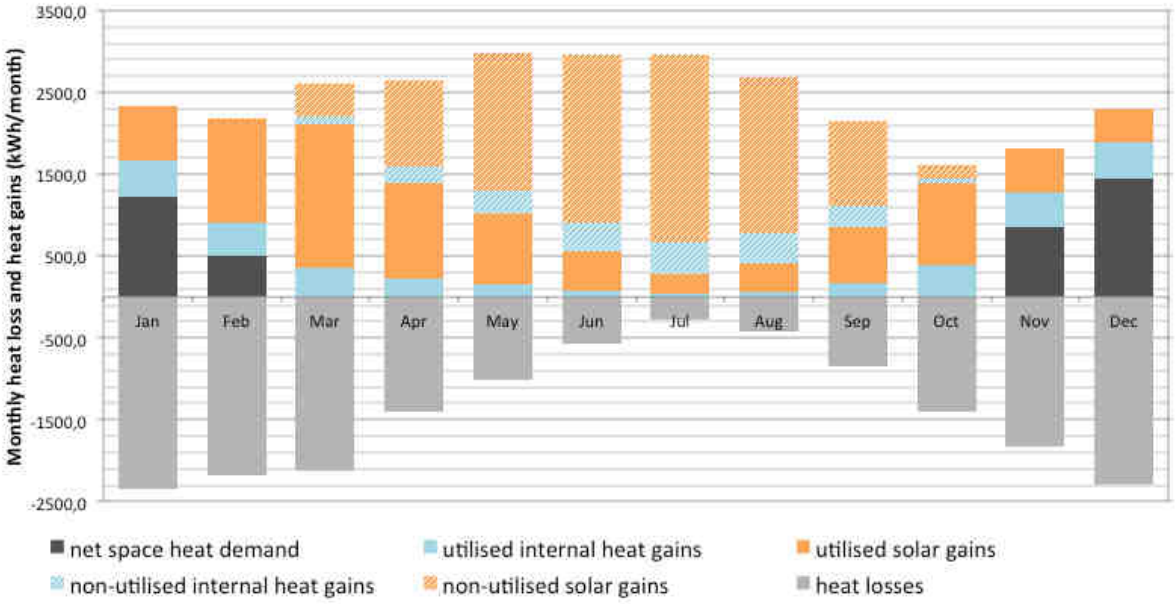

Figure 5 Estimated monthly heat losses and gains of the building (the effect of external movable shading elements are not taken into account for the summer months in this figure).

3. Final energy demand

Additionally to the heat balance and net space heat demand the heat losses of the heating system as well as domestic hot water system was calculated using PHPP2007 software package. Separately, the useful heat production of the solar thermal system was calculated using dynamic TSol calculation software by Sonnenkraft engineers. The useful heat demand for space heating and hot water production along with contributions of solar thermal as well as ground source heat pump system is given in figure 6. It can be seen that non-utilised heat losses from domestic hot water storage and distribution system have a big impact on total energy demand in the building when the energy demand of the building itself is radically reduced. This is mainly related to long pipe network, but also to 2000 l storage system of

solar thermal system, which has large surface area due to its size. The solar thermal system provides approximately 43% of useful energy for total heat demand in the building.

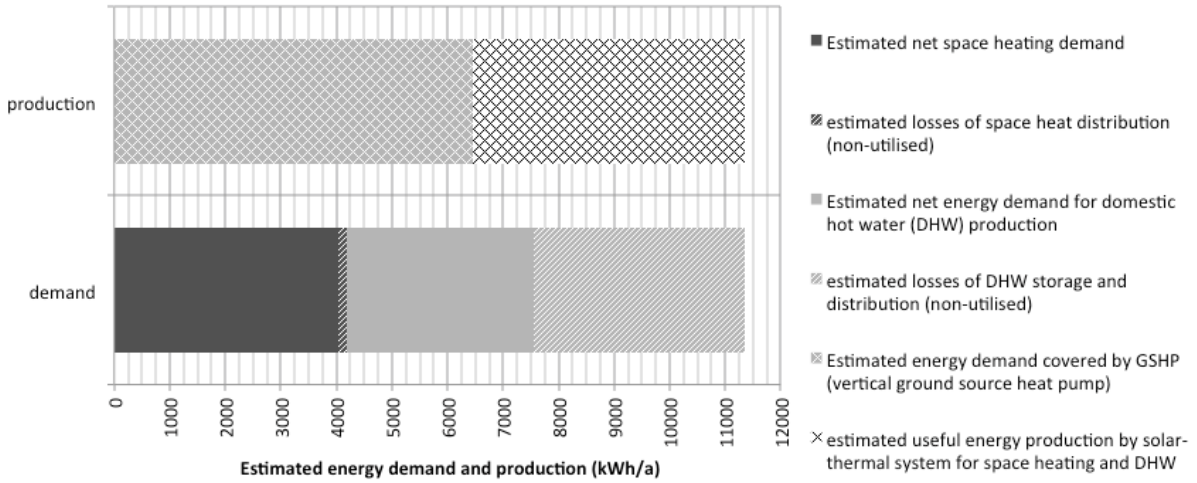

Figure 6 The useful heat energy demand of the building (including storage and distribution losses) and contribution of combined heating system.

In the end, the final energy consumption of the building was estimated for heating system, household appliances, lighting, technical appliance etc. based on standard usage. The necessary solar PV collector area was optimized to cover the final energy demand on a typical year. The electricity production of the PV system was estimated with PVGIS calculator using detailed configuration of the built system. As can be seen in table 1, the estimated final energy (electricity) demand of the building is approximately 10400 kWh/a, which corresponds to specific final energy demand of 37 kWh/(m^2a). The solar PV system produces approximately 10120 kWh/a, which nearly covers the total demand and shows that building a net-zero energy house is possible in Estonian climate.

Table 1 Estimated final energy (electricity) consumption and production of the building

	kWh/a
Estimated electricity production by solar PV (photovoltaic) system	**10120**
Total electricity demand of the building	**10356**
including electricity demand of GSHP (vertical ground source heat pump)	2149
including estimated electricity demand of technical installations (ventilators, pumps etc.)	2000
including estimated electricity demand of domestic appliances, lighting, sauna equipment etc.	6207

4. Monitoring

After completion in February 2013 the building has been equipped with extensive monitoring system to gather information about indoor climate and performance of building system as well as external wall construction. The air temperature, relative humidity and CO_2 levels are

monitored in several rooms, air temperature and relative humidity is monitored in ventilation system (air intake, preheated, supply, and extract airflows). Additionally energy consumption of heating system is measured along with solar thermal and solar PV system performance monitoring. Separately the external wall and massive clay partition wall layers are monitored.

5. Conclusion

The built project shows that through iterative calculation and design process a architectural solution is created, which allows extensive use of passive solar energy through the south facing glazed façade. The use of excellent building components along with favouring architectural solution radically reduces heat losses, which makes it possible to cover the entire energy demand of the building with renewable sources enabling to create net-zero energy building with the help of grid connected solar PV system. Maximizing the solar heat gain in the heating period, while keeping the transmission heat losses through the glazed areas is crucial when targeting the internationally defined passive house criteria in Nordic climate region.

6. Data and Project Participants

Object address: Metsa 5a, Põlva, Estonia. Owner: Kuldar Leis.
Architects: Martha Enriquez Reinberg and Georg W. Reinberg, Architekturbüro Reinberg ZT GmbH, Wien, Austria.
Treated floor area according to PHPP: 305 m²; Volume 1.586 m³
Construction time: October 2011 – May 2013

Consulters: Tõnu Mauring, Jaanus Hallik and Kristo Kalbe, University of Tartu (building physics, monitoring), Johannes Riebenbauer, Graz (static engineer), S&P Climadesign GmbH (technical systems), Margus Valge, Sense OÜ (project management and site supervision), PassiveHouse OÜ Estonia and Passive House Institute, Darmstadt (certification).

Short Summary

Life Cycle Assessment has been used for several years and has led to the development of different LCA tools worldwide.
Previous reviews have shown that each tool relies on its own data, methodological rules and environmental indicators, thus making comparison and interoperability difficult. To increase the harmonization and the widespread use of such tools in the construction sector, they need to be adapted to the different involved practitioners. For example, LCA can be used for early design but also for certification purposes (e.g. HQE, BREEAM, DGNB …). However, existing LCA tools do not entirely fulfil the user needs along the design process.

This paper presents general recommendations to move towards a new generation of building LCA tools. They are based on the findings from the recent European project EeBGuide. This project developed a comprehensive guidance document as an online InfoHub for building LCA practitioners and LCA tool developers [18]. The recommendations are breakdown according to the ISO 14040 standard and the ILCD Handbook steps (e.g. goal and scope definition, inventory analysis, impact assessment, interpretation) but also according to the conventional life cycle stages of a building (e.g. production, construction, use and end of life stages) defined in the new European standards EN 15978 and EN 15804. The scope of the guidance includes the different contributors of a building LCA: the building products and equipment, the construction site, the operational energy and water use, the transport of the users of the building.

The major outcomes are a proposal for adapting the data, calculation rules and methodology according to three different study types: screening, simplified and complete LCA. These study types let the possibility to conduct a LCA study in an early stage of a building by focusing e.g. on default values and adapted calculations rules while more detailed data can be chosen for specific assessment. Interests of the recommendations for the different stakeholders are discussed in this

paper. Then, the implementation of the recommendations on a case study of a detached house shows the feasibility to use adapted calculation rules within a building LCA tool.

Further works would now be needed, notably a validation works involving the comparison between a screening and a complete LCA. Another challenge is also the effort that needs to be done by building LCA tool developers to take into account the different study types within their own tools.

Keywords: LCA tools, buildings, products and equipment, water, energy consumption, screening, simplified, complete assessment.

1. Introduction

1.1 European context of Sustainable Construction

As new buildings now consume about the same amount of energy during an average 50 year lifespan as it is necessary to build them, new assessment methodologies encompassing the whole life cycle of building are required. Life Cycle Assessment (LCA) studies are being used more and more by leading practitioners as a means of demonstrating the ”whole life” energy efficiency of buildings. LCA studies analyse the impact of products, processes or services along the entire life cycle, which makes it a powerful tool to help companies optimise the ecological footprint of their products. For example, LCA enables to avoid problem shifting for the choice of energy systems of buildings as a whole by accounting of both direct and indirect impacts (e.g. upstream processes).
LCA has first been applied based on ISO 14040-44 [1][2] standards. However, these standards being too general, more specific guidance was recently released, e.g. the ILCD Handbook edited by the JRC of the European Commission [3].
In the construction sector, the recent European standards EN 15804 [4] and EN 15978 [5] are based on the LCA International standards ISO 14040-44. These standards define the general framework and general calculation methods for product LCAs and EPDs and building LCAs.
In the same time, in Europe, building LCAs are the foundation of many building certification schemes as well as of Environmental Product Declarations (EPD) for construction products. Yet the metrics and standards currently used in Europe can be interpreted and implemented in many different ways leading to inconsistencies and lack of comparability. Building certification schemes (like DGNB [6], HQE [7][8] or BREEAM [9]) use also individual sets of calculation rules for LCA in the construction sector.
Though previous papers on building LCA research perspectives recommend integrating the existing body of knowledge presented above (i.e. ISO 14040-44, ILCD, CEN standards) [10], it is unclear how a tool developer or a practitioner can currently do it due to current inconsistencies and diverging guidance [11]. As a consequence, the European landscape of LCA calculation rules is not dominated by harmonized methods, these inconsistencies being also found in available building LCA tools.

1.2 Review of existing building LCA tools

Several building LCA tools already exist in Europe and all over the world. They have been developed since the 1990’s along the development of the LCA methodology at the ISO (e.g. with the development of the ISO standards) or at SETAC level. Previous European projects funded by the seventh framework (e.g. PRESCO [12], ENSLIC-Building [13], LoRe-LCA [14]) have first reported and described the existing LCA tools in Europe. Generally speaking, these tools can be used depending on their goal e.g. for the comparison of design alternatives (ecodesign approach) or for the assessment of the environmental performance of a building (e.g. certification, labels). They can use different data and calculation rules. The environmental indicators are also different and not always comparable making difficult the comparison of studies between different tools.

Table 1 presents an updated review of some of the existing European building LCA tools. In total, 12 LCA software have been identified in Europe (including Switzerland). No general LCA software such as SimaPro or GaBi was considered in the state-of-the-art as we are mainly concerned on dedicated and user-friendly software for construction stakeholders. We also do not take into account other international building LCA tools such as the Impact Estimator [15] or the BEES [16] software developed in North America as the proposal of adapting the tools is first given under the European context for sustainable construction.
A template has been defined to report the main updated characteristics of existing building LCA tools. It includes: a short description of the tool, the country of development, the type of software [can it be used online or does the user need to install it on a personal computer?], the website, the purpose of the tool [are there different data or calculation rules within the tools e.g. for early design or more advanced assessment?], the modelling choices [what are the modelling choices e.g. situation A, B or C according to the ILCD Handbook?], the study type [are there different data or calculation rules within the tools e.g. for early design, complete LCA?], the data used [which LCA data are used in the tool e.g. generic data, EPD…], the life cycle stages assessed [which building stages are included in the tool?], the contributors assessed [which contributors of the building total impacts can be assessed with the tool?], the environmental indicators [which indicators are taken into account?] and the interpretation phase [e.g. is there any sensitivity analyses tool available to the user?]. The full review is freely available online in [17]. Table 1 only presents the main characteristics of available LCA tools for buildings.

* replacing the former LCA tool ENVEST II

The detailed characteristics of these tools show that each of them has been developed under a specific context and with a pre-defined goal in mind. Indeed, each building LCA tool currently lack in assessing the full “picture” of the building life cycle for the different user needs and objectives. For example, very few tools properly assess the impact related to the construction site, though construction companies are more and more interested in assessing this aspect. Not all of them propose different datasets (e.g. generic and specific data). Generally speaking, each tool has been developed to meet the need of some stakeholders but not all of them. In this paper, we present an approach for a new generation of building LCA tools based on a consistent framework (section 2) including different study types (section 3) with example of implementation (section 4).

2. Proposal for an improved framework for building LCA

2.1 Methodological approach and general framework

The existing documentations of LCA and buildings are rather not harmonized. Here, an approach is proposed to integrate existing knowledge in a structured way that could be further improved and updated. This is based on the findings of the European project EeBGuide [18]. The proposal consists in a list of important aspects to be taken into account for building LCA under different goal definitions e.g. assessment of a building stock, comparison of design alternatives within a design team, assessment of the environmental performance of a building, comparative assertions etc. The framework and the description of the aspects have been defined by a European LCA expert group including a panel of review experts as well as a public consultation process to get feedbacks from stakeholders on these recommendations.

Recommendations were structured according to the steps of the LCA methodology in ISO 14040 and in the ILCD Handbook (see Fig. 1): goal and scope definition (e.g. functional unit or equivalent of the building, cut-off rules, allocations, data quality, infrastructures treatment?), inventory and impact assessment (indicators to include?), interpretation (e.g. use of sensitivity analyses, uncertainty assessment?) and reporting (level of information?).
A first outcome is the proposal to adapt the building LCA tool to answer different goal definition (the “flexibility” perspective) next to a harmonization (set of commun rules). ILCD situations A and B referring to attributional and consequential modelling were thus analysed. Situation A refers to small changes in the background system while consequential LCA refers to bigger changes in the background system in response to a decision. As stated by [10], for the building sector, the electricity consumption may be subjected to situation B especially for large scale analysis in support to policies or regulations. In a simplified approach, consequential studies may also require light adjustments e.g. provide the users with different datasets (average and marginal consumption mix). In that case, the tool mainly relies upon attributional approach with marginal datasets for scenario analyses [21]. Such developments enable to improve the scope of the tools while keeping them as far as possible user-friendly for the construction stakeholders. The release of new generation of LCI databases may also help for this perspective.

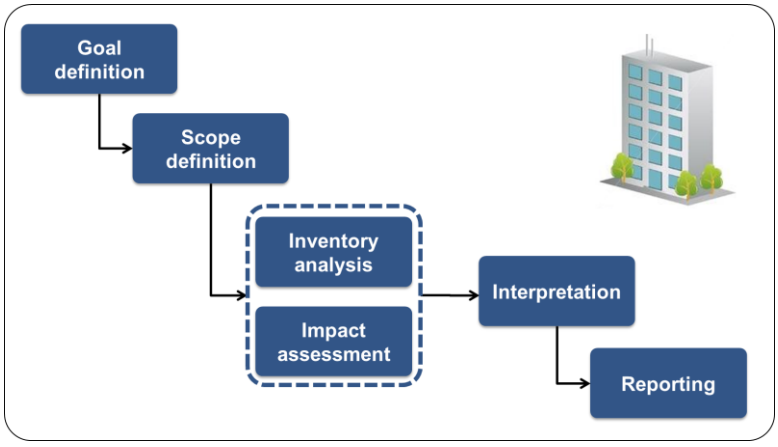

Fig. 1: Representation of the different steps of the LCA framework

With more than 100 important aspects identified and addressed, the EeBGuide Info Hub is a relevant source of information for building LCA tool developers willing to move towards a next generation of tools more adapted to the user needs and including the latest research (e.g. recent scientific results, previous EU projects results such as LORE-LCA) and standardization works on building LCA.

Beyond the content of each aspect (in terms of provisions, rules from both ILCD Handbook and CEN/ TC 350 standards, guidance), the recommendations provide a very systematic approach for carrying out building LCA studies.
Below are examples of important aspects mainly for attributional LCA that would need to be included in LCA tools according to the general framework:

- Development of filter functions in the tool to adapt or refine the goal and scope
- Develop and integrate different LCA datasets to match the users and project stages needs
- Inclusion of the different contributors of a building (see section 2.2)
- Implementation of different study types (see section 3)

Filter function and predefined rules may streamline the data and calculation rules for a specific goal definition. For example, this can be the case if we want to assess different refurbishment scenarios. To that purpose, a methodology to account for different refurbishment scenarios has been proposed in the guidance document [19]. When implemented in a tool, the different steps of the scope definition can be predefined for the final user by breaking down the different refurbishment stages for each scenario. Other goal and scope should follow a similar approach and are detailed in the online InfoHub [18].

Other specific aspects documented in the guidance document can be used as a basis by tool developers. Fig. 1 presents the steps of the LCA framework. The merging of both inventory analysis and impact assessment stages is due to the fact that most building LCA studies are done using already predefined data in terms of LCI or indicators (e.g. generic data or EPD of building products and processes). This is a simplification needed to keep building LCA tools (in opposite to general LCA software like SimaPro, GaBi, etc.) as user friendly as possible for the practitioners that are not and will not become LCA experts.

The full list of important general aspects to take into account in building LCA are reported in the online InfoHub for each step of the LCA framework. Other requirements are: the use of harmonized reporting templates as an output of the software [21], ability to perform sensitivity analysis and uncertainty analysis e.g. Monte Carlo, include the datasets complying with ILCD requirements, link the LCA assessment to CAD software and energy calculation software to optimize the workflow and to avoid user errors.

2.2 Towards conventional life cycle stages of a building and contributors

Most of the existing building LCA tools do not have the same system boundaries. They also do not present and separate the results in a harmonized way. One of the major outcomes of EeBGuide is to propose harmonization of the life cycle stages. Important aspects were classified per life cycle stage of a building as proposed in EN 15804 and EN 15978 (see Fig. 2): module A (production and construction processes), module B (use stage), module C (end of life) and benefits and loads beyond the system boundaries (notably recycling potentials). Fig. 2 presents the name of the modules and sub-modules according to the EN 15978 standard. The full list of important aspects to take into account in building LCA per life cycle step are reported in the online InfoHub for more information [18].
A building LCA can also be breakdown in different impact sources. Such a distinction with the contributors is essential as it enables the building practitioners to quickly identify the hotspots for both ecodesign and performance-based approaches. Building stakeholders are indeed more familiar with the notion of “contributor” than the life cycle stages as defined in EN 15978. The different contributors that should be included in an improved building LCA tools are: the building products and equipment, defined all along the life cycle of a building (modules A to C + D), the construction and deconstruction activities (modules A4-A5 and C1), the operational water consumption (module B7), and the operational energy use (module B6 in Fig. 2). Other contributors are the transport of the users of the building (within module B as additional information) and the waste produced by the users of the buildings (within module B as additional information).

Building Assessment Information			
Life cycle stage modules			**Name of the sub-module**
Building life cycle information	**PRODUCT stage**	A1	Raw material supply
		A2	Transport

Fig. 2: Life cycle stages of a building according to EN 15978

3. Proposal for three building LCA study types

In this section, a proposal for three study types are described for three contributors of the environmental impacts of a building: the impact related to building products and equipment, the impact related to the energy consumption and the impact related to the water consumption. Most of the guidance for these study types relates to the situation A of the ILCD i.e. the attributional situation. This is in line with the CEN standards. Fig. 3 presents the adapted calculation rules (scope) and data (LCI and impact) referring to different goal definition. Conducting LCA may be very time consuming and is not very often matching the design team needs [22]. As a result, screening and simplified LCA are proposed here to help during the early design or for quick assessment where no detailed modelling is possible due to a lack of information. In opposite complete LCA provides a broader scope with more requirements in terms of cut-off rules or specific data.

The contributor “energy consumption” enables to assess the impacts related to the use phase (module B6 of the EN 15978). The main interest is to breakdown in different level of details the assessment. The expected performance target was chosen for screening LCA i.e. complying to current regulations when designing a building. If more detailed results are needed, the use of regulatory tool or dynamic simulation software is suggested for simplified and complete LCA. The scope should also be enlarged and data more specified from screening to complete LCA. For example, if the user wants to assess the exported renewable energy produced on site, the energy consumption values from the thermal analysis software need to be presented per hour and per end use e.g. heating, domestic hot water (complete LCA) [23].

A similar approach is proposed for the water consumption contributor. Starting from statistical data for the building type in a country (screening LCA), a top down approach (simplified LCA) and a bottom up (complete LCA) approach are proposed to refine the analysis once more characteristics are available for the water equipment devices.

Finally, the contributor “products and equipment” needs data from cradle-to-grave i.e. for the modules A, B and C of the European standard EN 15978. Based on these system boundaries, adapted data are proposed for screening and simplified LCA using ratio e.g. kWh/m² for the different building elements or generic LCA data describing components, products and materials. Equipment are included even in screening LCA as they are not negligible to the building impact [24] though default values may be used as well as for building products. More precisions on screening and simplified methods are proposed in [25]. A full description of the study types for each contributor is also available in the InfoHub of the EeBGuide project [18].

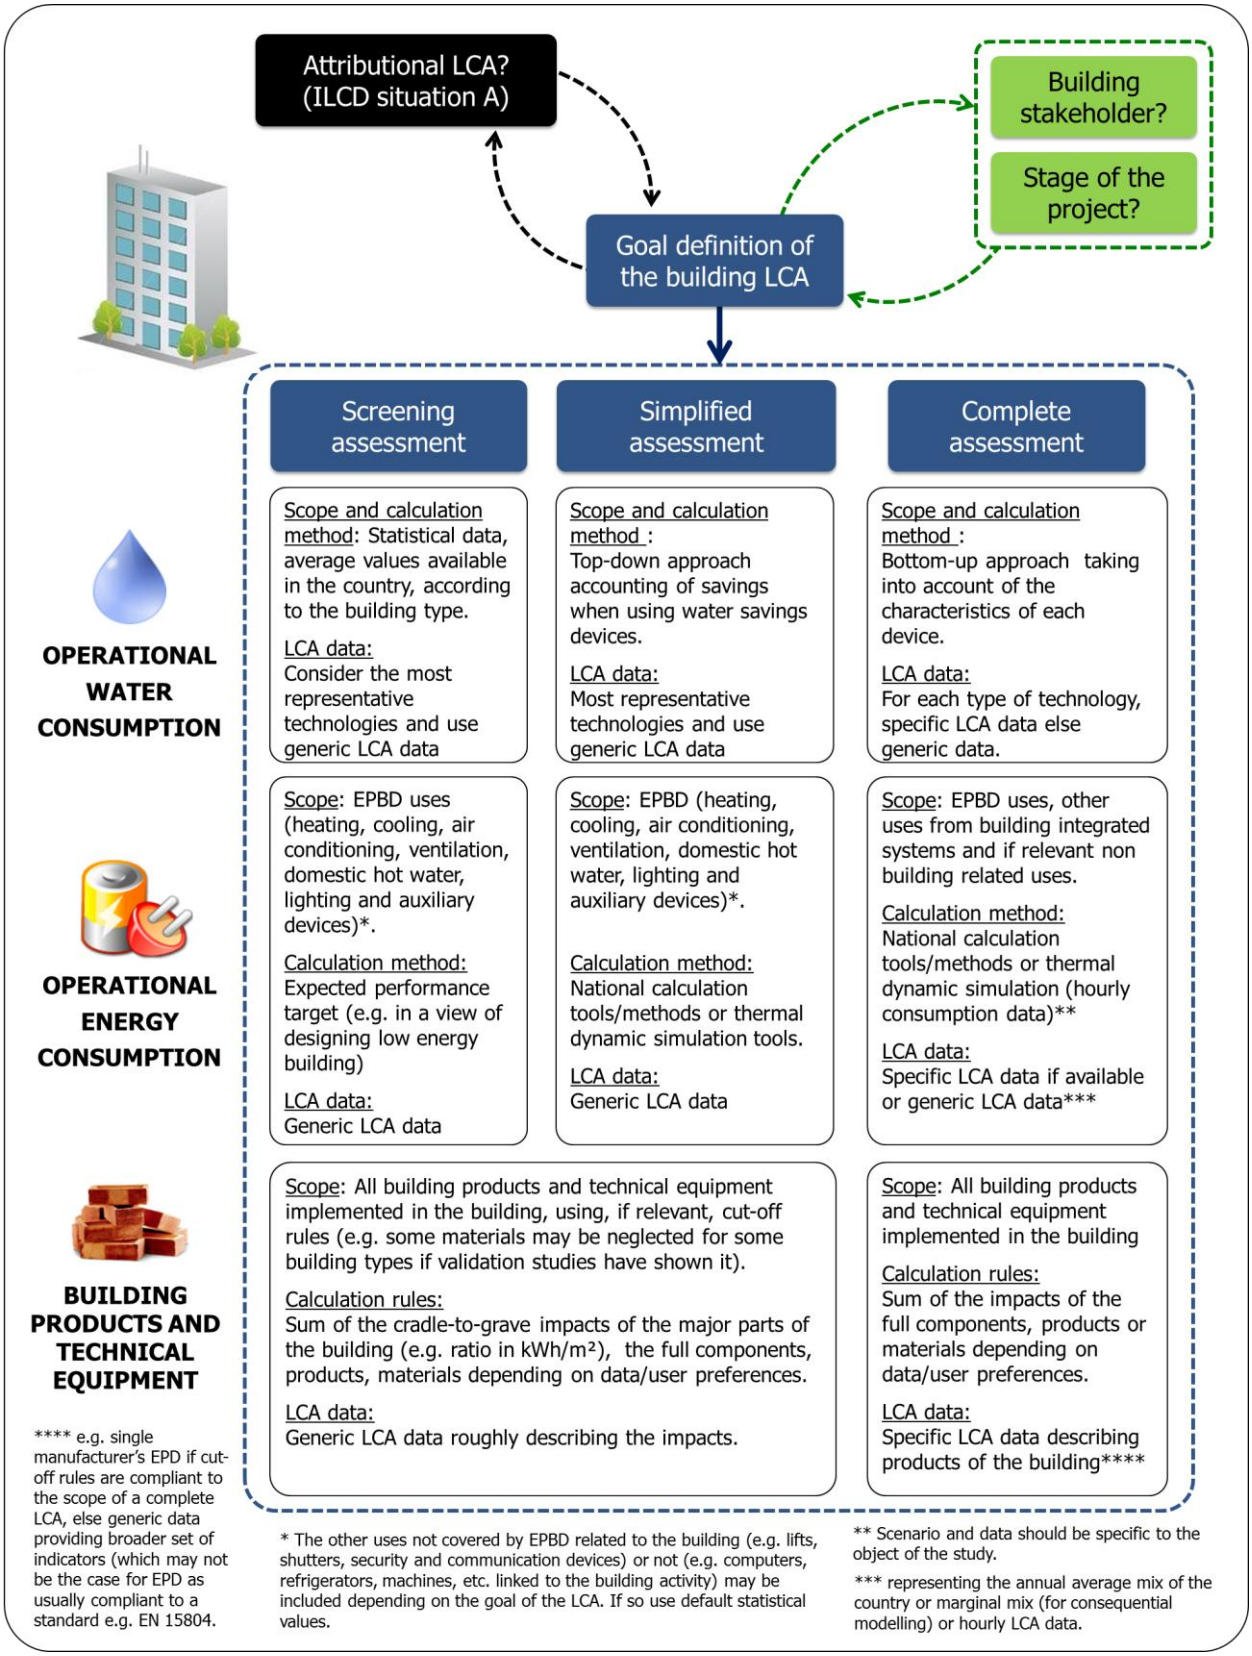

Fig. 3: Study types for the three contributors: operational water consumption, operational energy consumption, building products and technical equipment

4. Example of the use of the study types

4.1 Goal and scope

The aim of this study case is the calculation of the environmental performance of a single family house (stand-alone study, no comparative assertion).

4.2 Approach

The LCA analysis was undertaken in the context of the French pilot project HQE performance [26] concerning the assessment of the environmental performance of about 80 residential and non-residential low-energy buildings. This project allowed establishing first reference values indicator per indicator through a statistical analysis [27].The system boundaries are set from cradle to grave including the three contributors: water, energy and products and equipment. The reference study period is set at 100 years. To be in line with the requirements of HQE Performance project, a detailed assessment was chosen for these contributors. A detailed assessment corresponds to a complete LCA study type - see Fig. *3.* For example, the building products and technical equipment contributor was assessed using all the elements without cut-off rules in the description of the building. Moreover, specific data based on cradle-to-grave group or single manufacturer's EPD available in France [28] were used. 15 mid-point and Life Cycle Inventory (LCI) indicators were assessed based on the ones displayed in the French EPDs. All the case study assumptions are more detailed in [29].
In addition, the three study types (i.e. screening, simplified and complete LCA – see Figure 3) were performed for one contributor, i.e. the water consumption. The screening LCA was based on statistical data, considering a value of 48 m^3 / person / year. The simplified LCA was based on a top down approach, accounting for savings and extra consumptions compared to statistical data. Here, the example of two water saving devices: dual-flush toilet 3L/6L instead of single (traditional) flush toilet 6L and low-flow showerhead. The complete LCA was based on a bottom up approach, taken into account the specific data for all devices and users' behaviour.

4.3 Results and interpretation

Table 2 presents the global results for the three contributors for the complete LCA of the house. The contribution of products and equipment on total results is about 60% for the Global Warming Potential (GWP) indicator and 99% for the Non Hazardous and Inert (NHI) Waste. This is mainly due to the production of inert waste during the end of life of the building. It can also be noticed that the contribution of the operational energy use on total results is above 75% for the radioactive Waste (Rad W). This is explained to the use of the French grid mix having a 78% share of nuclear power plants (lower CO_2 emissions but higher radioactive waste). We finally noticed that the operational water use controlled the net fresh water indicator (about 95%). Further results for each contributor may be retrieved from [29]. The results obtained via the three study types for the water consumption contributor are given in Table 3.

Table 2: Results for the three contributors in complete LCA (reference study period of 100 years)

N°	Contributor *Unit per m²Net floor area*year*	GWP *[kg eq-CO2]*	Water *[L]*	NHI Waste *[kg]*	Rad W *[kg]*
1	Products and equipment	6.73	64.8	17.8	9.79E-04
2	Energy consumption	4.37	83.0	7.16E-02	4.40E-03
3	Water consumption	0.286	2600	3.32E-01	2.87E-04
	TOTAL	11.4	2747.8	18.2	5.67E-03

The results show that the study type does not mislead the assessment interpretation, since the same order of magnitude is found for the different indicators. The highest deviation is found for the net fresh water indicator with 30% of deviation between the complete and the simplified LCA and 7% between the complete and the screening approach. Such results were expected as this indicator is mostly driven by the operational water consumption contributor.

Table 3: Results for the three study types (complete, simplified, screening) for the Operational Water consumption contributor (reference study period of 100 years)

Study type *Unit per m²Net floor area*year*	GWP *[kg eq-CO2]*	Water *[L]*	NHI Waste *[kg]*	Rad W *[kg]*
Complete LCA	0.286	2600	2.85E-03	2.87E-04
Simplified LCA	0.200	1816	1.99E-03	2.01E-04
Screening LCA	0.267	2425	2.65E-03	2.68E-04

The deviation between the results is not linked to the complexity of the study type. With the data taken into account in this study, less deviation is noticed between the complete and screening than between complete and simplified. It can be concluded that each study type should be used according to the stakeholders' needs and data availability.

4.4 Interpretation and limitations

Other study types should be used and tested in another context e.g. in comparative assertions with a high emphasis on comparability purposes. In future works, it will also be useful to assess all the study types for all the contributors of a building.

5. Discussions

5.1 Relevance of study types for the building stakeholders and project stages

Designing a building is a complex process with different stakeholders. One possible option to ensure our proposal (section 2 and 3) is matching the user needs during their operational practice is to conduct surveys and interviews of these stakeholders involved at the different stages of a building project. So that, a tool developer can make sure his decision making tool and the related study types will be useful and used by designers, construction companies, labelling assessors etc. Such surveys are recently reported for the French context e.g. in [30].
In addition, depending on the stakeholders and on the stage of the design, the calculation method and the interface within the tool may be different even if general rules proposed in section 3 are the same. For example, to assess the impact related to products and equipment in screening and simplified LCA, architects, design offices or construction companies may want to use different level of data: more averaged or aggregated for the architect (willing to design elements and buildings as a whole) but more at the level of materials for the construction engineer (willing to quantify accurately kg of reinforcing steel and m3 of concrete). These preliminary works should be continued so that the tools and the proposed study types can be adapted accordingly.

5.2 Consistency, completeness and validation works between the study types

It is important to ensure consistency within the tool. The use of screening or simplified assessment only aims at easing the LCA in early design or for quick building LCA. Consistency should be ensured between the different study types by developing filter functions, default values for screening and simplified, use of a consistent LCA database within the tool providing generic and specific data [31], use of consistent Reference Service Life for products and equipment [32].

Different scope may also be defined within a study type. As the proposal does not want to be restrictive in further use and application, it may be possible to adapt the study type of the tool to the goal of the tool developer and to his user needs. For example, ideally, a complete LCA is based on specific datasets for a comprehensive set of impact categories. But very few data comply with these two requirements today. Indeed, specific data in the form of EPDs are usually limited in scope including a limited set of impact categories. If the tool developer has a special interest in assessing a broad set of impact categories, he may not use EPD according to EN 15804 that do not include e.g. toxicity and ecotoxicity indicators. In that sense, the current proposal is general

and should be refining according to the different use of LCA in the building sector.

Based on the proposal of this paper, validation works should also be conducted especially for screening and simplified assessment that may be subject to deviations with the complete LCA due to data gaps and differences (generic databases vs. EPD databases), limited scope (e.g. reduction of the system boundaries by neglecting life cycle stages or building elements) [33][34]. The proposal presented in section 2 and 3 is thus a first step towards harmonization of building LCA tools in Europe and then will be the basis of next generation of tools. Validation and inter-comparison should include the intra-validation between study types within a tool and then inter-comparison between the available tools. New validation exercises are needed in Europe to benchmarks the new kind of tools.

5.3 Challenges for European building LCA tool developers

The implementation of provisions and guidance briefly presented in sections 2 and 3 is a very challenging topic as we can see from the description of the main characteristics of existing LCA tools (section 1) that none of them include all the recommendations to date. These recommendations aim at increasing the use of the LCA in the building sector by proposing consistent guidelines according to different goal definitions and needs of the practitioners (that are not LCA experts). However, the implementation of the provisions and guidance can only be done in partnership with the European and national LCA networks (e.g. industry, research, tool developers, data providers) involved in LCA applied to the construction sector. For example, every national context does not have its own generic or EPD database today which can be a limit for the proper implementation of the proposed study types (e.g. for screening and complete LCA).
Concerning the study types proposed in this paper, the tool developer should carefully identify whether this proposal (mostly addressing an attributional situation) match his goal and scope. If not, other calculation rules should be defined e.g. for consequential modelling of buildings.

Collaborative work is also needed between the different software developers e.g. between thermal analysis software and building LCA software to make sure the output of one tool fulfils the needs of the other. Automatic link may be used but it depends on the user preferences e.g. a thermal analyst may be keen on having automatic link between thermal simulation software and LCA while a design office or a company willing to conduct an environmental assessment will only use the LCA tool. For some specific contributor of the environmental impacts of a building e.g. the construction site or the deconstruction activities, a closer cooperation with construction companies may be required for collecting statistics and on-site data as input for the building LCA tool.

The proper implementation of CEN/ TC 350 standards also requires feedback from the data providers to be sure the parameters used in the new European EN 15804 / EN 15978 standards are currently not easy to get from background data. For example, EN 15978 standard requests next to the LCIA indicators, “reminder flows” (according to the ILCD terminology) named as “indicators describing resources use” (according to CEN terminology e.g. “Use of non-renewable primary energy excluding non-renewable primary energy resources used as raw materials” or “Use of renewable secondary fuels”) though current versions of background databases (e.g. Ecoinvent v2 or GaBi v5) do not automatically calculate them today due to current IT structures of LCI databases.

5.4 Relevance of the proposal for non-European building LCA tool developers

As recently stated by the Athena Institute in their webpage, it is likely that some European works e.g. the modularity principle of life cycle stages presented in the European standards EN 15804 and EN 15978 may be also used outside Europe e.g. in North America [36]. Such information let us think that the general framework derived from the EeBGuide InfoHub and the related study types presented in this paper can serve as a possible source of information for tool developers though accounting of regional particularities (e.g. non-EU datasets of the corresponding country).

6. Conclusions and perspectives

If the LCA approach is to be applied in ecodesign, research projects, but also in building labelling schemes and EPD schemes, LCA practitioners need on the one hand provision and guidance, and on the other hand should be supported by reliable and easy-to-use building LCA tools. The proposal presented in this paper aimed at integrating the important aspects identified for building LCA in the European EeBGuide project and the proposed study types (screening simplified and complete). Other outcomes include the structuring of the results according to the life cycle stages of EN 15804 and EN 15978 standards for increasing the comparability of European LCA studies, the breakdown the results and the calculation rules per contributor. Finally it is important to move towards a core and consistent set of data, rules and indicators for the new generation of LCA tools to have more comparable building LCA results. In that perspective, it seems relevant to have core rules at the European level and then more detailed guidance e.g. within each European country.

Short Summary

The main constrain for the widespread use of LCA in the building sector is the lack of environmental data for most building materials, products and technologies. Based in the work of CEN TC 350 and in the work of iiSBE Portugal in the development of the Portuguese rating system SBTool$^{PT®}$, this paper aims at presenting and discussing the development of a method to simplify LCA for effective use during the design phase and in the processes of building sustainability assessment.

Keywords: Database, LCIA, LCA, Environmental performance, Sustainability

1. Introduction

It is widely recognised in the field of Building Sustainability Assessment (BSA) that LCA is a much more preferable method for evaluating the environmental pressure caused by materials, building assemblies and the whole life-cycle of a building. Life Cycle Assessment (LCA) is an effective and systematic tool to measuring the potential environmental burdens associated with a product, process, or activity by identifying, quantifying and assessing the impact of the used energy, and materials, and the wastes released to the environment [1]. The complete process of LCA includes goal and scope definition, inventory analysis, impact assessment, and interpretation. The process is naturally iterative as the quality and completeness of information and its plausibility is constantly being tested. LCA considers the potential environmental impacts throughout a product's life cycle (i.e. cradle-to-grave) from raw material acquisition through production, use and disposal. Although the LCA method was at first oriented to materials and products, its application in construction is generally accepted [1]. LCA is very important to compare several possible alternative solutions, which can bring about the same required performance but that differ in terms of environmental consequences. Life cycle impact assessment (LCIA) is the step of LCA in which the inventory (input and output flows of a certain system under analysis) is analysed for environmental impact. For instance, in the LCIA phase the volume of fossil fuel consumed during the transportation phase of a building material is converted in several impact categories, including global warming potential.

Although there are several recognized LCA tools, these tools are not extensively used in building design and most of building sustainability assessment and rating systems are not comprehensive or consistently LCA-based. Reasons for this failure are above all related to the complexity of the stages of a LCA. Besides of being complex, this approach is very time consuming and therefore normally used by experts at academic level. For these reasons most of the building sustainability

assessment methods are relied on singular material proprieties or attributes, such as recycled content, recycling potential or distances travelled after the point of manufacture [1].

The adoption of environmental LCA in buildings and other construction works is a complex and tedious task as a construction incorporates hundreds and thousands of individual products and in a construction project there might be tens of companies involved. Further, the expected life cycle of a building is exceptionally long, tens or hundreds of years. For that reason LCA tools that are currently available are not widely used by most stakeholders, including those designing, constructing, purchasing or occupying buildings. Due to its complexity most of them are used and developed only by experts, most times only at academic level.

In order to overcome this situation, most popular rating systems simplified LCIA for practical use. The simplified LCIA methods currently integrated in rating systems are not comprehensive or consistently LCA-based but they are playing an important role in turning the buildings more sustainable. Nevertheless, the LCA approach is not the same in the different sustainability assessment methods and therefore the results of the environmental performance assessment are not the same nor comparable. It is necessary to integrate more accurate environmental assessment methods in order to verify if the required performance has really been achieved, to accurate compare solutions and to compare the results from different rating systems [2].

In order to standardize, facilitate the interpretation of results and comparison between different building sustainability assessment methods developed within the European Countries, European Centre of Normalization (CEN) started on the Technical Committee 350 (CEN/TC 350 – Sustainability of construction works). The document EN 15643-2:2011 (Sustainability of construction works - Assessment of buildings - Part 2: Framework for the assessment of environmental performance) is a part of the a suite of European standards, technical specifications and reports written by CEN TC 350 that will assist in evaluating the contribution of buildings to sustainable development through the assessment of the environmental performance of the building. In these standards the assessment methodology is based on a life cycle approach for the quantitative evaluation of the environmental performance of the building. For now these standards are specific for buildings but, with the necessary adaptation, their approach could be adopted to any type of constructions.

The two most important barriers for the quantification of the environmental indicators and therefore to the incorporation of LCIA in rating systems are [2]: a lack of LCI data for all building products and the inherent subjectivity of LCA. Environmental Product Declarations (EPDs) are a good source of quantified information of LCI environmental impact data. In order to potentiate their use, rating systems should be based in the same LCIA impact categories, as stated in the CEN standard. An environmental product declaration (EPD) is a communication tool that provides quantified information of the potential environmental impacts of a product or process, through a life cycle assessment. The information can regard aspects such as raw material acquisition, energy use and efficiency, content of materials and chemical substances, emissions to air, soil and water and waste generation. EPDs do not provide an evaluation of the environmental performance but are a comprehensive and transparent set of environmental information covering a predefined set of life cycle stages. An important advantage of using EPDs is the possibility to add LCIA-based information in the supply chain. This feature makes EPDs particularly valuable for the building sector where the final building is based on a large number of materials, construction products, semi-manufactured products and processes. According to ISO 14025, Environmental Product Declarations act as a basis of information for life cycle assessment. Therefore this is a fundamental source of information for building sustainability assessment and certification. Nevertheless, at the moment, there are important limitations on this approach, since there is only a small number of companies either having or making publicly the EPD of their products.

This paper proposes a solution to overcome the abovementioned problems that is based in the development and use of databases with the LCIA data of the most used building materials and

components. Therefore, based in the work of CEN TC 350 and in the work of iiSBE Portugal (in the development of the Portuguese rating system SBTool$^{PT®}$), this paper will present and discuss the development of an LCIA database with the environmental data for conventional and non-conventional Portuguese building solutions (macro-components). A macro-component is, according to our definition, a component of a building for which a technical specification can be given in relation to a set of essential structural characteristics and that is actually a combination of various materials. This database is continuously updated and covers common building technologies for each building macro-component (floors, external walls, partition walls, roofs, windows and doors), the most used building materials and the impacts of the transportation processes, according to the used type of transportation.

2. Structure of the LCIA database

2.1 Environmental impact categories

The number and type of environmental impact category indicators are different in the several sustainable assessment methods. There is a wide range of impact category indicators, normally categorized according to the endpoints or the midpoints. Endpoints are also known as damage categories and express the effect of the product in the Human Health, Ecosystems Quality, Climate Change and Resources. LCIA methods that use this type of impact categories are damage oriented and they try to model the cause-effect chain up to the endpoint, or damage, sometimes with high uncertainty. The midpoints, also referred as indicators, express the environmental effects between the emissions and resource extraction parameters, from life-cycle inventory (LCI), and the damage categories. These impact categories are used in the classic impact assessment methods to quantify the results in the early stage of the cause-effect chain to limit the uncertainties. Midpoints group LCI results in the so-called midpoint categories ac-cording to themes as “destruction of the stratospheric ozone layer”, “acidification of land and water resources” or “global warming”.

LCIA can be incorporated into rating systems for buildings to quantify environmental burdens associated with the manufacture of building products. Such burdens include the consumption of primary resources and the output of gaseous, liquid, and solid wastes. Most of the rating systems use midpoint impact categories but do not assess the Building and Construction’s environmental performance in a LCA consistent way, because they do not include LCIA-based indicators [2]. Three examples of rating tools that integrates LCIA-based Environmental Performance Criteria are: SBTool, Green Globes and Code for Sustainable Homes. Nevertheless, they use a simplified LCIA approach to promote its practical use [2].

The differences between the environmental impact assessment approach in the several rating methods – because some of them are not LCIA-based, not based in a reliable LCA method (be-cause do not integrate the most common impact categories) or do not share the same impact cat-egories – turns difficult the comparison of results from different rating systems.

The goal of the work undertaken by CEN/TC 350 standardization mandate is to overcome this problem at the European level, through the development of an approach to voluntary providing environmental information for supporting the sustainable works on construction. This technical committee set the environmental indicators that should be used in the European building sustaina-bility assessment methods. The aim of the list of the impact categories is to represent a quantified image of the environmental impacts and aspects caused by the object of assessment during its whole life cycle. The assessment approach of the CEN standards is applicable to new and existing buildings. It provides a calculation method that covers all stages of the building life cycle (assembly, operation and disassembly phases) and the list of environmental indicators is developed in such way that potentiates the use of the LCI data issued from Environmental Product Declarations (EPDs).

According to EN 15804:2012 [3], the environmental parameters to be declared in a EPD are organized in three types: i) parameters describing environmental impacts; ii) parameters describing resource use; iii) Other environmental information describing different waste categories and output flows. Table 1 presents the environmental parameters to be declared according to this standard. The Portuguese building sustainability assessment method (SBTool$^{PT®}$) it is already updated according to the requirements of this standard. Therefore the developed LCIA database covers the six parameters that describe environmental impacts: i) Global warming potential (GWP); ii) Depletion potential of the stratospheric ozone layer (ODP); iii) Acidification potential of soil and water sources (AP); iv) Eutrophication potential (EP); v) Formation potential of tropospheric ozone (POCP); vi) Abiotic depletion potential (ADP).

Table 1: Environmental parameters according to EN 15804:2012 [3]

Parameters describing environmental impacts
– Global warming potential (GWP)
– Depletion potential of the stratospheric ozone layer (ODP)
– Acidification potential of soil and water sources (AP)
– Eutrophication potential (EP)
– Formation potential of tropospheric ozone (POCP)
– Abiotic depletion potential (ADPelements) for non fossil resources
– Abiotic depletion potential (ADP-fossil fuels) for fossil resources
Parameters describing resource input
– Use of renewable primary energy excluding renewable primary energy resources used as raw materials
– Use of renewable primary energy resources used as raw materials
– Total use of renewable primary energy resources (primary energy and primary energy resources used as raw materials)
– Use of non renewable primary energy excluding non renewable primary energy resources used as raw materials
– Use of non renewable primary energy resources used as raw materials
– Total use of non renewable primary energy resources (primary energy and primary energy resources used as raw materials)
Parameters describing resource use, secondary materials and fuels, and use of water
– Use of secondary material
– Use of renewable secondary fuels
– Use of non renewable secondary fuels
– Use of net fresh water
Other environmental information describing waste categories
– Hazardous waste disposed
– Non hazardous waste disposed
– Radioactive waste disposed
– Use of net fresh water
Other environmental information describing output flows
– Components for re-use
– Materials for recycling
– Materials for energy recovery
– Exported energy

2.2 Boundaries of the LCA analysis

As presented in Figure 1, a typical life cycle of a building can be separated into three distinct phases, each consisting of one or several life cycle stages. The assembly phase refers to the collection

of raw materials through resource extraction or recycling, the manufacture of these raw materials into products, the assembly of products into a building, the replacement of building products and assemblies, and intermediate transportation. The operation phase refers to heating and electricity requirements, water services and other services excluding material replacement. The disassembly phase refers to the decommissioning and demolition of the building, the disposal/recycling/reuse of building products and assemblies, and intermediate transportation steps. Each life cycle stage can consist of many unit processes.

The LCIA database for building technologies covers the “cradle-to-gate” impacts, i.e. the environmental impacts from the raw material extraction to the manufacturing of building products and assemblies and the disassembly phase. Additionally, the database covers the environmental impacts derived from the transport of the demolition waste to the treatment units and with its treatment. The considered processes are highlighted in Figure 2.

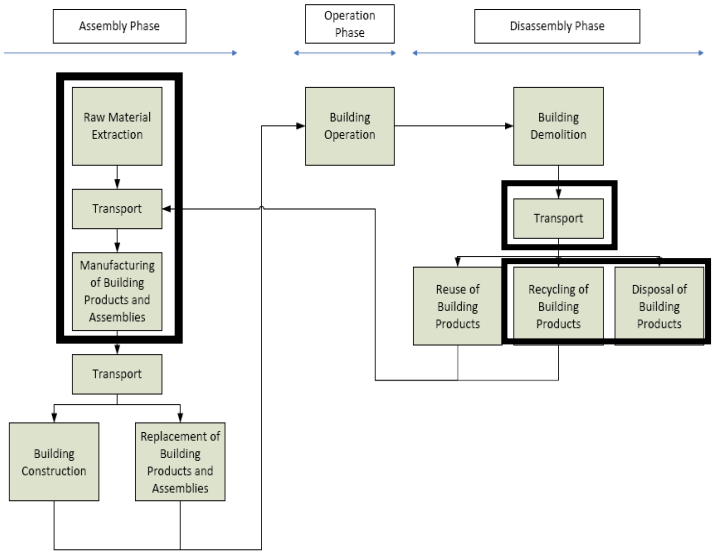

Fig. 1: Life cycle of a building [4]

2.3 Life-cycle inventory and waste scenario

The inventory analysis entails the quantification of the flows for and from a product system. In traditional life cycle environmental analysis, the inventory flows include inputs of water, energy and raw materials, and releases to air, land and water. Taking into consideration the aims of this approach, the production and final destination of waste should also be included in the inventory. Therefore the database presents the quantified potential environmental impact categories for the embodied flows (cradle-to-gate) and the flows of the end-of-life scenarios, based in data from the companies that manufacture the materials and components.

Table 2 presents the considered end-of-life scenario, which is based in the Portuguese average context. In this context, the building materials that are normally recovered after demolition are the steel-based ones. The LCIA database also covers the potential environmental impacts of the transportation processes, according to the used type of transportation.

Whenever was not possible to found specific inventory data related to a process, average European databases (generic data) was used (e.g. EcoInvent [5]). Nevertheless the database is prepared to be updated whenever specific LCI data for a product is communicated from a manufacture.

Table 2: Considered waste scenarios

Material/waste	Waste scenario	Percentage
Reinforcing steel	Recycling	80%
Steel in profile	Recycling	95%
Other	Construction waste (inert) to landfill	100%

2.4 Life-cycle Environmental Impact Assessment (LCIA)

According to EN ISO 14044, Life Cycle Environmental Impact Assessment (LCIA) is a phase of LCA aimed at understanding and evaluating the magnitude and significance of the potential environmental impacts for a product system throughout the life cycle of the product. Impact assessment should address ecological and human health effects together with resource depletion. A life cycle impact assessment attempts to establish a linkage between the product or process and its potential environmental impacts. Therefore, this tasks aims to convert the LCI data collected into potential environmental impacts using one or more normalized LCIA methods. As above mentioned, this database covers six environmental impact categories. The environmental impact categories and the used LCIA methods for their quantification are presented in Table 3.

Table 3: Environmental impact categories declared in LCIA database for building technologies and the used LCIA methods

Environmental impact categories	Unit/declared unit	LCIA methods
Depletion of abiotic resources	[kg Sb eq.]	CML 2 baseline 2000 [6]
Global warming potential (GWP)	[kg CO2 eq.]	CML 2 baseline 2000 [6]
Destruction of atmospheric ozone(ODP)	[kgCFC-11 eq.]	CML 2 baseline 2000 [6]
Acidification potential (AP)	[kg SO2 eq.]	CML 2 baseline 2000 [6]
Eutrophication potential (NP)	[kg PO4 eq.]	CML 2 baseline 2000 [6]
Photochemical Ozone Creation (POCP)	[kg C2H4 eq.]	CML 2 baseline 2000 [6]
Non-renewable primary energy	[MJ eq.]	Cum. Energy Demand [7]
Renewable primary energy	[MJ eq.]	Cum. Energy Demand [7]

In order to facilitated the quantification process, a life-cycle analysis software (SimaPro [8]) was been used to modulate the macro-components' life-cycles and to assess the mentioned life-cycle impact categories.

2.5 Communication format

Figure 2 presents how the information is organized in the LCIA database for a building macro-component and the list of environmental indicators and LCIA methods used. In the database of the building components the quantification is presented per each component's unit of area (m^2) and in the materials database, figures present the environmental impacts per each unit of mass (kg). Quantification is presented for two life-cycle stages: "cradle to gate" and "demolition/disposal". Using this database it is possible to estimate the overall impact of a building using a bottom-up up approach. The quantification begins at the level of the embodied environmental impacts in building materials and ends at the whole building scale. To evaluate the transportation impacts, the designer must know (for each building material or product) the distance from the factory to the construction site and the distance from the construction site to the recycling/management centre. By multiplying the distance (km) by the weight (ton) and by the unitary impacts associated to the used type of transportation it is possible to estimate the transportation impacts of the building technology. Adding the transportation impacts to the figures presented in Figure 2 it is possible to estimate the overall life-cycle impacts of a building technology. Table 5 illustrates the calculation principle of the total environmental of the building life cycle using the SBTool$^{PT®}$ LCIA database.

At this stage, the developed database covers more than 100 building's macro-components (16 floors, 28 external walls, 22 partition walls, 23 roofs and 18 types of windows), 47 construction materials and the potential environmental impacts associated to the use of 12 acclimatization and hot water production equipments [9].

3. Conclusions

Although LCA is considered the best method available to assess the environmental performance of a product, its application in construction is very complex. This is because the huge number of different materials, actors, processes and also the wide life cycle span of a construction product.

Based in the work of CEN TC 350 and in the development of the Portuguese sustainability rating system (SBTool$^{PT®}$), this paper presented some solutions to overcome the difficulties in the integration of more accurate LCA-based approaches is the assessment of the environ-mental performance in rating systems. The development by experts of databases with the LCIA data of the most used building technologies and materials is a good solution to integrate more accurate and LCIA-based approaches, without turning the rating systems too complex for practical use.

Compared to other existing databases, the one presented in this paper has two main differences that could promote the practical implementation of the LCIA approach during the design of a new construction or refurbishing operation. Consequently, it will promote the practical implementation of the sustainable construction concept.

The first difference is that this database covers a larger number of environmental parameters (those that are included in the EN 15804:2012). Therefore it could be directly used to support the environmental performance assessment of a building according to recent standardization work (EN 15643-2:2011).

The other advantage is that this database presents the environmental data for construction macro-elements normally used in the construction of buildings (e. g. slabs, walls, panels, etc.) and not for single materials and products (i.e. bricks or cement) as in other databases. The purpose of defining a set of macro-component typical for the construction and renovation of buildings is to establish a data bank that has information about the essential environmental characteristics, in order to support design teams in the processes of designing and rating sustainable buildings.

This database will decrease the time and cost for conducting an environmental life-cycle analysis of a building. Additionally, this advantage could indirectly promote the design and construction of more sustainable buildings.

Summary

The construction sector is responsible of several environmental impacts among which energy and water consumption, climate change and waste generation. For instance, the primary energy consumption for regulatory uses (heating, air-conditioning, ventilation and hot water) on a 50-year period for a French building is about the same as the embodied energy for its manufacturing and construction processes. In this context, new assessment tools are required to assess the global environmental performances. Thus, there is a growing need to assess the environmental performance of buildings by means of Life Cycle Assessment (LCA). Databases are also needed to make available Life Cycle Inventory data of building materials and processes for each national context. However, in Brazil, few data have been provided so far by the building industry e.g. by means of Environmental Product Declaration (EPD). Two solutions can be distinguished: development a new national LCI database or adaptation of existing LCI databases. If the first option is the most relevant, it requires time and resources, while the second solution is scientifically acceptable and practicable.

The aim of this paper is to present an approach to adapt existing LCI data of building products for the Brazilian context in order to propose a set of consistent and representative LCI datasets. The approach is based on literature researches, analyses of Brazilian and generic LCI data and on the adaptation of European LCI data for the Brazilian context for some key parameters e.g. the energy mixes, the types and distances of transportation. The feasibility of the methodology is then supported by case studies comparing the environmental indicators of concrete, considering the use of Brazilian, original and adapted LCI data.

The approach can be easily applied to other building products. The comparisons show the weaknesses of some Brazilian data e.g. in terms of completeness of the system boundaries. The results for primary energy and global warming potential indicators show that the adapted LCI data

is found to have less impact than the indicators calculated with the original LCI (differences between 5 and 10%). This is mainly explained by the efficiency of the Brazilian energy mix despite the large consumption of the non-renewable energy due to the type and distance of transportation. The adapted LCI must now be improved e.g. by working closely with Brazilian producers to get more accurate data on the foreground processes.

Key-words: performance, environmental requirements, Life Cycle Inventory – LCI, Life Cycle Impacts Assessment – LCIA.

1. Introduction

The construction sector is responsible of several environmental impacts and Life Cycle Assessment (LCA) databases are needed to assess the environmental performances of any construction product or process. The environmental impacts are closely related to the type of product, the suppliers and to the national characteristics of waste and energy processes.

Many countries, such as UK, France, Japan and Australia, have developed sectorial LCA databases to assess the environmental impacts of buildings over their life cycle. These databases are then used for building sustainability assessment using LCA-based indicators (global warming potential, energy use, waste generation, and other related impacts). However, sectorial databases often present cumulative LCI (Life Cycle Inventory) or selected indicators that cannot be adapted to other countries. These data often related to EPD describe the impacts of producers that sold their product in the given country. As a result, it is generally not recommended to directly reuse data for other contexts (e.g. South America).

In opposite, LCA data can also be made available by major background data providers. For example, the Swiss Ecoinvent database provides more than 4500 unit processes describing the impacts of materials products and processes mainly for the Swiss and European context. In this case, the data are breakdown into processes with raw data and LCI that can be adapted for a new context by means of LCA software (e.g. GaBi, SimaPro).

As the development of new LCI databases can be time and cost consuming, adapting existing background LCI databases to other national context can be seen as a consistent and more adapted way than having no data at all or non-adapted data.

The main benefits for the country (e.g. Brazil) is to take into account the completeness of these background databases (e.g. for the energy and transportation processes) but also to be able to change the foreground date based on the national practices (e.g. share of energy carriers or distance and truck load for the transportation of building materials).

Looking more specifically at the Brazilian context in South America (scope of this paper), few LCA data exist on the impacts of building materials (GOLDEMBERG; AGOPYAN, JOHN, 2011). When data are available, there are calculated using different rules and no central database has been developed to date.

Therefore the aim of this paper is to present an approach to adapt existing LCI data of building products for the Brazilian context in order to propose a set of consistent and representative LCI datasets which can be used to conduct an environmental assessment of buildings. This assessment will be, not to a specific product, but represent the building industry because it will be done based one generic database.

2. Research method and analysis

The approach is based on literature researches, analyses of Brazilian and generic LCI data, and on the adaptation of LCI data for the Brazilian context.

The Brazilian data of building materials used on this paper were taken from previous studies (Lima, 2010; Souza, 2012; Saade et. al., 2010; Campos, 2011 and Punhagui et. al.,2012). Some studies has also been conducted by producer associations such as the IABr (2010) that conduct a study related to the LCA of steel.

The existing Brazilian data is used only in order to compare them to adapted LCI data from the Ecoinvent database v2. The adaptation of LCI data for the Brazilian context considered aspects relating to energy mix, types and distances of transportation. Ecoinvent version 2.2 was the generic database selected, and the LCI adaptation was done using the software SIMAPRO Version 7.3.

The feasibility of the methodology is then supported by case studies comparing the environmental indicators of concrete, considering the use of Brazilian, original and adapted LCI data.

3. Approach to adapt existing life cycle inventory of building products for the Brazilian context

Ideally, country-specific data for the life cycle inventory analysis should be collected in the respective country and no 'transferability' approach would be necessary. Nevertheless, while this data collection process is in progress or still to be started, a systematic approach need to be defined in order to enable the performance of LCA studies in any country with reliable results (Colodel, 2008).

Colodel (2008) proposed an approach organized in four main steps:

- assumptions and conditions;
- overview the country indicators at branch level: 'top down' approach;
- overview of the influencing parameters at a process level: 'bottom-up' approach;
- transfer factor calculation/ 'adjusted' inventory.

Then, this paper show an approach organized from these four steps that detail the aspects that must be considered to Brazilian context. Table 1 presents the approach detailed. This approach has ten steps, organized in four groups: scope and database definitions (step 1 and 2); data collecting considering overview of the country technologies and manufacture process (step 3 and 4), calculated method (definition of LCA method and also uncertainties method e.g. steps 5, 6 and 7), and the results analyze (steps 8, 9 and 10).

The approach takes into account five impacts indicators: Consumption of primary energy; consumption of the non-renewable energy; climate change; water consumption and waste generation. Somme researchers suppose the consumption of primary energy, related to non-renewable resources, must adopted as an environment impact indicators, because most of the others impacts indicators have strict relation to the consumption of non-renewable energy (LASVAUX, 2010). In addition, the Brazilian building sector have already some macro indicators related to these indicators, so it was choose in this approach for permitting some analyses and comparisons.

Table 1- Steps to adapt existing LCI data for the Brazilian context (adaptation of Colodel, 2008; HODKOVA and LASVAUX, 2012)

1- Goal and scope definition
Set the building product functional unit and building process phase to analyze (cradle to gate or cradle to grave)
2- Selection of a Generic LCI data (the proposal is to adopt Ecoinvent database)
In the Ecoinvent there are specific documents that demonstrate the context and the parameters in which the building products were inventoried. These documents present the main technologies adopted, type and distances of transportation, standard deviations, etc. (KELLENBERGER , 2007 and Frischknecht, 2007). In addition, the inputs of Ecoinvent database can be modified using for example the software SIMAPRO. In this approach the SIMAPRO will be used in order to modify the Ecoinvent LCI to Brazilian context.
3- Identify the Brazilian context and indicators – Overview the differences related to energy mix, technologies/process, market size, etc – *Top down approach*
3.1- Identify the indicators considering the Brazilian context and building product – mostly energy mix and technologies/process; 3.2 – Identify if the Brazilian context serve for all country or it is restricted to certain parts; 3.3 - Verify the differences between the inputs considered in the Ecoinvent data base and the Brazilian context. KELLENBERGER (2007) detail the Ecoinvent information; 3.4- Compare the technologies and the process between Brazilian context and the onefrom Ecoinvent. Only process with similar technology can be compared. This means that the flows of each unit process must be the same for both countries, exception to type of transportation; 3.5- Make certain considerations and set transfer factors related to the analyze of countries inputs – making attention to functional unit to set the transfer factor.
4- Adapt the generic data base inputs related to the process - Overview the inputs of the inventories concerning the process - amount of raw materials, transport distance, etc – *Bottom up*
4.1- Compare the amount of raw materials from Ecoinvent and from Brazilian context; 4.1.1- Verify the amount of raw materials with the most important impacts and not consider that materials have less than 2% of influence; 4.1.2- In the SIMAPRO, modify the inputs/ flux until the forth level, or at least second level; 4.1.3 - Set correct transfer factor taking care to the functional unit; 4.2- Compare type and distance of transportation between the Ecoinvent LCI and the Brazilian context /data; 4.2.1 Consider an average distance of 100 km to Brazil (hypothesis adopted when it does not know the real mean data)- 100 km go and 100 km back, in the back tour the transport vehicle is without load, as a result only the vehicle weight will be considered; 4.2.2 – Make attention to functional unit to set the transfer factor, take care to relation among amount of raw materials, distance of transportation, and load transported.
5-Verify the data quality of the inputs data – identity the uncertain values adopted on Ecoinvent
5.1- For the changed inputs - identity the uncertainties of the inputs from Ecoinvent, calculate the uncertainties of the Brazilian context using the Pedigree Matrix method (Pedersen and Wesnaes, 1996) and compare the two uncertainties. Chose three of the most important inputs to verify the uncertainty, or select the inputs that influence more the impact. It is not suggested modifying the uncertainty adopted in LCI Ecoinvent, avoiding to rise the deviations. The analysis will serve to justify the use of the module adapted. 5.2 - For the non-changed inputs – adopting a process similar to 5.1
6- Set the impacts indicators to be considered and analyzed
The hypotheses considered take into account: Consumption of primary energy; consumption of the non-renewable energy; climate change; water consumption and waste generation
7- Selecting on SIMAPRO the method to calculate the impacts, also considering the standard deviation by Monte Carlo simulation

7.1 - It is proposed to select the French method that integrates the IPCC[1], CML[2] and CED [3]method. Adopting the French method will be possible to analyze the indicators related to consumption of primary energy; consumption of the non-renewable energy; climate change; water consumption and waste generation; 7.2 – Determining the Number of iterations for Monte Carlo Simulations – As the Monte Carlo method is time consuming we have consider 500 iterations. (The number of iterations change a little the results and their deviations, so it is an aspect to study in the future)
8- Results presentation- Set a worksheet model to be fulfilled for each LCI adapted, granting reliability and transparence
8.1 – Fulfilled one worksheet to each LCI adapted, making evident all hypotheses and considerations (methodology, adaptation, uncertainties, results, calculus demonstration). 8.2 – Present the impact indicators data in terms of mean value and of the minimum and maximum value, with standard deviation. 8.3 – The primary energy source must be the addition of non–renewable energy and renewable energy – considering the need of software that perform environmental assessment;
9- Data Analyses - Macro Comparisons among environmental indicators calculated by Brazilian LCI, original and adapted LCI
9.1 – Calculate the environmental indicators of building product using the LCI from Ecoinvent data without adaptation – impact indicators also calculated from SIMAPRO, considered 500 iterations in Monte Carlo simulations; 9.2 –Calculate the environmental indicators of building product using the LCI from Ecoinvent data adapted – impact indicators also calculated from SIMAPRO, considered 500 iterations in Monte Carlo simulations; 9.3 - Calculate the environmental indicators of building product using the LCI from Brazilian data, if existed, even if this data not fit the methodology proposed (weak data), the propose is only compare macro-values; 9.4 – Compare the results among these environmental indicators, analyzing the macro-values, deviations and tendency, trying validate the indicators with LCI adapted.
10- Others observations
10.1 Remove any type of transportation means input “0” at SIMAPRO; 10.2 Include other type of transportation need consider the uncertainty; 10.3 The LCI take into account in general cradle to gate – until end production - transportation of the raw material extracted and at the plant is considered – the transportation out of production plant is not considered.

4. Case studies on building materials

The table 2 shows the details considered to adapt LCI concrete data to the Brazilian context using the approach proposed at table 1.

Table 2- Methodology applied to adapt the module concrete normal at plant to Brazilian context

Step	Method	Considering
1	Goal and scope definition	1m^3 of normal concrete adapted to Brazilian context - module consider cradle to gate (production phase)
2	Identify the Generic EPD data base selected	module base: concrete normal, at plant/CHU - Ecoinvent
3	Identify the Brazilian context and indicators – overview the differences related to mostly energy matrix and	use the Brazilian energy matrix
		changing means of transportation-consider only dumpers for cement and bricks, and mixer truck to concrete

[1] IPCC 2001 is a method developed by the International Panel on Climate Change. Climate Change 2001. IPCC Third Assessment Report. The Scientific Basis. Available on http://www.grida.no/climate/ipcc_tar/

[2] CML (Center of Environmental Science of Leiden University) proposed a set of impact categories and characterization methods for the impact assessment.

[3] Cumulative Energy Demand (CED). Details on the CED method may be found in Bösch *et al.* (2007)

	technologies/process, etc				
4	Adaptation of the generic data base inputs related to the process - Overview the inputs of the inventories concerning the process - amount of raw materials, transportation distance, etc	production phase -concrete production including transportation of raw materials to the concrete production site			
		change transport distances			
		remove transportation by boat and train			
		remove transportation by 20 and 28t			
		include 32T truck to transport cement, sand and gravel (100 km round-trip to sand/gravel and 200 km round trip to cement)- consider the same uncertainties of 20-28t			
		change amount of electric energy at plant - 2, 05KWh/m^3 (Brazil data, from Souza 2012)			
		remove natural gas			
		losses were not considered neither water losses			
5	Verify the data quality of the inputs data	inputs/flow	Uncertainties		
			from Ecoinvent	calculate for Brasilan context	
		cement	1,3	1,3	
		electricity	1,22	1,22	
		lorry 28t	2	2	
		lorry>32t	2	2	
6	Identify the impacts indicators to be considered and analyzed –	Consumption of primary energy (non-renewable)			
		climate change (kgCO2 equiv)			
		water consumption			
		waste generation			
7	Selecting on SIMAPRO the method to calculate the impacts with the uncertainty estimations calculated by Monte Carlo simulation	French Method (because its included CML, IPCC and CED)			
		500 iterations to perform Monte Carlo simulation			
8	Results	Module adapted: Normal Concrete, at plant/CH U-module BR-Ecoinvent/SIMAPRO			
9	Validation and Macro Comparisons	Macro Comparisons among environmental indicators calculated by Brazilian LCI, original and adapted LCI			
10	Others points/observations	transportation of concrete is classified in construction site phase, as EN 15978 (2012)			

The table 3 shows the LCI original and the adapted LCI. The table 4 shows environmental indicator of concrete calculated with the adapted existing LCI data.

Table 3 - Adaptations of Life cycle inventory (LCI) data from Ecoinvent to Brazilian context – normal concrete, at plant

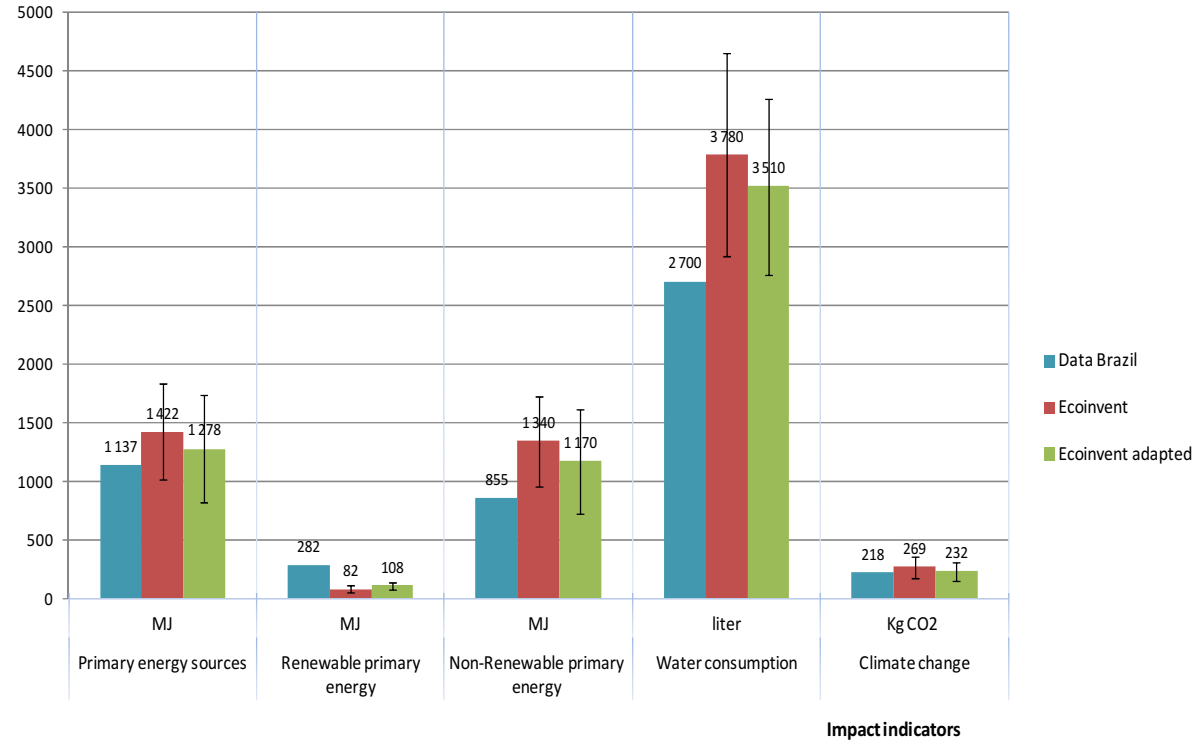
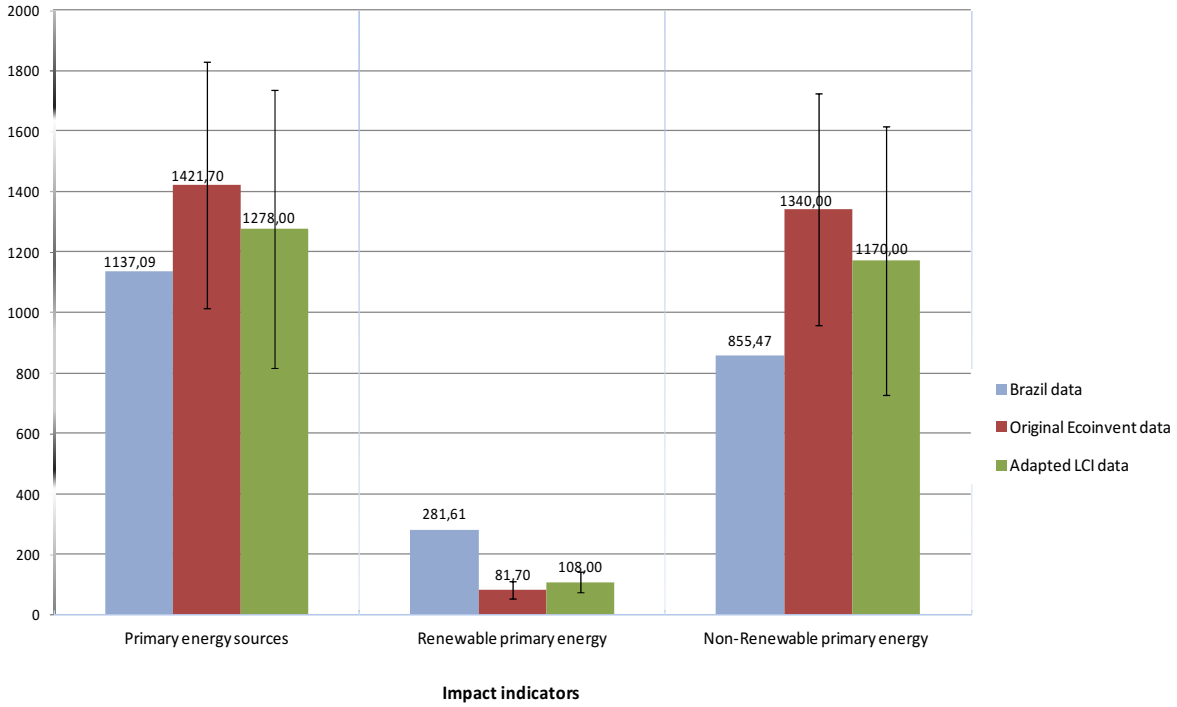
5. Comparison among Brazilian, generic and adapted LCI data.



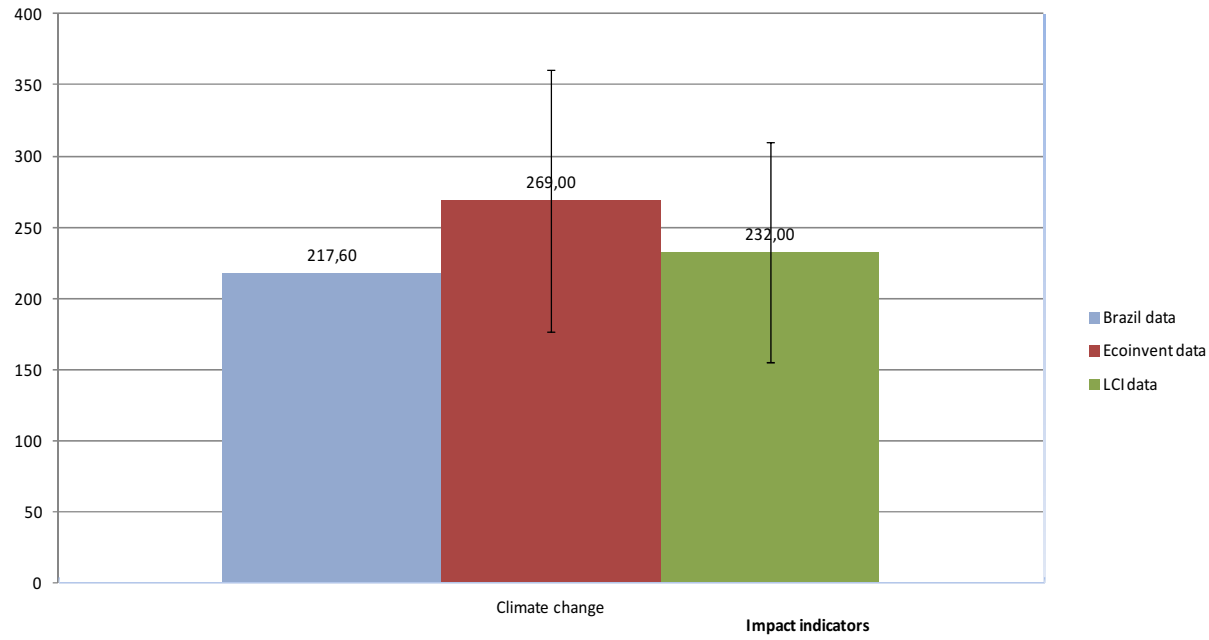
The approach set the phase 9 - Data Analyses – which aims the comparison among environmental indicator came from three types of LCI: Brazilian, original and adapted LCI:

1- Brazilian environmental indicators: it was organized the environmental impacts data of six building products, according to EN 15.804 (2012): cement, sand, brick, crude steel, concrete and concrete block. However, only data of normal concrete is show in this paper.



2- environmental indicators from original LCI (from Ecoinvent): seven building products had their impacts calculated by SIMAPRO using the LCI data from Ecoinvent without adaptations: cement, normal concrete, concrete block, mortar, reinforced steel, fiber cement board, gypsum plaster board. These LCIs consider only the production phase. However, only the data of normal concrete is show in this paper.

3- environmental indicators from adapted LCI: seven building products had an LCI adapted in order to fit the Brazilian conditions: cement, normal concrete, concrete block, mortar, reinforced steel, fiber cement board, gypsum plaster board. Only the indicators from adapted LCI of normal concrete is show in this paper. The table 2 and 3 show the adapted LCI concrete data. The table 4 shows the environmental indicator of the concrete calculated by SIMAPRO using the adapted LCI.



The graphics 1 to 3 show this comparison. The uncertainties was taken into account to data from original and adapted LCI, because the Brazilian LCI does not have this information; but this information is very important because the mean value is analyzed and not an specific producer.

Graphic 1 – Comparison among impact indicators (primary energy, water consumption and climate change) calculated from Brazilian, Ecoinvent and adapted LCI data

Graphic 2 – Comparison among primary energy, renewable energy and non-renewable energy indicators calculated from Brazilian, Ecoinvent and adapted LCI data

Graphic 3 – Comparison among climate change indicators calculated from Brazilian, Ecoinvent and adapted LCI data

6. Conclusions

As the Brazilian building sector does not have organized and centralized LCI or LCA database, adaptation of overseas data (from Europe) is suggested in this paper to facilitate the environmental assessment of buildings using consistent yet not fully representative datasets. Once producers are willing to get involved, original data can be modified and raw data from producers could replace the Ecoinvent data based on the Swiss context (i.e. adapted Ecoinvent data).

To date, our approach is a first step, as some parameters were adapted such as the transportation distances and the energy mixes. The methodology is based on previous research studies from Colodel (2008) and Hodkova et al (2012).

Case studies looking at the concrete building materials (considering Brazilian, original and adapted LCI) show the weaknesses of some Brazilian data e.g. in terms of completeness of the system boundaries. The results for primary energy and global warming potential indicators show that the adapted LCI data is found to have less impact than the indicators calculated with the original LCI (differences between 5 and 10%). This is mainly explained by the efficiency of the Brazilian energy mix despite the large consumption of the non-renewable energy due to the type and distance of transportation. The adapted LCI must now be improved e.g. by working closely with Brazilian producers to get either a more accurate generic data for Brazil or different specific data representing different concrete manufacturers producing concrete for the Brazilian construction sites.

Short Summary

Continuously changing household needs and evolving building standards require a frequent upgrade and renovation of our existing residential building stock. A lack of adaptability of buildings, however, often leads to destructive interventions, resulting in financial and environmental impacts. The goal of this paper is to contribute to the search for new design concepts enabling easier and more cost-effective upgrade and renovation of buildings. It should moreover contribute in achieving a lower life cycle environmental impact. A more dynamic design is evaluated in the specific context of a social housing project in Mechelen (Belgium). In this context, building elements with reversible detailing techniques facilitating disassembly and component reuse are compared to more traditional static elements. The benefits and drawbacks are assessed at the building level using a life cycle approach of economic and environmental aspects, i.e. a Life Cycle Costing (LCC) and Life Cycle Assessment (LCA). Different renovation scenarios are simulated focussing on the internal restructuring of the housing units. Two alternatives were investigated: dynamic assemblies of all internal walls versus dynamic assemblies of only those internal walls which are expected to change more frequently. The analysis revealed that the building concept and layout are important for making more dynamic design beneficial or not. Building layouts which provide opportunities for change generally require limited constructive adaptations during the building life span. Application of dynamic assemblies to only those walls which are assumed to be changed in future is then preferred over an application to all internal walls. This could be called a ‘selective’ approach. Such a ‘selective’ approach can result in life cycle environmental benefits while the additional financial costs remain limited.

Keywords: adaptability; building level, life cycle assessment; life cycle costing; renovation.

1. Introduction and objectives

Continuously changing household needs (e.g. due to demographic changes and fluctuations in household composition), evolving building standards (e.g. comfort standards and energy performance regulations) and changing performance desires (e.g. improved acoustical performance or fire resistance) require a frequent upgrade and renovation of our existing residential building stock. A lack of adaptability of buildings, however, often leads to destructive interventions (i.e. demolition works), resulting in financial and environmental impacts. To avoid these, a more dynamic design approach can be proposed, using concepts like disassembly,

adaptability, transformability and multi-functionality. The basic principle is the integration of time as design parameter in order to enable buildings to deal with changing needs over their building life cycle [1].

The goal of this paper is to apply and evaluate a dynamic design approach in the specific context of the upgrade of the social housing neighbourhood “Mahatma Gandhi” in Mechelen (Belgium). The paper is based on a research project commissioned by the Public Flemish Waste Agency (OVAM), looking at adaptable design in buildings [2]. The focus is set on the evaluation of a number of representative renovation scenarios at the building level, considering dynamic alternatives for internal wall systems (i.e. assemblies using reversible detailing techniques, in order to facilitate disassembly and component reuse) [1]. Based on a life cycle approach, the financial and environmental benefits and drawbacks of these dynamic alternatives are compared with traditional solutions.

In the subsequent section the assessment method is briefly summarised, including Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) and the dynamic design scenarios. Section three focusses on the case study, describing the results of both a qualitative and quantitative assessment. Some conclusions are drawn in the final section.

2. Methodology

2.1 General

The financial and environmental assessment method used for the evaluation of the dynamic building solutions is based on the methodology developed in the SuFiQuaD (“Sustainability, Financial and Quality Evaluation of Dwelling Types”) research project which proposes an integrated method combining economic and environmental impact calculations during the whole building life cycle, i.e. Life Cycle Costing (LCC) and Life Cycle Assessment (LCA) (Fig. 1) [3],[4]. This means that not only the initial construction stage is taken into account but also the use and maintenance, and the end-of-life (EOL) stage of buildings and subparts. With such approach the long term advantages and/or drawbacks of dynamic design solutions of buildings can be analysed over the total building life cycle.

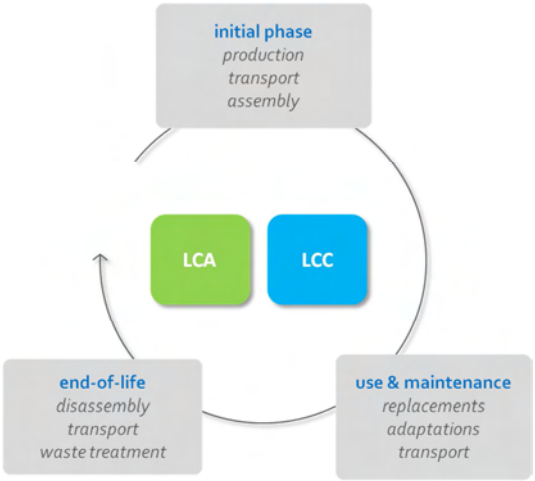

Fig. 1: Integrated life cycle approach in buildings [1]

Another important feature of the SuFiQuaD methodology is the evaluation structure based on the element method for cost control [5]. The basic principle is the hierarchical subdivision of the building in functional elements (e.g. walls, floors, technical installations) for which financial and/or environmental data can easily be calculated. A distinction can be made between five scale levels: building materials (e.g. brick, mortar, plaster), work sections (e.g. brickwork, plasterwork), building elements (e.g. internal wall including finishes), buildings and neighbourhoods (Fig. 2). This hierarchical structure allows using easily the results from the lower scale level for analysis at the

higher scale levels. In the context of the research presented, the dynamic design approach was analysed at three scale levels: the building element level, the building level and the neighbourhood level. This paper focuses on the results at the building level.

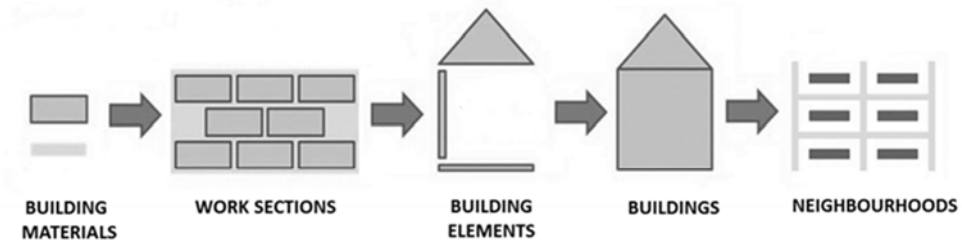

Fig. 2: Element method for cost control and scale levels [2]

In the subsequent paragraphs the applied LCC and LCA method and the scenarios used for the life cycle analysis are explained in more detail.

2.2 Life Cycle Costing (LCC)

The financial costs which occur during the different life cycle stages are assessed via an LCC. These include the costs for material acquisition, the labour and indirect cost, costs for transport and EOL treatment. The financial data are based on Belgian cost databases and product specific data from catalogues and tenders (for the cost estimation of dynamic assemblies) [1]. Future costs are integrated with initial costs by calculating their present value. The following is assumed – based on Belgian statistical data - regarding the economic parameters [1]:

- Inflation rate: 2%
- Real discount rate (above the inflation): 2%
- Real growth rate labour costs (above the inflation): 1%
- Real growth rate material costs (above the inflation): 0%

2.3 Life Cycle Assessment (LCA)

The environmental impact assessment is based on the LCA method developed in the MMG ("Milieugerelateerde Materiaalprestatie van Gebouwelementen") research project, commissioned by the Public Waste Agency of Flanders (OVAM) [6]. This project focuses on the elaboration of an evaluation method for the environmental performance of building elements, adapted to the Belgian context. Besides individual impact indicators, the MMG assessment method allows to assess the environmental impact based on an aggregated indicator, expressed in environmental costs (external costs caused by environmental impacts). In this paper, this monetary indicator is used to evaluate the environmental impact of the proposed dynamic assemblies for internal walls. The environmental impact simulations are made with the Simapro software using the Ecoinvent database (version 2.2) [7][5],[8], which was adapted to the Belgian context (replacing the Swiss electricity mix and transport processes by European corresponding processes).

2.4 Service life scenarios

Scenarios must be defined regarding the life span of buildings and the replacement of building elements and subcomponents in order to evaluate the benefits and/or drawbacks of using dynamic construction. Based on the methodology used in the PhD research of Paduart [1], service life scenarios are defined at three levels: building, building element and subcomponent (Fig. 3). For the *building*, an average life span of 60 year is determined as representative for residential buildings in Belgium [3]. At the *building element* level, a functional service life is used to take into account the changing needs of residents and building standards. Based on a survey among social housing companies [1], the following scenarios are defined:

- Scenario without periodic intervention
  The building element undergoes no major renovation interventions during the building life span (i.e. functional service life equals 60 years), except for the replacement and maintenance of subcomponents at the end of their technical service life.

- Scenario with periodic intervention
  The building element position is altered due to major renovation during the building life span. For internal walls a periodic turnover of 15 year is defined. When the functional service life is exceeded, building elements are replaced by identical new components, except for dynamic assemblies (Design for Disassembly – DfD) where disassembly and reuse of subcomponents can take place (Fig. 3).

Finally, a technical service life is attributed to the analysed *subcomponents* based on reference values from literature for the building sector [9]. For this study average values are used for the simulations. When the technical service life of subcomponents is exceeded, the subcomponent is replaced, eventually together with adjacent subcomponents if those are connected with irreversible connections [1].

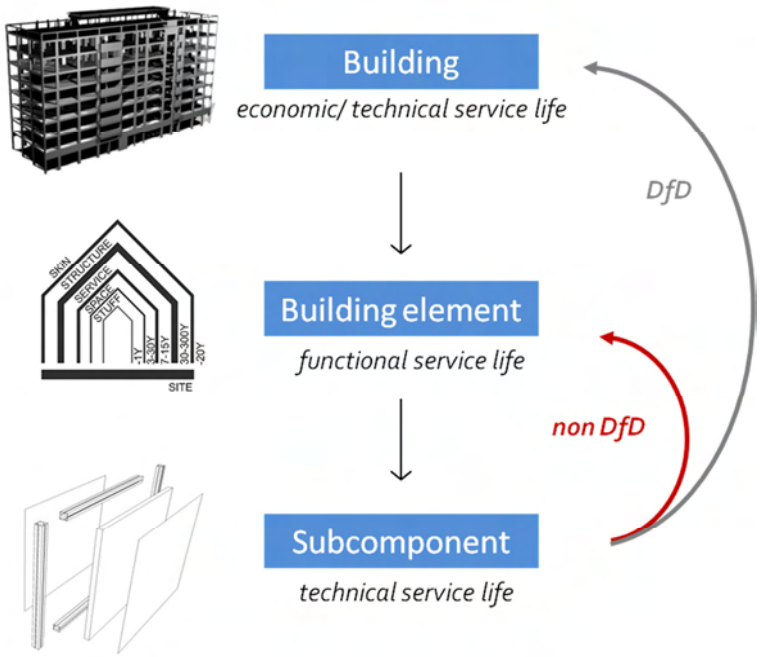

Fig. 3: Service lives on three levels: building – building element – subcomponent [1]

3. Evaluation of case study at the building level

The dynamic design approach is applied and evaluated in the specific context of the upgrade of the social housing neighbourhood “Mahatma Gandhi” in Mechelen (Belgium). Besides the renovation of existing buildings the project includes the demolition of a number of outdated apartment buildings that will be replaced by new collective building blocks (subdivided in 3 parcels).

The case study consists of the first building block (parcel 1) designed by KPW-architecten (Fig. 4). This building is composed of a mix of one-bedroom and two-bedroom apartments. A representative housing unit with two bedrooms is selected for the analysis at the building level (Fig. 4). Before starting the quantitative life cycle analysis of this building block - as described in the previous section - the original building renovation design was analysed (qualitatively) to investigate to what extent dynamic concepts were already integrated. This qualitative analysis was done for three aspects: the construction method, the characteristics of the building layers (*structure*, *circulation*, and *service)* [11], and the plan layout of the housing units. Based on this analysis renovation scenarios, including dynamic assemblies for internal walls, were proposed for the quantitative assessment.

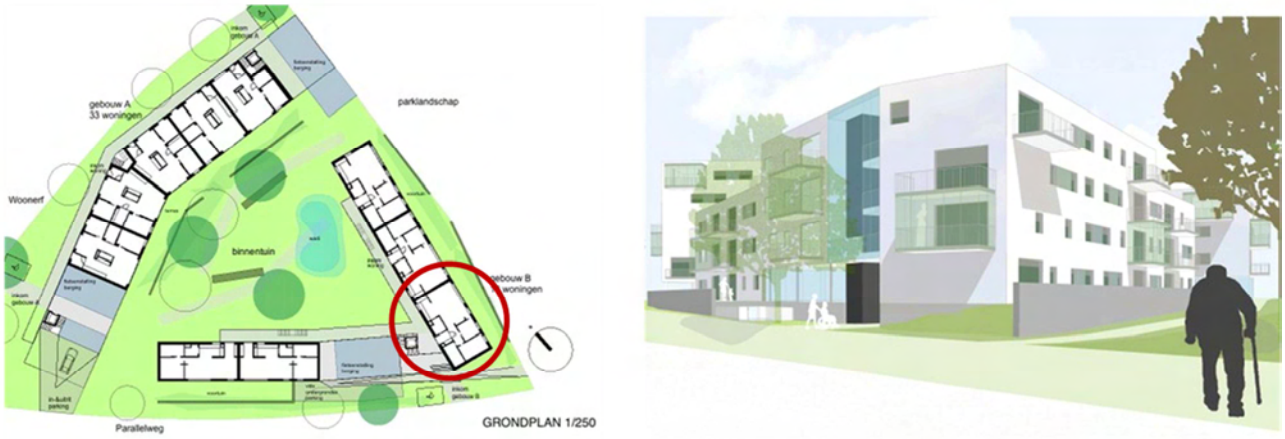

Fig. 4: Ground floor plan (left) and perspective view (right) of the building block (Parcel 1 – neighbourhood Mahatma Gandhi) [10]. The red circle indicates the analysed housing unit.

3.1. Qualitative assessment of the building

3.1.1 Construction method

The buildings of parcel 1 are constituted of masonry walls and concrete floors. This traditional construction method is characterized by irreversible connections (i.e. use of cement mortar) making disassembly and reuse of subcomponents impossible (Fig. 5). In the quantitative assessment (§ 3.2) dynamic alternatives for internal walls are simulated at the building level and compared with the traditional masonry walls.

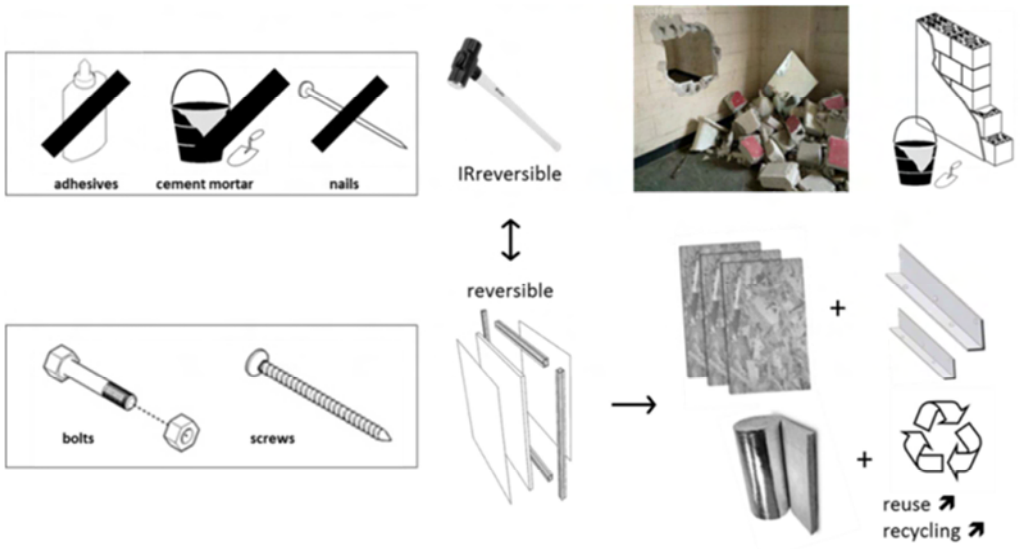

Fig. 5: Static versus dynamic assemblies [1]

3.1.2 Building layers: Structure, Circulation, Services

An analysis of the building layer characteristics identified the opportunities and limitations for adaptability (Fig. 6). The facades, partitioning walls and some internal walls consist of a structure of loadbearing walls. Loadbearing walls can be an obstacle for future adaptations of the layout of housing units. Concerning the circulation, vertical circulation (staircases and elevators) is grouped and the apartments can be accessed via an external gallery. This organisation does not impede the internal subdivision in housing units. Finally, technical services are clustered in central technical ducts increasing the plan flexibility.

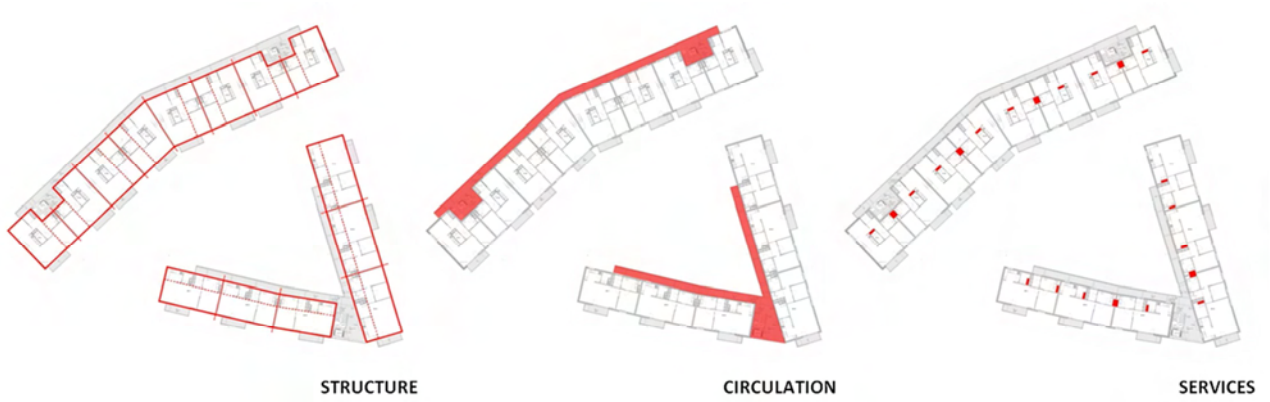

Fig. 6: Analysis of the building layer characteristics: structure, circulation and services (Parcel 1 - neighbourhood Mahatma Gandhi) [2]

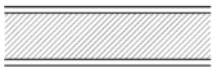
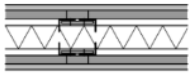
3.1.3 Plan layout housing unit

The housing units are characterized by their flexible plan layout. Attention is paid to the grouping of rooms (distinction between living areas and technical and wet rooms) and the clustering of technical ducts, in order to increase the possibilities for future adaptations of the dwelling. Moreover the configuration of the plan lay-out is adapted to wheel chair users (dimensioning of space considering the wheelchair turning radius)

Fig. 7: Flexibility of the analysed housing unit [2]

3.2 Quantitative assessment of renovation scenarios for a housing unit





The quantitative analysis at the building level is carried out in three steps. In a first step, renovation scenarios for the internal restructuring of the dwelling are defined. In this paper two scenarios for the transformation of the housing unit from a two-bedroom to a one-bedroom apartment are discussed (Fig. 8 and Fig. 12). As is shown in the figures, the dwelling consists of fixed-positioned internal walls (i.e. walls undergoing no intervention during the building life cycle, except the periodic replacement of subcomponents) and variable-positioned internal walls (i.e. walls of which the position is altered in the course of the building life cycle).
In a second step, the two renovation scenarios at the building level are translated into scenarios for the internal walls. This is done by defining the use period (i.e. period within which the wall is used in the housing unit) and the periodic turnover of each internal wall. Based on these wall scenarios the life cycle environmental impact and financial cost can be calculated for each internal wall type (per m^2 of wall).

In a final step, the LCA and LCC results at the element level (i.e. of the internal walls) are translated to the building level by multiplying the results per m^2 wall by their respective ratio (i.e. m² wall/ m² floor area). The final results at the building level are then expressed in cost and impact per m^2 floor area.

For the simulations three categories of internal walls have been analysed (Table 1) going from traditional (static) wall systems (masonry walls and dry walls) to dynamic assemblies (Design for Disassembly (DfD) walls, using reversible connections and reusable subcomponents) [2].

Besides the evaluation of the different variants described in Table 1, two alternatives are compared per renovation scenario: the use of dynamic assemblies for all internal walls (simulations “1 wall type”) and a selective approach focussing on dynamic assemblies for the variable-positioned walls (simulations “2 wall types”).

Table 1: Composition of the analysed internal wall categories [2]

Category	Composition	Thickness
 Masonry wall	- brickwork:	
	a) perforated clay bricks (case study)	140 mm
	b) cellular concrete blocks	150 mm
	c) hollow concrete blocks	140 mm
	- plaster + painting	12 mm
 Dry wall	- metal studs	50 mm
	- mineral wool	40 mm
	- gypsum plasterboard	12.5 + 12.5 mm
	- painting	
 DfD wall	- metal framework	50 mm
	- glass wool	40 mm
	- OSB boarding+	15 mm
	a) MDF boarding	12.5 mm
	b) gypsum fibreboard	12.5 mm
	c) gypsum plasterboard	12.5 mm
	- painting	

3.2.1 Renovation scenario 1: Transformation from a two-bedroom to a one-bedroom apartment with an enlarged living room

In the first renovation scenario a two-bedroom apartment is transformed into a one-bedroom apartment by using the small bedroom as extension of the living room (Fig. 8). Moreover the wall between the kitchen and the living room is removed to create an open kitchen. This renovation scenario can be translated into wall scenarios (Fig. 9), looking at four consecutive periods of 15 years (year 0 until year 15, year 15 until year 30, year 30 until year 45 and year 45 until year 60) in which the apartment is switched from a two-bedroom to a one-bedroom apartment and vice-versa. A distinction can be made between fixed-positioned walls (red walls in Fig. 9) and variable-positioned walls (orange and yellow walls in Fig. 9). For the walls with an interruption of the analysis period (the yellow walls are not present in the housing unit in period “15-30 year” and “45-60 year”) the assumption is made that dynamic assemblies are stored (or eventually used in another dwelling) in order to be reused later in the housing unit.

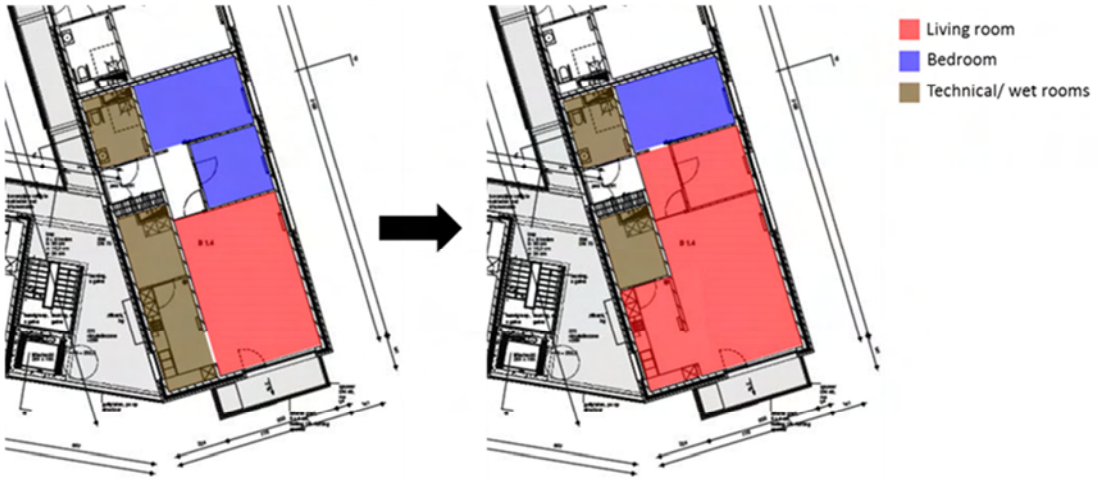


Fig. 8: Renovation scenario 1 (transformation from two-bedroom apartment to one-bedroom apartment) [2]

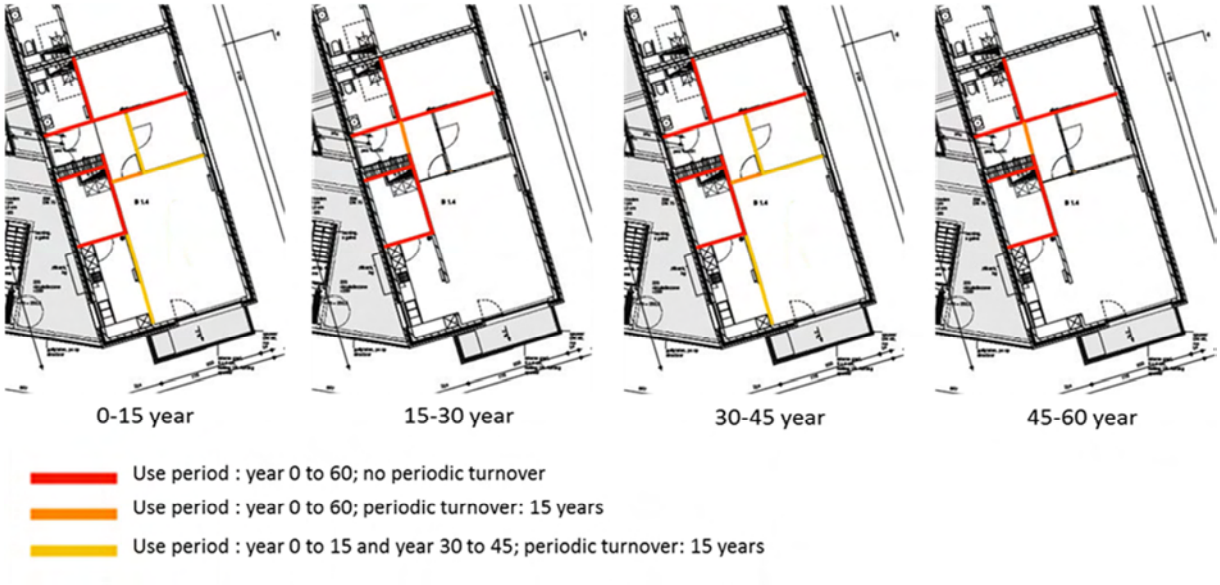

Fig. 9: Wall scenarios in renovation scenario 1 [2]

The LCA results (Fig. 10) show that dynamic assemblies for all internal walls (simulations “1 wall type”) are not beneficial compared to masonry walls. This is due to the design of the floor plan-layout which requires a low number of interventions in order to transform the housing unit from one typology to another. When a selective application of dynamic assemblies is chosen (simulations “2 wall types”), the life cycle environmental costs can be reduced. The reduction compared to the “1 wall type”-simulations is however limited because a large part of the internal walls (yellow walls in Fig. 9) are moved to another housing unit during the building life cycle, so that the benefits of component reuse are allocated to that unit.

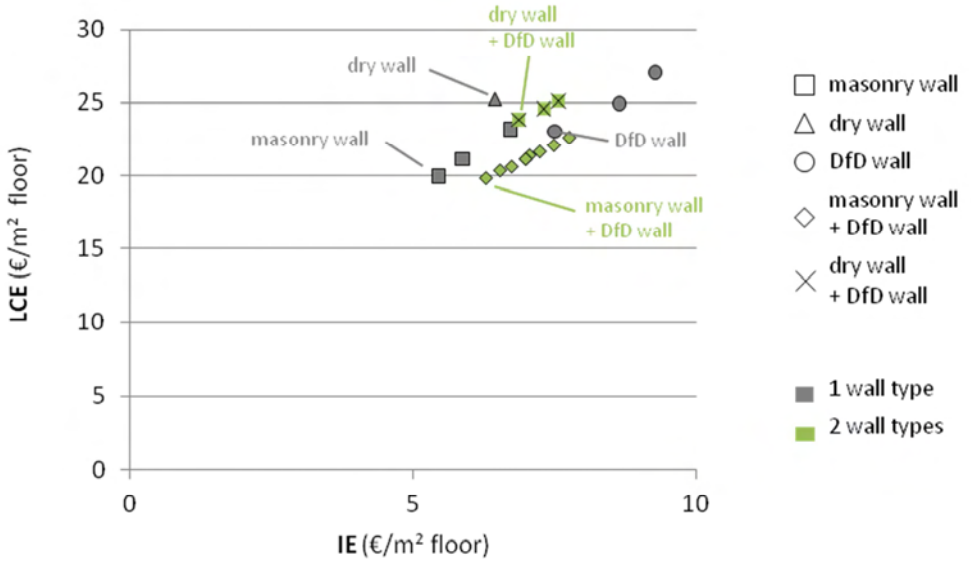

Fig. 10: Overview of the initial environmental costs (IE) and life cycle environmental costs (LCE) for renovation scenario 1 for simulations with 1 or 2 wall types [2]

Concerning the financial evaluation (Fig. 11), the "1 wall type"-simulations show that dynamic assemblies can compete with masonry walls (cost reduction resulting from the pre-assembly of dynamic variants [1]) but are more expensive than dry wall systems (the labour costs for disassembly and reassembly of dynamic variants are higher than the saved material cost resulting from component reuse [1]).

A selective approach for the use of dynamic assemblies (limited to variable-positioned walls) in combination with masonry walls can be interesting (decrease of the initial and life cycle financial costs compared to the use of masonry walls for all internal walls). On the other hand a combination with dry wall systems results in a limited additional cost compared to the generalized use of dry walls.

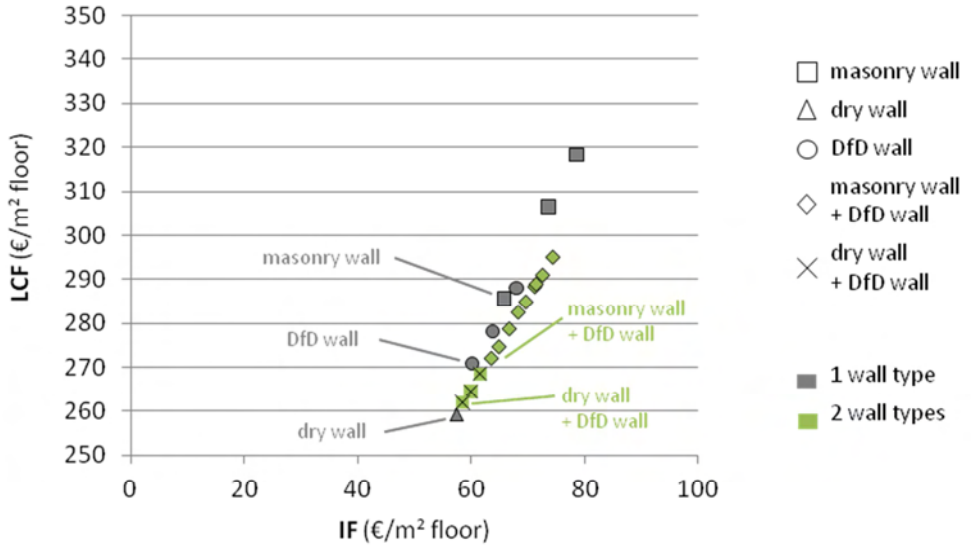

Fig. 11: Overview of the initial financial costs (IF) and life cycle financial costs (LCF) for renovation scenario 1 for simulations with 1 or 2 wall types [2]

3.2.2 Renovation scenario 2: Transformation from a two-bedroom to a one-bedroom apartment with a living room subdivided in a sitting and eating room

The second renovation scenario (Fig. 12) is similar to the previous scenario, except that a part of the internal walls can be reused to divide the living room in a sitting and eating room. This renovation scenario enables to evaluate the impact of higher reuse capacity of internal walls inside the housing unit and the possible environmental and economic benefits of dynamic assemblies. The wall scenarios are shown in Fig. 13.

The LCA and LCC results show the same trends as in renovation scenario 1. From an environmental point of view, a generalized use of dynamic assemblies is not beneficial while from an economic point of view, dynamic assemblies for all internal walls can compete economically with masonry walls but are still more expensive than dry wall systems. A selective approach of dynamic variants results in a higher reduction of environmental costs, compared to renovation scenario 1. This is the direct consequence of the higher reuse of internal walls inside the housing unit. From a financial perspective, a selective approach of dynamic assemblies is advantageous in combination with masonry but leads to additional costs in combination with dry wall systems. Compared to renovation scenario 1, the additional costs are even higher because of additional disassembly steps due to the higher reuse of internal walls inside the housing unit.

Fig. 12: Renovation scenario 2 (transformation from two-bedroom apartment to one-bedroom apartment) [2]

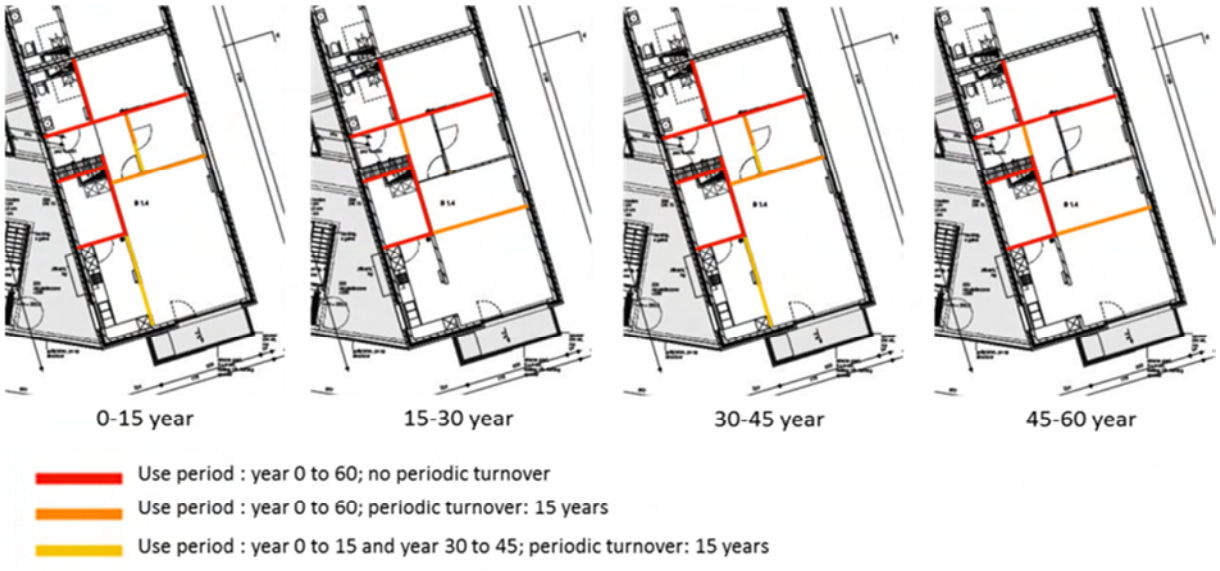

Fig. 13: Wall scenarios in renovation scenario 2 [2]

4. Conclusions

It can be concluded that the building concept and layout are important to make dynamic design beneficial or not. The qualitative assessment of the housing unit revealed that different aspects related to adaptability were integrated in the design proposal of the case study (flexible plan-layout, space and room clustering, adaptability for wheel chair users, external circulation). In consequence, renovation scenarios only required limited interventions and made a generalized use of dynamic assemblies not beneficial, neither from an environmental nor financial perspective. Instead, a more selective application of dynamic assemblies, i.e. to only those walls which are assumed to be changed in future, was proven to be preferred. This selective approach can result in life cycle environmental benefits while the additional financial costs remain limited.

As the conclusions drawn are only valid for the analysed case study with a flexible and polyvalent plan layout, it might be that the advantages of dynamic assemblies were not fully highlighted. It is therefore recommended to apply the same analysis to other case studies. This would allow a more representative picture of the benefits and drawbacks of dynamic assemblies at the building level. Furthermore research should be done about the impact of scenarios for the renovation frequency and service life span of subcomponents. Based on sensitivity analysis at the element level [1], it is expected that those parameters can have an important influence on the evaluation results.

5. Acknowledgements

The authors would like to thank the Flemish Public Waste Agency (OVAM) that commissioned this research and all members of the steering committee for their input and suggestions in the course of the project.

Guidelines and Indicators for Sustainable Mega-Event-Buildings

Natalie Essig
Prof. Dr.
Fraunhofer-Institute of Building Physics;
Munich University of Applied Sciences
natalie.essig@hm.edu;
natalie.essig@ibp.fraunhofer.de

Short Summary

Over the past years organisation committees of mega-events, like Olympic Games or European or World Football Championships, have more and more been demanding for the evaluation of the sustainability performance of their venues. These assessments have been made with different instruments and a comparison of the sustainability is not yet possible at all. Therefore the abstract will show a common set of sustainability indicators for the whole life-cycle of mega-event venues that integrate ecological, social, and criteria, as well as aspects for sport events.

Keywords: Sustainable mega-event venues, sport facilities, planning instruments, assessment methods

Introduction

Mega-event venues are not only sport facilities, they stand for national and regional representation and shall show the competence of technology, engineering and architecture of the Olympic cities or European or World Football Championships countries. In the last years the organisation committees of sport events are demanding for environmental assessments for their temporary and long-lasting buildings (venues, multi-functional halls, exhibition centres etc.) and also tools for legacy and sustainability aspects have been implemented in the planning process of mega-event venues to guarantee ecological, economic and social infrastructures for sport events. Further on slogans, like „Green Games“ or „The Greenest Games in Modern Times“ have been shown during the recent Olympic Games, like Beijing 2008, Vancouver 2010 or London 2012. The Olympic cities seem to compete for the greenest Games. But are these slogans just a “Greenwashing” or will these „Green Games“ and „Green Venues“ concepts be reality?

1. Green and Sustainability Guidelines and Assessment Methods for Mega-Event Venues

It is clearly true, that mega-events have strong additional and long-lasting impacts on the surrounding environment of the host countries and cities and could never be announced as “sustainable”. Especially the mega-event buildings have the greatest visible and long-lasting effects [1]. The impacts of mega-events could be reflected by a variety of aspects, influencing the environment, the society or the countries’ economy as well in a negative, as in a positive way. For the construction sector the following positive successes could be announced [2]:

- Introduction and improvement of environmental laws and building standards in the field of energy efficiency, sustainability and protection of historic buildings and monuments

- Promotion of energy-efficient and environmental technologies for the building construction sector
- Development of planning tools for the evaluation of the sustainability performance of buildings

To implement sustainable concepts in Olympic Games or in Football World and European Championships, the IOC (International Olympic Committee) and also the FIFA/ UEFA (Federal International Football Association/ Union of European Football Associations) have started to demand for sustainability impact assessments for venues since a couple of years. Regarding to this demand different sustainable planning concepts and the use of sustainability assessment methods have been adopted by the host cities and organisation teams. Examples are the venues of the Vancouver 2010 Olympic Winter Games (LEED Canada certification), the London 2012 Olympic Games (BREEAM certification) or for the Stadia for the Football World Cup of Brasilia (LEED U.S. certification). But this process is just at the beginning and the implementation of sustainability aspects into mega-event venues is still on an early stage [2].

1.1 Environmental and Sustainable Guidelines of Non-Profit-Organisations (NON), Sport Federations and Organising Committees

To define and reduce the enormous additional impacts of mega-events, the national and international sports federations and organizers of sporting events have launched various sustainability initiatives in recent years. However, the intent of these guidelines and projects is focused more on the environmental friendly management of the events, rather than on the planning, construction and operation of sustainable venues. For mega-events in general the guideline "Green Champion - Guide for Large Sporting Events" has been developed by the German Olympic Sports Confederation (DOSB) together with the Federal Ministry of Environment (BMU) in 2009. For European and World Football Championships the project “Green Goal” has been advanced for the World Cup 2006 in Germany. The Green Goal concepts aim to reduce the impact on the environment and the climate. The main topics of this label are energy, water, waste, mobility and catering. The concept was overtaken for the Football World Cup 2010 in South Africa, as well for the Women World Cup 2011 in Germany [3].

While football associations, like FIFA or UEFA have launched the implementation of environmental topics just for a few years, the IOC has started to support the Host Cities since the early nineties. This circumstance promotes both the quality and the attractiveness of the Games, as well as the sustainability. Some of the important steps are shown in the following [2]:

- 1994: Announcement of the environment as the third dimension of the Olympism
- 1996: Implementation of an environmental chapter in the Olympic Charter
- 1996: Foundation of the Sports and Environment Commission.

In addition, numerous voluntary guidelines, such as the Olympic Movements Agenda 21, the Manual on Sport and Environment or the IOC Guide on Sport and Environment have been established. This development is supported by further mandatory IOC tools, the so-called “Five Pillars” of the Olympic Games Management [2]:

- the Applicant and Candidature Procedure and Questionnaire
- the Olympic Games Study
- the Transfer of Knowledge
- the Global Impact of the Olympic Games
- and the Audit and Masterplan.

To implement sustainable Olympic venues, the IOC demands in its Candidature Procedure and Questionnaire that sustainability impact assessments for all Olympic venues have to be carried out already in the candidature phase. Yet this demand is answered by the future host cities by employing different assessment methods: starting from sustainability reports of NGOs, like UNEP, Greenpeace or WWF to national assessment methods, like the American Label LEED or the British system BREEAM [2].

1.2 National and International Assessment Methods for Sustainable Venues of Large Sport Events

While FIFA and UEFA are claiming for an environmental assessment of the venues based on the American label LEED, the IOC is asking for national sustainability evaluations. This development goes back to the Olympic Games 2000 of Sydney, where benchmarks have been launched for the ecological assessment of venues the first time. The national Australian assessment methods Green Star (Green Building Council Australia – GBCA) and NABERS (National Australian Built Environment Rating System, Australian Government) have been developed on the basis of the Olympic indicators [2].

	Methods	Facilities	Assess-sess-ment	Development
Sydney 2000	**ESD** (Environmental Sustainable Development)	Olympic Village and Venues	*	**Green Star** **NABERS** (National Australian Built Environment Rating System)
Salt Lake City 2002	**LEED New Construction (U.S.)**	Venues	*	Existing assessment system
Turin 2006	**GBTool** (Green Building Tool)	Media Village	*	**Protocollo Itaca**
Beijing 2008	**GOBAS** (Green Olympic Building Assessment System)	Olympic Village and Venues	*	**GBAS** (Green Building Assessment System)
	LEED for Neighbouring Development	Olympic Village	Gold	Integration of LEED in China
Vancouver 2010	**LEED New Construction Canada** Types: LEED for Neighbouring Development Canada, LEED Interior Design	Olympic Village and Venues	Silver to Platin	Existing assessment system
London 2012	**BREEAM** Types: BREEAM Bespoke, EcoHomes, BREEAM Communities	Olympic Village and Venues	Code Level 4, Excellent	Existing assessment system: Development of **BREEAM for Olympic Park and Venues** (based on BREEAM Bespoke) Development of the pilot version BREEAM Communities
Sochi 2014	**EIA** (Environmental Impact Assessment)	*	*	*
	BREEAM Russia	Olympic Village and Venues	*	Integration of BREEAM in Russia
Rio de Janeiro 2016	**LEED New Construction (U.S.)**	Venue	*	Existing assessment system

Fig. 1: Assessment methods for the evaluation of the sustainability performance of Olympic facilities [5].

The organising committees of the Olympic Winter Games of Vancouver 2010 (VANOC) and the London Summer Games of 2012 have certified their new and existing competition venues and non-competition facilities by applying existing national assessment schemes to build and operate Games facilities, that would ensure a minimal environmental footprint. Vancouver, for instance, has used the North-American system LEED Canada (Leadership in Energy and Environmental Design) to assess its Olympic sports facilities. For the London Games 2012 the label “BREEAM for Olympic Park and Venues” was developed by BRE (Building Research Establishment) within the national sustainability method BREEAM (BRE Environmental Assessment Method) to assure the ecological implementation of the Olympic venues [5]. Especially for the Olympic venues of the Beijing 2008 Games, the Chinese Ministry of Construction (MoC) and the Ministry of Science and Technology (MoST) developed the Green Olympic Building Assessment System (GOBAS), which is based on the Japanese assessment method CASBEE (Comprehensive Assessment System for Building Environmental Efficiency) and the North-American LEED system. For the Olympic Winter Games of Turin 2006, the Turin media village was assessed by means of GBTool, which provided the basis for the current national assessment method PROTOCOLLO ITACA. The example of the Winter Olympic Games of Sochi 2014, however, shows that the use of assessment methods for Olympic venues has not yet been enforced at all. First approaches to assess the Olympic venues of Sochi, has been mentioned in the Bid Book (application form), but concrete implementations are not visible one year before the Games. At the moment the development of a BREEAM Russia version to assess the venues is under discussion [2].

Considering that the IOC is only demanding for assessing the sustainability performance of the facilities, but not giving out common mandatory indicators and benchmarks, the host cities have fulfilled this requirement with different assessment tools in the last year. Due to these diverse instruments, the evaluation results of the venues are not comparable at all, have different significances according to environmental, economic and social aspects and are not integrating the entire life cycle of sport venues (Olympic legacy).

2. Criteria and Indicators for the Sustainability Performance of Mega-Event Venues

At the moment a comparison of the sustainability performance of mega-event buildings is not yet possible at all. In most cases just ecological and energy efficiency aspects and the use of the buildings during the mega-event were analysed. Social, economic, technical, functional, process and site orientated criteria, as well as the re-use of the buildings after the event have not been addressed so far.

Therefore the abstract shows a new set of common criteria, indicators and benchmarks for the sustainability performance of mega-event sports architecture. This set of indicators is based on the results of the dissertation “Sustainability of Olympic Venues” that was published in 2010 [1], and on the outcomes of the research project “Guidelines for Sustainable Venues of Mega-Events” that was supported by the BMWi (Federal Ministry for Economics and Technics) from 2012 to 2013 [2]. The main goal of these projects was to develop a guideline for the assessment of buildings of mega-events in order to be able to compare the sustainability of mega-event buildings over the whole life-cycle (design, event, post-event and end-of-life). During these studies, analyses of the concepts and impact assessments for recent Olympic Games and Football Championships have been done. Also sustainability reports of NGOs, like UNEP, Greenpeace or WWF have been integrated into the analyses, as well as the sustainability guidelines and regulations of the IOC and the FIFA/ UEFA. The main objective of this research project was the derivation of criteria for sustainable mega-event venues.

2.1 Structure and Methodology for the Sustainability of Mega-Event Venues

The structure of the indicator catalogue is based on the results of the EU project "OPEN HOUSE". The main goal of the OPEN HOUSE, which was initiated in the seventh research framework

programme, was to develop a European methodology for assessing the sustainability performance of buildings (time period: February 2010 to August 2013). During this project all existing Europe assessment methods have been compared with each other and a catalogue of sustainability criteria for the construction of office buildings have been developed (www.openhouse-fp7.eu). The structure and the content of the OPEN HOUSE project is an international sustainability assessment method, that is based on environmental and energy aspects, social and economic issues and the latest international and European standardization (ISO TC 59 SC 17: Sustainability in Building Construction, CEN TC 350: Sustainability of construction works - Framework for assessment of buildings) [6].

Besides the OPEN HOUSE six pillars model
- Ecological Quality
- Social/ functional Quality
- Economic Quality
- Technical Quality
- Technical Characteristics
- Process Quality
- and the Site

special indicators for mega-events have to be considered as well. After analysing the voluntary and mandatory guidelines of the IOC and the FIFA/ UEFA and the sustainability reports of the NGOs, like UNEP, Greenpeace or WWF and discussions with mega-event experts, the new category
- Quality of Mega-Event Venues

was added [3].

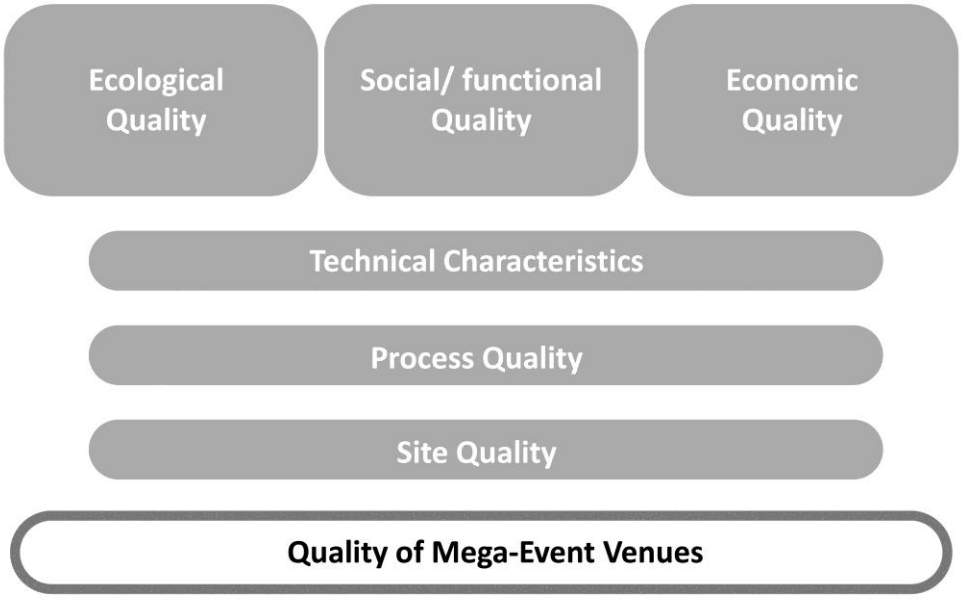

Fig. 2: Sustainability categories for mega-event buildings based on OPEN HOUSE [3].

2.2 Sustainable Indicators for Mega-Event Facilities

Based on the results of the research project the following catalogue with 63 indicators for sustainable mega-event buildings have been developed [2 and 3]:
- Ecological Quality:
  Resources, energy, life cycle assessment (LCA), water, waste, materials, land use, recycling, biodiversity etc.
- Socio-cultural and Functional Quality:
  Comfort, healthiness, user, barrier free accessibility, area efficiency, reuse, security, public

accessibility, service comfort, architecture and design, regional and cultural aspects, innovation etc.

- Economical Quality:
  Value stability, life cycle costs etc.
- Technical Quality:
  Fire protection, durability, cleaning and maintenance, resistance against hail, storm, high water and earthquake, technical building equipment, building shell, ease of deconstruction etc.
- Process Quality:
  Planning process, integral planning, tendering, construction site, operation etc.
- Site Quality:
  Risks at the site, options for transportation, circumstances at the site, bicycle comfort, image and conditions at the neighbourhood, vicinity of amenities etc.
- Quality of Mega-Event Buildings:
  Re-use and legacy, temporary and existing buildings, sport functional aspects etc.

In summary 25 core goals for sustainable venues could be derived from the main catalogue. These core indicators could be used as a simplified and transparent decision-support-tool for decision-makers of major events and should provide a first overview of the sustainability performance of mega-event facilities (see figure 3).

Environmental Quality	1. Life-Cycle Analyses (LCA: GWP, Primary Energy etc.)
	2. Biodiversity and Depletion of Habitats
	3. Water and Waste Water
	4. Land Use
	5. Waste Management
Social/ Functional Quality	6. Barrier-free Accessibility
	7. Security and Healthiness
	8. Comfort
	9. Public Accessibility
	10. Conversion Feasibility
	11. Responsible Material Sourcing
Economic Quality	12. Building-related Life Cycle Costs (LCC)
Technical Characteristics	13. Noise Protection
	14. Quality of the Building Shell
	15. Ease of Deconstruction, Recycling, and Dismantling
Process Quality	16. Quality of the Project's Preparation
	17. Integrated Planning
	18. Construction Site impact/ Construction Process
	19. Commissioning and Monitoring
The Site	20. Options for Transportation
Ouality of Mega-Event Buildings	21. Integration of the Olympic Buildings into the urban planning (Master Plan)
	22. Quality of the Legacy: concepts for re-use

23. Temporary and Existing Venues
24. Sport-functional Requirements of the Ifs (International Associations): Sportsmen and visitors
25. Enhancement of Sustainability in Education (Architects, Engineers, Construction worker etc.)

Fig. 3: Core indicators for sustainable mega-event buildings [3].

3. Criteria and Indicators for the Sustainability Performance of Mega-Event Venues

Based on the results of the named studies the following advantages for the use of assessment methods for the sustainable performance of venues could be noted [3]:

- Promotion of subsequent use and degree of capacity utilization of the Olympic sports arenas after the Olympic games through higher competitiveness and considerable increase of added value of the sports venues through their whole lifecycle (Olympic Games and thereafter) Securing the comparableness of the Olympic sports venues on an international level.
- Promotion of the Olympic values through an integral sustainability assessment of the Olympic sports facilities (ecological, economic, socio cultural and Olympic aspects).
- Improvement of the transparency of the Olympic planning process through characterization of sustainability quality of the Olympic sports venues and through the provision of information for operators and users of the sports facilities.
- Guarantee of the implementation of sustainable building quality of Olympic sports facilities through monitoring und promotion of the integrative planning process.
- Promotion of the quality standards of the international construction of sports venues by accelerating the introduction on the market of new and energy efficient technologies and ecological materials for the construction of sports arenas.
- Reduction of the negative effects of the mega event Olympic Games on the environment through improvement of the building quality, comfort for the user, the energy efficiency and the public effects of the Olympic sports facilities.
- Certification as marketing instrument for sustainable Olympic sports facilities.

A free building assessment tool facilitates change in the construction sector towards environmental, economic and social sustainability

Dr. Susanne Geissler
Director
ÖGNB
Österreichische
Gesellschaft für
Nachhaltiges Bauen
Austria
geissler@oegnb.net

Short Summary

The ÖGNB offers a comprehensive sustainability criteria framework for residential and non-residential buildings which should be used from the very beginning of a building project, especially as a checklist for the meetings between the design team and the client which serve to shape the project and to define the design targets. ÖGNB members recognise ambitious building performance requirements to approach the goal of sustainability in the building sector. However, there are also concerns regarding the related costs, on the one hand for the building assessment procedure itself, and on the other hand regarding a potential increase in construction costs as a consequence of building performance requirements. In 2012, ÖGNB organised a series of workshops for the ÖGNB members to deal with these concerns and to elaborate the basis for revising the assessment criteria, scales and guidelines accordingly. These review workshops resulted in many small adjustments, based on the experience gained during the utilisation of the assessment tool. In addition, the workshop participants agreed on some major revisions, among others for the criteria *energy, building operation, accessibility without barriers,* and *fire safety*, which represent selected examples described in this paper. The revision of the building assessment framework contributed to the discussions among the ÖGNB members and initiated discussions in the respective associations and companies. It did not only improve the assessment framework but also contributed to awareness creation regarding the costs of the building assessment itself, the feasibility of the required building performance and the associated construction and life cycle costs, thus revealing the need and the potential for technological innovations.

Keywords:Green building; building assessment; integrated planning; building optimization

1. Introduction

The ÖGNB - Österreichische Gesellschaft für Nachhaltiges Bauen (English: Austrian Sustainable Building Council) builds on the experience gained from the participation of its founding members in the international *Green Building Challenge* starting from 1996. Austria joined 1998 and experts from different fields developed the first Austrian building assessment scheme with the support of three Austrian Federal Ministries. [1]

Today, ÖGNB still runs this building assessment scheme in the form of a further developed version and offers also building certification based on this system.

However, the organization’s focus is rather on providing a platform for further developing technical concepts, enabling product innovations and discussing new ideas and concepts than on promoting building certification.

Therefore, above all, the building assessment scheme is used as a communication and information tool as well as an instrument to facilitate change in the construction sector. In this regard, in 2012 a sequence of criteria-review workshops has been conducted with the members of the ÖGNB, to discuss the assessment criteria, the targets, allocation of scores and required supporting documents in the light of new technical developments, changing framework conditions, lessons learnt from previous building assessments, European research projects and experiences of other building assessment schemes offered in Europe.
This conference contribution presents selected results of the criteria-review workshops and their implication on the assessment scheme, resulting in an adjusted version. Like the previous one, the adjusted version is publicly accessible via the Internet, free of charge and available in English.
It is easy to understand and to operate and van be used in education, for quality control, risk assessment and product innovations, in order to facilitate the change in the construction sector towards environmental, economic, and social sustainability.

2. Background information: ÖGNB building assessment procedure

ÖGNB offers a comprehensive criteria framework for the sustainability assessment of residential and non-residential buildings which should be used from the very beginning of a building project, especially as a checklist for the meetings between the design team and the client which serve to shape the project and to define the design targets.
This criteria framework is available in the internet and corresponds with the web-based tool which is applied to collect building related information during the building assessment process to prove whether requirements are met or not. These are the so-called supporting documents which are specified for each criterion to ensure the comparability of assessment results.
In short, the ÖGNB building assessment procedure is carried out in five steps:

- Building documentation using online declaration tools; carried out by consultants who are appointed by the ÖGNB
- Handover of submitted project to the ÖGNB and application for building surveying
- Verification of proof by ÖGNB auditors, who are listed by the ÖGNB; if necessary revision of proof by ÖGNB consultants
- Approval of assessment results by ÖGNB after consulting with submitters
- Publication of assessment results in ÖGNB press, above all on ÖGNB website

3. ÖGNB building assessment – review workshops

ÖGNB members recognise ambitious building performance requirements to approach the goal of sustainability in the building sector. However, there are also concerns regarding the related costs, on the one hand for the assessment procedure itself, and on the other hand regarding a potential increase in construction costs as a consequence of building performance requirements. In 2012, ÖGNB organised review workshops to deal with these concerns and to elaborate the basis for revising the assessment criteria, scales and guidelines accordingly.
The main objectives of the review were the following ones:

- To compare assessment criteria and targets with the technical development and the development regarding the regulatory framework, and to agree on necessary adaptations
- To check whether the procedure to produce supporting documents can be simplified
- To analyse the relation between the efforts needed to meet a requirement and the scores allocated to this requirement, and to agree on necessary adaptations

The review workshops resulted in many small adjustments, based on the experience gained during the application of the criteria, scales and guidelines, and the utilisation of the assessment tool.

In addition, the workshop participants agreed on some major revisions such as for the following criteria representing selected examples which are described in the next chapters:

- Energy (adapt to change of regulation to save effort for preparing supporting documents)
- Building operation (in view of nearly zero energy buildings and plus-energy buildings: what to consider to ensure low energy consumption during building operation)
- Accessibility without barriers (take into account construction costs of building assessment requirement)

- Fire safety (relation between the efforts needed to meet a requirement and the scores allocated)

3.1 Energy

The ÖGNB building assessment builds on Austrian practice and framework conditions. It is the objective to use available documents as supporting documents during the assessment procedure, whenever possible. This limits additional costs caused by the building assessment itself. Therefore, energy-related criteria comply with the respective regulations. Due to the recast EPBD (Energy Performance of Buildings Directive, Directive 2010/31/EU) there was the need to adapt the ÖGNB assessment framework accordingly.
The main indicators to be assessed in terms of building energy performance correspond with the indicators displayed in the new Austrian energy performance certificate according to recast EPBD (Directive 2010/31/EU).
These indicators are the following ones:

- HWB - Heizwärmebedarf, heating energy demand: describes the energy related quality of the building envelope (refers to transmission losses);
- fGEE - Faktor Gesamtenergieeffizienz, total energy efficiency factor: describes the efficiency of building energy use (includes also energy conversion losses caused by the building services, such as the heating system);
- PEB - Primärenergiebedarf, primary energy demand: this indicator includes the amount of energy needed to provide the energy used in the building and thus refers to the ecological dimension;
- CO2 - Carbon dioxide emission: This indicator refers to CO2 emissions caused during building operation and thus refers to the amount of renewable energy used by the building, taking into account the amount of energy produced at the building site.

3.2 Building operation

This criterion refers to the fact the user behaviour is an important aspect regarding the actual energy consumption of the building. Therefore this criterion asks for the appropriate building equipment in terms of separate measuring the energy consumption by major consumers such as heating, ventilation, cooling, lighting, and pumps. In addition, appropriate user information is required, e.g. manuals which describe the equipment, addressing occupants but also facility managers. Only if the appropriate equipment is installed and information is available it will be possible to steer the users' behaviour during building operation and to ensure that the actual energy consumption does not exceed the predicted level.

In view of developments such as nearly zero energy buildings and plus-energy buildings user behaviour and actual energy consumption becomes even crucial.

In one of the workshops it was discussed that energy accounting and separate measuring of energy consumption by consumer is very important but needs to be complemented by occupancy data. During building operation it is necessary to verify energy accounting data against occupancy data, because only if it is known which part of the building is actually in use at what time, energy data will be interpreted correctly and measures to steer actual energy consumption will be effective. This aspect should be included in manuals especially addressing facility managers in large buildings.

3.3 Accessibility without barriers

Building requirements must be economically acceptable. While in new construction additional costs caused by sustainability requirements are modest or even not existing taking into account the entire life-cycle of a building, this might be completely different in building renovation. In general we believe that the same criteria should be applied to new and existing buildings, due to the fact, that the occupants are interested in the building performance as such, irrespectively whether the building is a new or an existing one. However, in some cases like to following one, exemptions are justified.

Access for all without discrimination is essential and must be taken into account when designing a new building. It is an important criterion in the ÖGNB assessment framework, but in building renovation there is a major trade off with costs, especially in residential buildings for social housing where affordability is the key issue.

Therefore, in terms of accessibility without barriers, the assessment of new and existing buildings will be different in future, and the scale of the criterion was adapted in the following way for the assessment of existing buildings and building renovations:

- It is the minimum requirement that in the course of a building renovation at least one apartment must be adapted to meet the requirements of accessibility without barriers.
- At the same time, at least those parts of the building leading to that apartment must be free of barriers, as well.

3.4 Fire safety

In Austria, structural fire protection is very much advanced and so is the mandatory level required by the building code (large buildings).

Increase in safety can be achieved by additional requirements in the area of organisational fire protection measures, e.g. additional fire alarm boxes, fire smoke boxes, fire hydrants on each floor and even smaller building units. This strengthens the occupants' perceived safety, actually helps in case of emergency, and additional costs are acceptable.

Therefore, the outcome of workshop discussions was to change the weightings of the sub-criteria *structural fire protection* and *organisational fire protection*, resulting in more scores for the organisational fire protection measures compared with the predominantly mandatory structural fire protection measures.

4. Conclusion

The revision of the building assessment framework contributed to discussion among the ÖGNB members and initiated discussions in the respective associations and companies. It did not only improve the assessment framework but also contributed to awareness creation regarding the costs of the building assessment itself, the feasibility of the required building performance and the associated construction and life cycle costs, thus revealing the need and the potential for technological innovations.

SCHOOLS GO GREEN - EXTENSION OF THE BNB-CERTIFICATION METHODOLOGY FOR EDUCATIONAL BUILDINGS

Carl-Alexander Graubner
Head of Fachgebiet Massivbau,
Technische Universität Darmstadt
Germany
Graubner@massivbau.tu-darmstadt.de

Carmen Schneider
Managing Director
LCEE Life Cycle Engineering Experts GmbH
Germany
c.schneider@lcee.de

Short Summary

The development and implementation of a sustainability certification methodology for buildings is considered to be a milestone of establishing principles for sustainable construction. In order to anchor this approach as widely as possible within the construction practice a continual extension of the certification methodology for different types of buildings is necessary. This paper outlines such a process on the basis of the system development and implementation for sustainable educational buildings.

Keywords: Sustainability; certification methodology; educational facilities; new system implementation

1. Introduction

Worldwide the sustainability approach is considered as a strategic response to global challenges of increasing scarcity of resources and climate change [1]. Germany committed to this approach by its national sustainable development strategy as well. Therein the construction and real estate industry plays a crucial role and is addressed by corresponding objectives and measures [2] since this key sector takes responsibility for enormous extractions out of and substance loads into our environment by constructing, operating and dismantling buildings. More than one third of all energy and material flows are, for instance, caused by the construction industry. In addition a comparable proportion of all CO2-emissions of the OECD-countries is induced only by residential and commercial real estate and furthermore construction industry waste represents approximately 60 % of the entire German waste production (fig. 1).

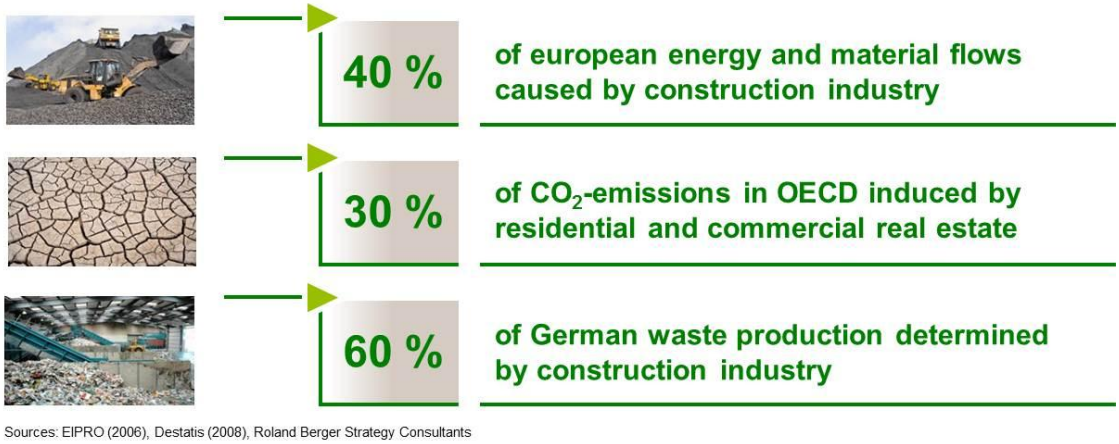

Fig. 1: Environmental impacts of the construction and real estate industry

An accelerated life-cycle approach to buildings by taking into account ecological, economical and socio-cultural aspects equally and completed by technical and functional concerns - that means in fact the establishment of principles for sustainable construction - is one of the key elements of the construction industry's sustainable development [3]. A logical consequence is that such a systematization of the sustainability approach requires making the sustainability quality of buildings measurable and transparent.

Therefore the development of the German sustainability assessment or certification system "Nachhaltiges Bauen für Bundesgebäude" (BNB) involving all relevant stakeholders created the basic prerequisite for public building projects. This system was initially launched as a basic system appropriate for the typology of office buildings. Fig. 2 shows the essential methodology of the described BNB-basic system.

Fig. 2: Assessment and certification methodology of BNB-basic system [3]

However the large variety of building typologies belongs to the main attributes of the construction and real estate industry. This means that a macroeconomic anchoring of strategy and principles for sustainable construction needs an enlarged portfolio of BNB-system versions beyond office buildings and for the entire range of market relevant types of buildings.

2. System draft "Nachhaltige Unterrichtsgebäude"

Educational buildings represent such a relevant type of buildings because the according real estate stands for a significant part of the total public building stock [4]. For this reason a working group formed of municipal and federal representatives as well as scientists and planners was engaged by the Federal Ministry for Transport, Building and Urban Development to develop a system draft for the assessment of sustainable educational buildings which is able to be embedded in the existing BNB-certification methodology. This further development of the BNB-basic system towards a system version for educational buildings is challenging because the different forms of use to be mapped (elementary schools, secondary schools, universities, training centres) vary considerably and the consequential heterogeneity of the user structure leads to an enormous range of requirements and quality respectively sustainability criteria to be integrated in a corresponding system draft.

Although several assessment criteria of the BNB-basic system could be adopted, a large number of criteria had to be adjusted to specific needs of educational buildings (i.e. criterion for the assessment of acoustic comfort). Furthermore additional criteria had to be developed for the aimed system version "*Nachhaltige Unterrichtsgebäude*" [5] (see fig. 3).

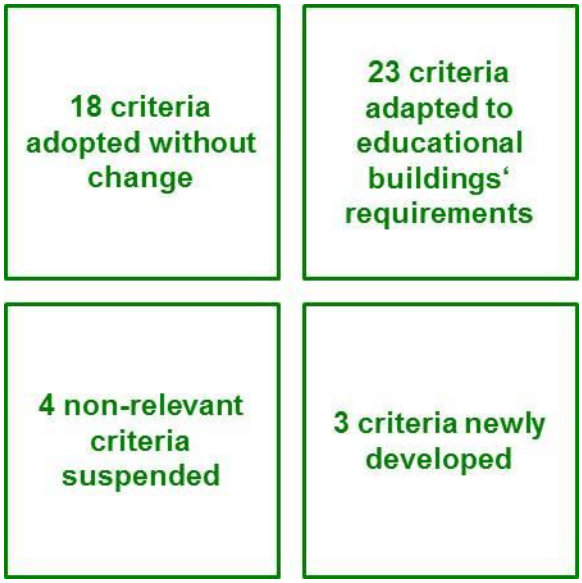

Fig. 3: Main results of system version development

One of these new criteria is for instance the quality of an educational building concerning the prevention of damages due to vandalism. This procedure was essential in order to ensure an adequate capacity of mapping specific sustainability aspects of educational buildings and furthermore a high acceptance of the assessment or certification system itself. Moreover especially the assessment methods and levels had to be configured without advantaging or discriminating one special form of use.

3. System implementation and initial application - Key findings

As part of the development and market implementation of sustainability assessment or certification systems it is common practice to check the application suitability of a system draft by realising a pilot study. During August 2011 to November 2012, the authors of this paper carried out a research project on behalf of the Federal Ministry for Transport, Building and Urban Development in order to test and check intensively the described first version of a system draft for sustainable educational buildings by implementing a phase of initial application. The group of participating pilot projects consisted of seven new built educational buildings of different usage forms from all over Germany which had to face a sustainability assessment by applying the system draft. Pilot projects and their basic characteristics are shown in table 1.

Table 1: Participating pilot projects

Fig.	Number	Name	Usage form	Floor area [m²]	Certification performance
	0001	Uckermark-Kaserne	Lecture hall building	1564	68 %
	0002	Technologiezentrum Holz	Vocational school centre	2976	59 %
	0003	Bildungszentrum Fischbeck	Educational/ cultural centre	6976	68 %
	0004	Fachhochschule Erfurt	Lecture hall/ laboratory	2246	*under examination*
	0005	Berufsbildende Schule Mainz	Vocational school centre	5521	70 %
	0006	Universität Regensburg	Lecture hall building	7649	71 %
	0007	Romaneum Neuss	Cultural centre	9400	65 %

First objective of the project was on the one hand the professional supervision and technical support of the sustainability coordinators of the participating pilot projects by preparing the certification and documentation data. Based on this data the pilot projects' conformity assessment was implemented regarding its compliance with the requirements of the system draft as far as the sustainability quality of sustainable educational buildings is concerned. The results of the conformity assessment led to the calculation of a certification performance and finally to the awarding of sustainability labels (see table 1).

On the other hand the operable completion of the system draft, this means the finalisation towards an operational market version, was the second basic element of the research project. Therefore the participating pilot projects' results and key findings of the conformity assessment had to be analysed concerning possible weaknesses and deficits of the system draft. Thereby especially the feedback of the pilot projects' sustainability coordinators played a highly important role. First of all one conclusion and key finding (see fig. 4) is that the system draft is basically suitable for a sustainability assessment of multiple forms of educational buildings.

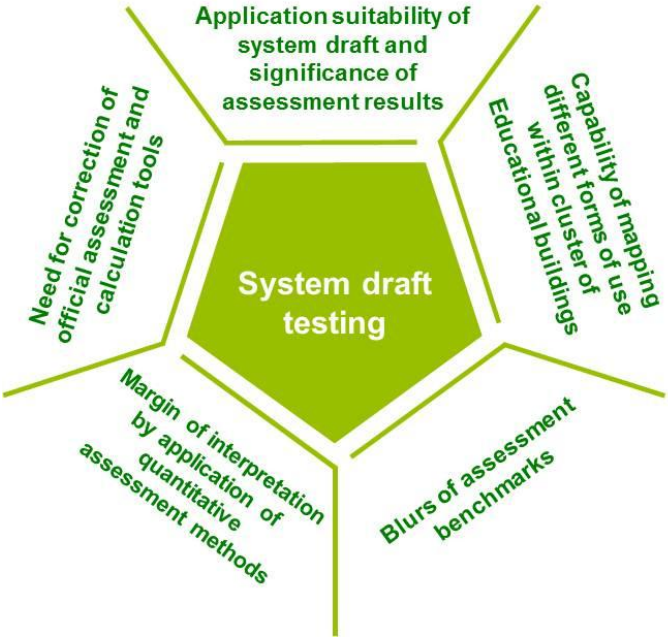

Fig. 4: Key findings of system draft testing

But secondly particular assessment criteria were not adequately specific to map different forms of use or showed selective blurs in assessment benchmarks. Lastly several assessment methods left inacceptable margins of interpretation by their application and particular assessment or calculation tools showed marginal need for correction [6].

4. System finalisation - Market version 2013

By a change of perception - from diagnostic inventory towards a means orientation - the identified conclusions could be transformed into a correlated strategic approach of finalising the system draft for a operational market version (see fig. 5).

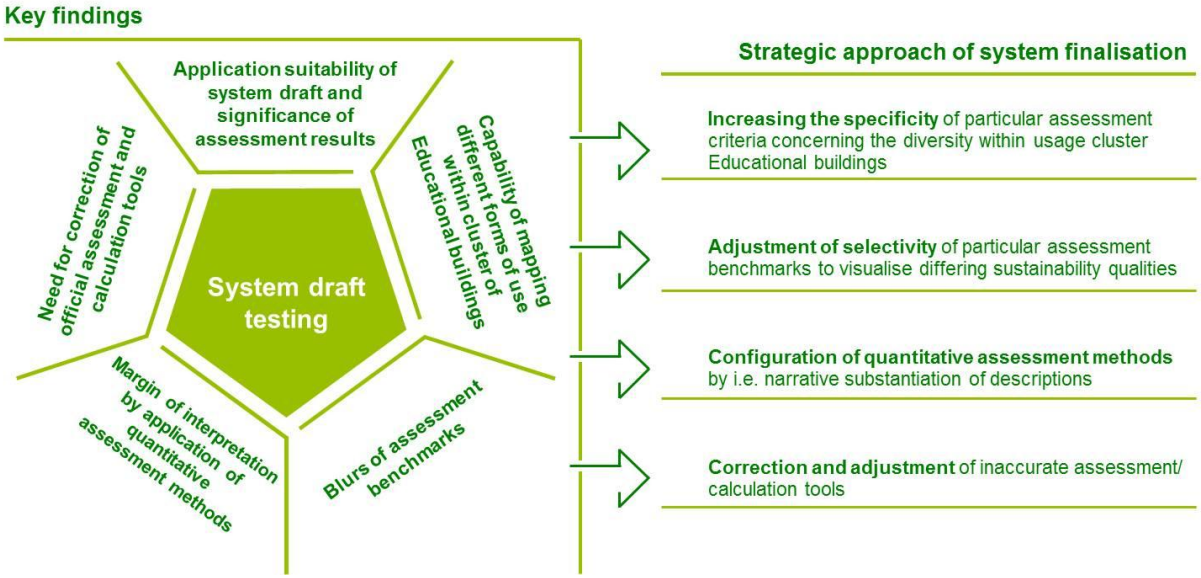

Fig. 5: Strategic approach of system finalisation

An increased specificity of particular assessment criteria concerning the diversity within the usage cluster of educational buildings was achieved i.e. by splitting and individualising their assessment methods with regard to the expected age of building users. The adjustment of selectivity was furthermore ensured by a more precise partition of the assessment benchmarks, whereas undesirable margins of interpretation as part of the application of quantitative assessment methods was repaired through a new configuration of these methods, i.e. by narrative substantiation of descriptions. Finally a correction and adjustment of inaccurate assessment or calculation tools was realised in cooperation and coordination with the Federal Ministry of Transport, Building and Urban Development.

On this basis the implementation of the market version is scheduled for the early year of 2013. But since sustainability assessment or certification systems always have to be adapted to the technical and scientific progress, the market version for sustainable educational buildings will also be part of a continuous development process of system updating.

Summary

Since the first LCA study was conducted in the 70ies and 80ies [14], Life Cycle Assessment (LCA) had to face multiple challenges. Most of them were related to data availability and methodological questions like a consistent approach to conduct LCAs. Some of the challenges are still up-to-date (e.g. data availability), others were solved by the International standards ISO 14040 [12], ISO 14044 [13] or the more construction specific European standards EN 15804 [5] and EN 15978 [6]. Also the ILCD Handbook [7], [8], [9], [10], [11] helped to form a transparent and commonly discussed basis for LCA. Hence, there are still some LCA challenges to be solved today. Some are similar to the first which appeared, others elaborated over time. This paper states challenges of LCA today based on the outcomes of the European research projects OPEN HOUSE and EeBGuide and should be considered as a start for discussions and not as complete summary.

Keywords: LCA, challenges, OPEN HOUSE, EeBGuide

1 Introduction

After the oil crisis in the 70ies and due to the increasing energy prices for oil and natural gas, Europe took a path leading to energy reduction and independency. In the last decades energy efficiency not only was considered in legislation (Energy Performance of Buildings Directive (EPBD) [4]) but also as an aspect for planning and evolution of buildings. Hence, building types were developed that have a very little energy demand, e.g. “minergie [29]” buildings, “Passivhaus [30]” buildings or even “plus energy” buildings. Due to that the overall environmental impact of the operational phase of a building decreased tremendously. By the reduction of energy consumed during operation and therefor the decrease of environmental impacts dedicated to these, the production phase and the End-of-Life (EoL) of the building materials gain in importance. Figure 1 illustrates this tendency.

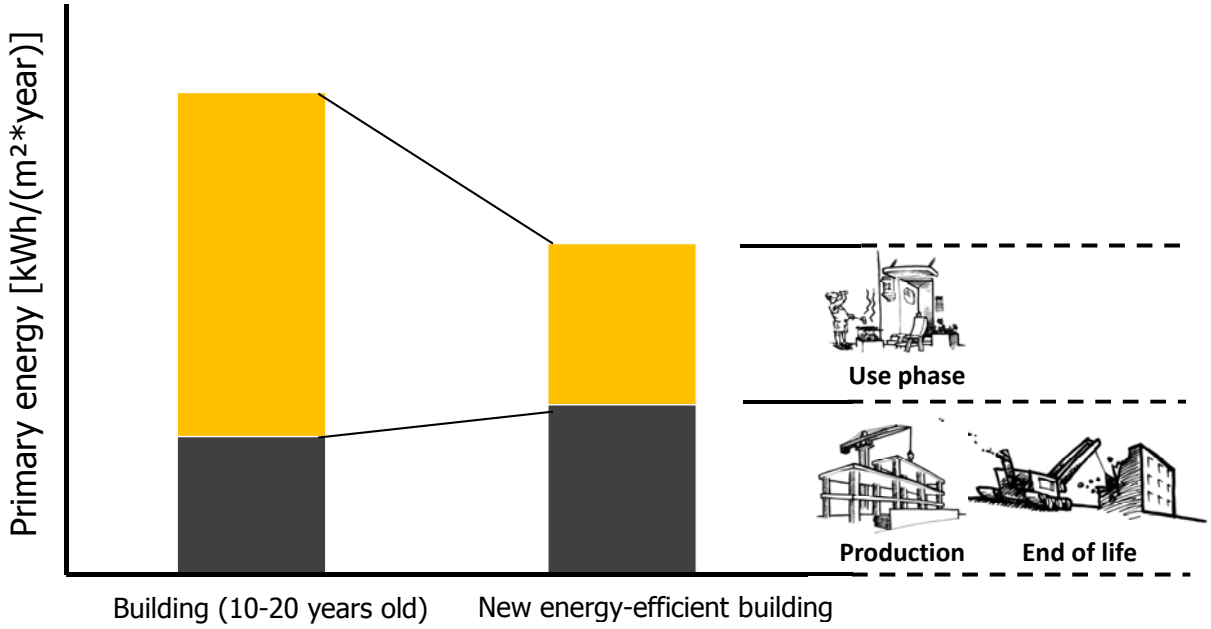

Figure 1: Ratio of use phase to production/EoL for a 10–20 year old building compared with a newly built “Passivhaus” [2]

The trend for more energy efficiency therefore created a need for a holistic view over the whole lifecycle of a building in order to avoid shifts of burden between different lifecycle stages. One important methodology to support planners and architects is Life Cycle assessment (LCA). In recent years LCA in the building sector has increasingly gained in importance. They are applied in the certification of sustainable construction (e.g. BREEAM, HQE, VERDE, DGNB), provide a base for environmental declaration of building products (EPD) and progressively serve as well for decision support. Nevertheless on a European level LCA still faces some challenges. For future progress in LCA it is important that these are transparently pointed out and discussed within LCA experts. Therefore the major challenges figured in the European research projects OPEN HOUSE [1] and EeBGuide [2] are addressed and set in the overall European context.

2 Challenges of LCA in the future:

In order to form a discussion basis, the following major challenges figured in the European research projects OPEN HOUSE [1] and EeBGuide [2] are addressed and set in the overall European context. Hereafter, some of these challenges are stated and explained in more detail. When relevant, potential solutions are pointed out.

2.1 Inconsistency of current guidance documents and standards on LCA

Inconsistency in LCA guidelines and LCA standards is problematic for the widespread use of LCA in general but more specifically in the construction sector. The different available legislative guidelines (e.g. ILCD handbook) and standards (e.g. ISO 14040 [12], ISO 14044 [13], EN 15804 [5], EN 15978 [6]) differ from each other regarding Life Cycle Impact Assessment (LCIA) and other LCA related methodological aspects. This fact can be explained due to the expert groups that differ between the ILCD Handbook (only LCA experts with no specific focus in the construction sector) and the CEN TC 350 standards (EN 15804 and EN 15978) where less LCA scientists attend the committee meeting but more construction stakeholders and building LCA experts. In the end, the goals of these two documents are diverging and many inconsistencies can be noticed based on EeBGuide results [2].

Following the ILCD may let the user adopt a consequential approach while the CEN TC 350 standards approach is only attributional. The first option can be relevant when analyzing large building stocks that can influence the background system (e.g. on national energy level) over their very long service life or decisions on a policy level.

Another example concerns the Life Cycle Assessment (LCIA) stage of the LCA framework.

Differences in completeness between ILCD and CEN TC 350

The ILCD handbook proposes recommended LCIA methods for the different impact categories including mid-point (e.g. global warming, acidification, human toxicity, ecotoxicity potentials) and end-point (e.g. damages on resources, ecosystem, human health) indicators. These methods were proposed at the end of several ILCD expert meetings gathering LCIA developers. The recommendations included all the impact categories though a level of maturity of each LCIA method was also added for information to the final user. Finally, highly uncertain impact categories like human toxicity are recommended to be included, using e.g. the latest developments (USETox), though, limitations were reported in the ILCD reports. In opposite, impact categories like GWP are judged not too uncertain and a recommended method is the one generally accepted (e.g. the IPCC method).

When the LCIA discussions moved within a sector-specific standardization committee (e.g. the CEN TC 350 for Sustainability of Construction Works), the approach may be slightly different. Robustness and agreement of the LCIA method may prevail on the latest scientific works. The share of the committee e.g. diversity of LCA experts, building stakeholders and industry trade unions can also play a role when deciding what should be or should not be included in the standard. It is crucial that in standardization work both visions on LCA – the academic one as well as the business perspective – shall be took into account in order to have the latest scientific results included in the standards but also in order to focus on applicability and relevance of these new developed methods. In addition, relevant indicators for sector specific committees may differ from the general practice. For example, the construction sector may prefer assessing MJ of primary energy and kg of waste.

In EN 15804 and EN 15978, no toxicity, ecotoxicity, ionizing radiations and land use LCIA indicators were taken into account as they were judged by the CEN TC 350 committee as not “mature enough“. Interestingly, the ILCD provision for the calculation of LCA results gives a background justification:

ILCD provisions for the calculation of LCIA results

> *ILCD Handbook – Part – Analysing of existing Environmental Impact Assessment methodologies for use in Life Cycle Assessment*
>
> *4 Requirements for specific impact categories*
>
> *“For some impact categories, many alternative methods have been selected. This can be seen as a sign that there is no clear consensus on how to model such a method. Clear examples are acidification, eutrophication, land use and resources.”*

As the standard reflects a consensus (in that sense, it is a different approach than doing research activities and working on guidance documents), it may be explained why in EN 15804 and EN 15978, no such indicators are included.

Surprisingly, additional LCI information is provided in the standards corresponding, according to the ILCD wording, to reminder flows (see the caption below) which are useful for the interpretation of results (i.e. useful for a reviewer but not corresponding to a proper parameter for impact assessment).

ILCD provisions for reminder flows (e.g. MJ of energy, secondary fuels, recycled waste…):

I)	*MAY – Use reminder flows to keep original information for specific purposes*
II)	*SHALL – Exclude reminder flows from impact assessment*
III)	*SHALL – Clearly identify reminder flows in the flow name*

In that case, the standards in a way go beyond ILCD recommendations by providing next to the 6 LCIA indicators more than 10 reminder flows corresponding to the breakdown of primary energy, water input, resource efficiency (material input, secondary fuel and material), waste (hazardous, non hazardous, radioactive) and recycled waste.

Finally, putting the two aspects together, we can question whether the ILCD recommended LCIA methods are fully applicable [18] due to lack of feedbacks and shortcomings still existing in the latest methods like USETox [11] and the choice of the construction sector standards to only use 6 LCIA indicator but around 10 reminder flows are not appropriate for impact assessment and thus for decision making.

Differences in LCIA hypotheses between ILCD and CEN TC 350

Another aspect are the differences in LCIA hypotheses between the ILCD Handbook [7] and the EN 15804 and EN 15978 standards. This is the case e.g. for the acidification and eutrophication potential. The reference units proposed in case of acidification (EN standards: kg SO_2- Equiv.; ILCD: moles H+ Equiv.) and eutrophication potential (EN standards: kg PO_4^{3-}- Equiv.; ILCD: mole N Equiv.) does not match. Indeed, the CEN TC350 standards are about to go towards a CML approach for calculating these two indicators while the cumulative exceedance method was chosen as the most appropriate by the ILCD Handbook.

Similarly, different LCIA methods exist in the case of abiotic depletion potential for non-fossil resources (ADP-elements). Historically, the CML approach (widely used in LCA) calculated the ADP by dividing the extraction rate of resources by the square of the ultimate reserves out of the same for the reference reserve (the antimony). The ILCD now recommends using the reserve base approach which only considers reserves that meet specified minimum

physical and chemical criteria related to current mining and production practices. Again, the CEN TC 350 standards are about to choose the CML approach.

The advantage of the standard choice is to stay with known methods but the issue is to increase the differences between ICLD and CEN requirements in a European context.

Furthermore LCA practitioners have to keep in mind, that some of the newly ILCD-recommended methods may not be implemented in commercial LCA. This can be the case because of newness but also due to the fact that these methodologies have not yet proven to be valid in practice in terms of giving meaningful results and applicability [18]. As a result, also regarding future developments in LCA (e.g. Product environmental footprint (PEF)) it is necessary to have a consistent approach in ILCD Handbook and the European standards.

2.2 Availability and inconsistency of LCA datasets and EPD

The amount of available LCA datasets increased steadily over the years, but compared to construction products available on the market, the number of existing construction LCA datasets in databases is still quite low. Even the increasing number of EPDs is hardly covering a certain range of construction products. Also in the ILCD database [19] just a small number of datasets are implemented that are sometimes outdated and not sufficiently documented to be used in LCA studies. So far, the majority of available datasets are not consistent regarding modelling principles and usually not sufficient concerning documentation. For example, the question how to handle carbon capture and storage are treated differently in various EPD schemes and countries. Therefore the use of EPD from different EPD schemes within the same environmental assessment is so far not possible.

To overcome all of these issues concerning data availability, the different EPD programmes, among others INIES [20], IBU [21] and BRE Profiles [Q], should come to an agreement with regard to system boundaries or used product construction regulation (PCR). The benefit would be using different EPD datasets from different EPD programmes in one LCA study and being able to use producer specific EPDs in different European countries. The ECO platform [Q], as European EPD umbrella organization, is already trying to solve some of these issues, but so far no major arrangement has been established.

Also the current ongoing developments in France could help to form a consistent LCA database. In the next few years every construction product in France should have an environmental product declaration based on EN 15804 if the company plans to communicate about the environmental performance of its product [28].

2.3 Inconsistency of current labelling schemes

Another challenge is the diverging LCA approach in the different labelling schemes for sustainability. Building labelling schemes use their own individual sets of calculation rules for building LCA. Even if referring to EN 15978, none of them are fully compliant with it to date. In some of the labelling schemes like LEED [22], LCA has been recently incorporated, whereas in other building labelling schemes like HQE Performance [16] and DGNB [17], LCA is already a fundamental part. But even if LCA is used to assess the environmental impacts, the system boundaries and cut-off rules are often not consistent between them and included life cycle stages and materials considered may vary. For example, in DGNB the transport of the materials to the construction site and the transport of the materials at the EoL are not considered. The selected LCIA indicators can also be different out of the usual GWP. For example, the HQE Performance scheme includes cradle-to-grave impacts of the building products and technical equipment (embodied impacts), the impact of water and energy consumption (operational impacts). These contributors are quantified for the primary

and non-renewable energy consumption, the water consumption and the different waste indicators. In contrast, DGNB is only assessing the water demand in the operational phase (but not the embodied water demand) and wastes are not considered from an LCA perspective. In order to transparently state all of these differences in the methodological approaches and try to overcome them, the SB Alliance project [23] has undertaken research activities and set up common metrics towards a first harmonization. Especially the choice of important environmental indicators and LCIA methodologies is one of the major outcomes of the SBA common metrics (see Figure 2).

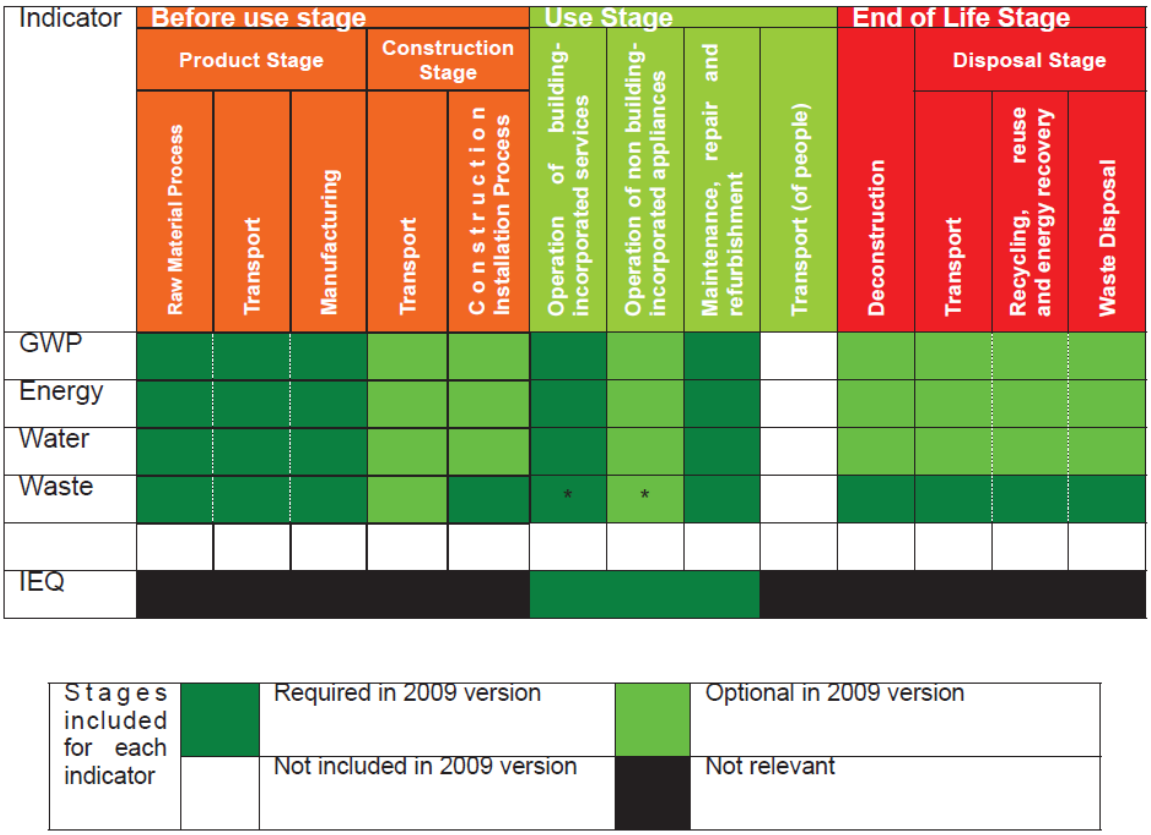

Figure 2: Lifecycle stage included in the framework for common metrics [23]

Also within the research project EeBGuide [2] different system boundaries for construction products as well as buildings were defined within a group of LCA experts all over Europe and verified in a public consultation process. EeBGuide also gives guidance on how to adapt these system boundaries regarding different levels of complexity (Screening, Simplified, Complete). Figure 3 shows a table presenting the framework for the production and construction regarding system boundaries, datasets and included materials.

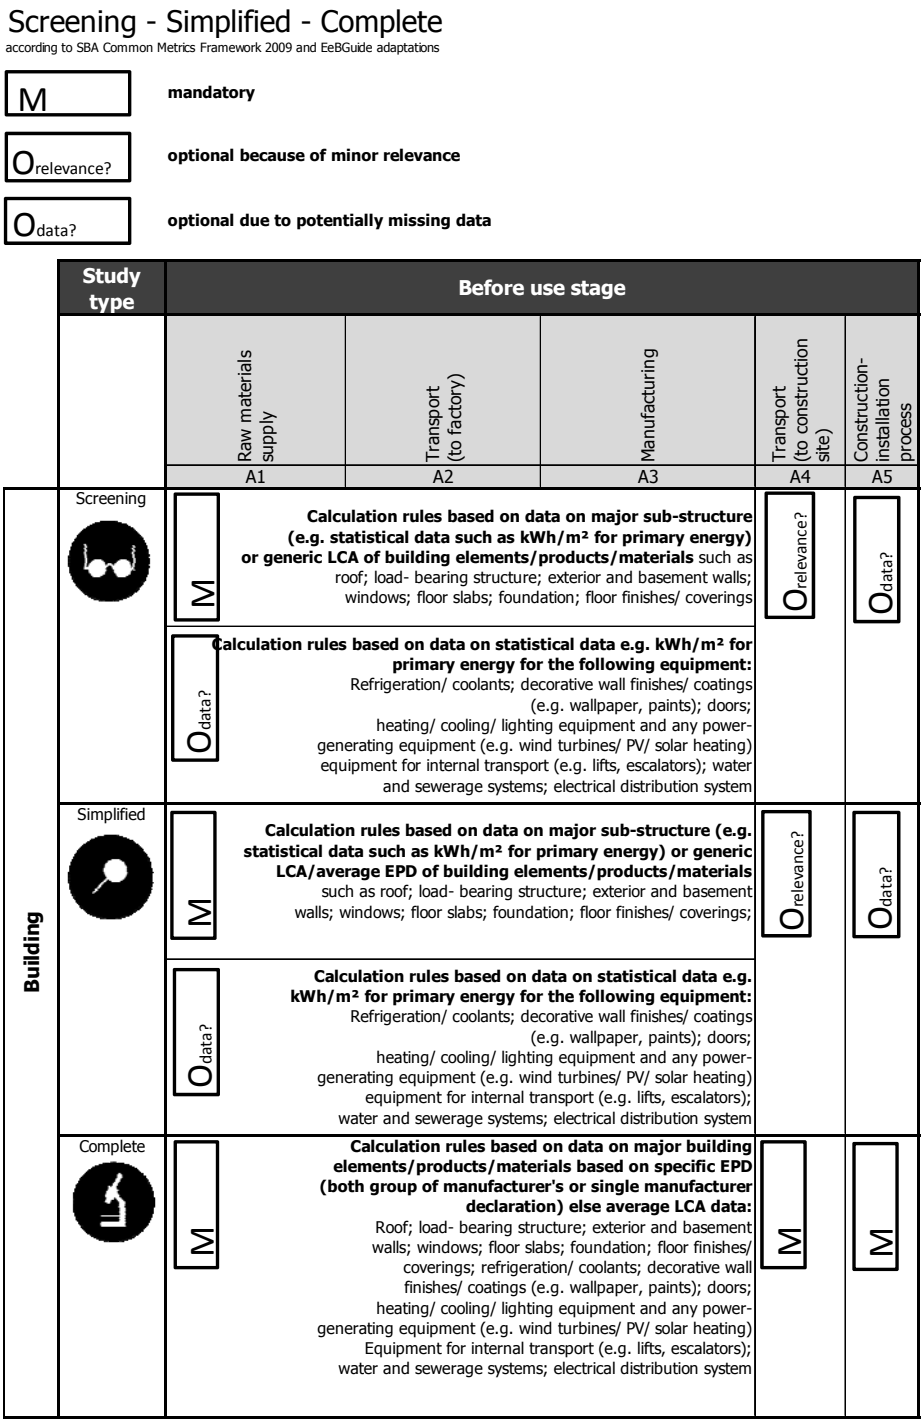

Figure 3: Caption of the definitions of the included materials and system boundaries [2]

2.4 Reference service life

LCA studies in the construction sector are often characterized by having very long reference service lives. Service lifespans of one or more decades are typically more difficult to oversee than service lifespans of consumer products, for example. Therefor the choice of reference service lifespans can have a major influence on the overall LCA results. Besides basic principles mentioned in ISO 15686 [24] and guidance paper F [25], data about average service lives and laboratory findings regarding repair, refurbishment and maintenance of construction products are so far very rare. Also there are still ongoing discussions if a theoretical reference service life should be applied or statistical collected real life data.

2.5 National and European reference buildings

Another important issue is that so far very little information about reference buildings in different countries is available. Not only for building labelling schemes, but also for European research projects reference buildings for different countries/ regions/ Europe would be highly valuable. It is hardly possible to interpret or even compare the results from different research projects. As an example, energy efficient measures and technologies are normally proven by means of a real building. But often this building is so special and extraordinary in terms of technical equipment, user behaviour, situation, etc. that it is not easily possible to transfer the results to another building. In order to compare and value the outcome of different research projects this would be necessary. Therefor, it would be highly beneficiary to have different reference buildings for different climatic regions and also for different regional existing construction types (e.g. heavy structured buildings, light structured buildings, etc.).

2.6 Surface calculation methodologies and national EPBD versions

Another challenge for building LCA on a European level is the difference in surface calculation methodologies and national EPBD versions. Both are crucial input data for building LCA, but differ by large numbers depending on the country. In the European research projects ASIEPI [3] and OPEN HOUSE [1] these differences were found to be tremendous (see Table 1).

Table 1: Results of LCA questionnaires of OPEN HOUSE [1]

Questionnaire topic	Answers by 76 case studies
Additional information about national practices	
Implementation of EU standards/directives/regulations Are such standards implemented / existing in your country?	Most European countries already have a national version of the EPBD and regulation on the calculation of the surfaces. During the project time the national EPBD version was just to be implemented in Turkey, but could not be considered anymore for this project. In the majority of cases national regulations on the service life time of construction products / components were not existing.
National standards and/or regulations Specifications regarding the national EPBD Specifications regarding the surface area calculation methodology	National EPBD versions: One outcome of the questions regarding some of the main assumptions of the different EPBD versions was that there is no common calculation methodology but a multitude of differences. Especially the system boundaries of the EPBD versions are not consistent (e.g. inclusion of electricity consumption of building equipment, lifts, etc.). Also the temperature levels and user behavior was not consistent. National regulation on the calculation of building surfaces: Similar results could be seen by the different national calculation methodologies. This methodologies are similar, but by a detailed look differences could be found regarding the boundaries (e.g. niches included in NFA) and the calculation methodology (e.g. surface calculation of the exterior walls from the outer edge/ mid of the wall, etc.).
National basic and best practices Are there any national basic and best practices (EPBD and LCA)?	In most of the countries national best practices/ regulations regarding the operational energy demand of buildings were available, but very few information is available regarding LCA related environmental impact categories. So far DGNB is providing information regarding best practice values for LCA. Additionally in UK values for GWP can be found.
Annex 1.1_7 Questionnaire Expansion of System Boundaries	In most of the European countries there is little information available regarding the lifecycle modules A4 (Transport to construction site), A5 (construction stage), B2 (Maintenance), C1 (Deconstruction) and C2 (Transport to EoL).

Especially the national EPBD versions vary quiet a lot regarding system boundaries (e.g. interior temperatures) and calculation methodology (fix reference value vs. reference

building). A major issue are the differences in included or excluded energy consumers. For example in some countries the electricity demand of the user equipment is included in the calculation of overall energy demand of a building, whereas some countries explicitly exclude it. As a result, EPBD versions can hardly be used for LCA studies on a European level, because the results can not be transparently compared. If the assessment of the overall energy demand of a building can not be stated by a thermal dynamic simulation, a consistent and common energy calculation approach, e.g. ASIEPI should be used. In order to overcome the huge differences in the surface calculation, a European measuring code should be implemented in a European standard. A starting point could be the already existing measuring code for buildings of the European commission [22].

4 Conclusion and outlook

All in all, LCA in construction already passed a long way and established the life cycle thinking idea in construction industry. But there is a huge need for standardization and harmonization on a European level in order to maximize the output of every LCA study and to be able to rely on these results. Furthermore some of the differences in national standards, like the measuring code for surfaces, can be a huge market barrier in and for Europe. A lot of activities are already undertaken towards a harmonization of standards and guidelines, but there are still different tendencies. Legislative Top Down approaches are competing with industry developed established standards. LCA approaches in different countries are competing with each other. All of this currently prevents LCA to gain its full potential.

Short Summary

In March 2011, the reworked Guideline for Sustainable Building was introduced by the German Federal Ministry of Transport, Building and Urban Development (BMVBS). Thus the Federal Building Authorities were obliged by edict to evaluate Office and Administration Buildings, using the Assessment System for Sustainable Building (BNB). Using the Assessment System is voluntary for other building authorities, such as Federal States, municipalities or the private sector.

Every assessment system requires the most diverse basic data and practical instruments to work efficiently. Parallel to the BNB-System several tools and instrument were developed, as WECOBIS (Web-based Ecological Building Material Information System) or Ökobau.dat (German building material database) and other Checklists and worksheets. They are supporting the user in the planning and building process as well as in evaluating the building with the BNB-System.

Keywords:Building; Guideline; Assessment; Tool; Instruments; WECOBIS; Ökobau.dat;

1. Introduction

According to the national Sustainability Strategy the German Federal Ministry of Transport, Building and Urban Development (BMVBS) published a Guideline for Sustainable Building in 2001 for the first time. It was made obligatory for the Federal Building Authorities and operate as a practical aid in the planning phase, the construction, the utilisation including the structural maintenance and the modernisation.

New scientific standards, technical developments and changing of requirements in regulations and norms made it necessary to review the guideline fundamentally. In March 2011, a reworked version of the Guideline for Sustainable Building was introduced by the German Federal Ministry of Transport, Building and Urban Development (BMVBS). Thus the Federal Building Authorities were obliged by edict to evaluate Office and Administration Buildings, using the Assessment System for Sustainable Building (BNB). Therefore the Guideline is orientated to the chronological progression of the planning phases according to the “Guidelines for the Realisation of Federal Building Measures - RBBau” or the performance phase of the “German Fee Scales for Architects and Engineers - HOAI”. Using the Assessment System is voluntary for other building authorities, such as Federal States, municipalities or the private sector.

The Guideline for Sustainable Building was revised once more and completed in 2012/13 [1] with the following structure:

- General Part
- Part A Basic Principles of Sustainable Building
- Part B New Buildings
- Part C Recommendations for Sustainable Operation and Maintenance
- Part D Building Stock / Complete Modernisation

The Guideline directly refers to the Assessment System for Sustainable Building (BNB) [2], based on several research project, financed by the BMVBS research initiative “Future Building”. The quality of sustainability, as requested in the Guideline with silver level, is to verify by using the BNB-System. This system based on a holistic assessment procedure which considers the life cycle of a building and a comprehensive quantification.

The Assessment System based on protective goods and goals of sustainability, which were extracted for the construction sector. They are allocated to the well-known dimensions of sustainability – Ecological Quality, Economical Quality and Socio-cultural/functional Quality. Those qualities are complemented with horizontal qualities, as Technical Quality and Process Quality. The Location Profile describes the local characteristics. They are separately evaluated from the objective qualities and shown as additional information.

These five main criteria groups are divided in criteria files and can be measured or evaluated according to quantifiable amounts.

2. Practical Aids and Tools

Every assessment system requires the most diverse basic data and practical instruments to work efficiently. Parallel to the BNB-System several tools and instrument were developed, involving the working groups of the Round Table of Sustainable Building. At present three important instruments are available:

- WECOBIS (Web-based Ecological Building Material Information System)
- Ökobau.dat (German building material database)
- Use life of Construction Parts
- Checklists and worksheets.

WECOBIS and Ökobau.dat will be described in the following chapters.

The German assessment methodology uses a holistic assessment procedure which considers the life cycle of a building and a comprehensive quantification. In this context the focus is not only on the construction of buildings but also on the operation and the maintenance.

The BMVBS therefore provides free available quantitative data for life cycle analysis, which ensure that sustainability criteria ca be included in planning and construction processes and comprehensively documented. The calculation is made for a period of 50 years. Therefore not only the demand of resources and the environmental impact but also the certain useful life of construction products is important and necessary. The Table of Use Life gives information about the average useful life of building material and constructions.

Furthermore several schemata and tableau are supporting the user in the planning and building process as well as in evaluating the building with the BNB-System, par example:

- Schedule for objective agreement
- Requirements for sustainability in architectural competitions
- Functional specification for energetic requirements
- Pre-Check report

- Evaluation reports

These tools are published on the Internet Portal Sustainable Building.

In the moment a research project is in progress, in which an EDP-aided assessment and documentary report (eBNB) is to work out. This report has to take into account the requirements of the criteria of the BNB-System, but also important framework conditions of the public building sector, as the “Guideline for the Realisation of Federal Building Measures (RBBau)”.

3. WECOBIS

WECOBIS as a “Web-based ecological building material information system” supports the planning team with qualitative information to sanitary and ecological aspects of building material. A substantiated choice and assessment of building products during the planning phase is one of the main challenges for sustainable planning, construction and management of buildings. WECOBIS serves as a practical aid, allows a qualitative assessment of main construction materials and products and should aid for tendering. Therefore WECOBIS offers basic information and important links to continuative sources and web portals.

The objectives of WECOBIS are:

- Neutral information to health, ecological, technical and functional aspects of construction products
- Raw material, production and manufacturing process, use and re-use of the products
- Online links with further sources of information and data.

The WECOBIS can be used by architects, planners, auditors et.al.:

- Simple selection of building products or materials by a simple navigation
- Acquire a basic knowledge to general and special information concerning technical and functional aspect, health and ecology
- Compare different products to each other by viewing at the sam time and choose the most suitable
- Manage your projects in MyWECOBIS by arranging the documents accordingly to the phases of the planning or the phases of the lifecycle.

The web page of WECOBIS, which has its origins already in 2000, is operated by the Federal Ministry of Transport, Building and Urban Development (BMVBS) in cooperation with the Bavarian Chamber of Architects (BayAK). The administrative office has been set up in the BBSR, Division II 6 Construction and Environment. The online presentation will allow continuous updating.

4. Ökobau.dat

The Ökobau.dat contained generic quantitative information on the ecological quality of building material. The Ökobau.dat is used in the Life cycle assessment (LCA) and other criteria.

The Ökobau.dat includes data for the assessment of environmental impact of building products:

- Global Warming Potential
- Ozone Depletion Potential
- Photochemical Ozone Creation Potential
- Acidification Potential
- Eutrophication Potential

It based on the Environmental Product Declarations (EPD) with proved manufacturer based information (environmental indicators). They are available for various building products and are undergoing an independent review. In Germany the examination is conducted by the Institute for Building and Environment (IBU). The systematic and standard data basis – currently available for national buildings – enables an ecological evaluation of a building in a building block system of declarations of individual constructions. Use of resources and emissions in the environment are included into the entire manufacturing process.

5. Conclusions

The Guideline for Sustainable Building will be implemented into the practical work of the Federal Building Authorities. The Assessment System BNB enables a transparent, objective and comprehendible evaluation or qualification of the sustainability of buildings. The tools would be able to support the building authorities to implement the assessment into practice. The publication is carried out with the Information Portal Sustainable Building “www.nachhaltigesbauen.de”.

Short Summary

In order to develop a methodology for building ecological and economic assessment and optimization from the early design stage, a framework that facilitates the integration of Life Cycle Assessment (LCA) and Life Cycle Costing (LCC) with Building Information Modelling (BIM) is proposed. Buildings are described in the Revit model as assemblies with information of construction, material and cost, whereas in the LCA and LCC model, they are described as elements of different life spans, which are linked to the life cycle inventory (LCI) data of building materials. Energy load is calculated with Energyplus and related to inventory data of Chinese energy products. BIM provides a parametric database including cost, material, and elements. This framework is applied to a retrofit project in Tianjin. The geometric model combined with dynamic information of mass and energy flows, environmental impacts and costs helps to monitor and manage the construction, renovation, operation, refurbishment and demolition of buildings.

Keywords: BIM, LCA, LCC; building; assessment; China

1. Introduction

The development of building stock accounts for considerable part of energy consumption and environmental impact in the Chinese cities. The design of more performing new buildings, the renovation of existing buildings and the management of the end-of-life phases need new assessment tools. The life cycle impacts and costs must be estimated in a consistent way to avoid partial decisions. A common framework and calculation tools concerning new buildings and refurbishment will be the basis for design and management decisions as well as for advanced sustainability certificates.

In line with international standard (ISO TS 21929-1), life cycle oriented environmental and economic criteria have been introduced in several major building sustainability assessment systems in the recent years, such as the European LEnSE and the German BNB/DGNB system. Integrated Life cycle analysis (LCA) and life cycle costing (LCC) methods and tools are the basis for calculation and developing the benchmarks. Conventional LCA need detailed description of the building according to 2D CAD drawings and quantity survey data, which is time consuming. Moreover, the calculation and interpretation process needs specialized knowledge, which makes it difficult for designers to optimize the project in the early design stage. Building Information modeling (BIM) provides a platform integrating 3D geometrical model with various text and numerical data. The input data needed for LCA can be derived from BIM. It can largely reduce the effort for building description and enable the assessment results be feedback to the designing process.

In China, the inventory database for major building material and energy products is being developed in the recent years, although much has to be done in comparison to the European databases. Chen Y. & Zhu YY (2010) studied the LCA method for residential buildings. Zhang Z.H. (2010) presented the building life cycle carbon emission calculation method. However, there is so far no integrated LCA and LCC tools. Moreover, the calculation methods are mainly based on

quantity survey data, which cannot indicate some important information of building assemblies, such as construction, position, life span and physical performance. Hence the result is difficult for architects and decision makers to interpret and to feedback in the designing process. It is important to develop a method, which integrates the geometrical information, life cycle impacts and costs in the same framework, and allows the dynamic feedback between assessment results and the design scheme.
This contribution aims to develop an integrated BIM-LCA framework with supporting tools that can be easily applied to the designing and evaluating process of the Chinese buildings. The methodology could enhance the efficiency and accuracy of the assessment. It also helps evaluate and optimize the project from the early design stage.

2. Methodology

The integrated life cycle environmental and economical analysis features the 2nd generation of building sustainability assessment system, whereas the BIM-LCA methods will be the basis of the 3rd generation in the future (Koenig H., et al, 2009). The methodology was discussed in the EU FP7 project 'SuPerBuildings' report (2012).
The assembly database is the bridge that links BIM to LCA. The assembly category and material schedules derived from BIM can be imported in the integrated LCA model and be linked to LCI data and costs, so that the inventory analysis of building LCA can be largely simplified. Moreover, the information of life cycle impacts and costs of the assemblies can be reimported to the BIM database, which helps the designers to choose building elements with low environmental impacts in the early design stage.
The BIM model can also carry information for operational energy calculation, such as the U values of building elements, window to wall ratio and space information. The results from energy simulation tools are linked to the integrated LCA and LCC model, too.
Figure 1 demonstrates the structure and tools of a simplified BIM-LCA framework.

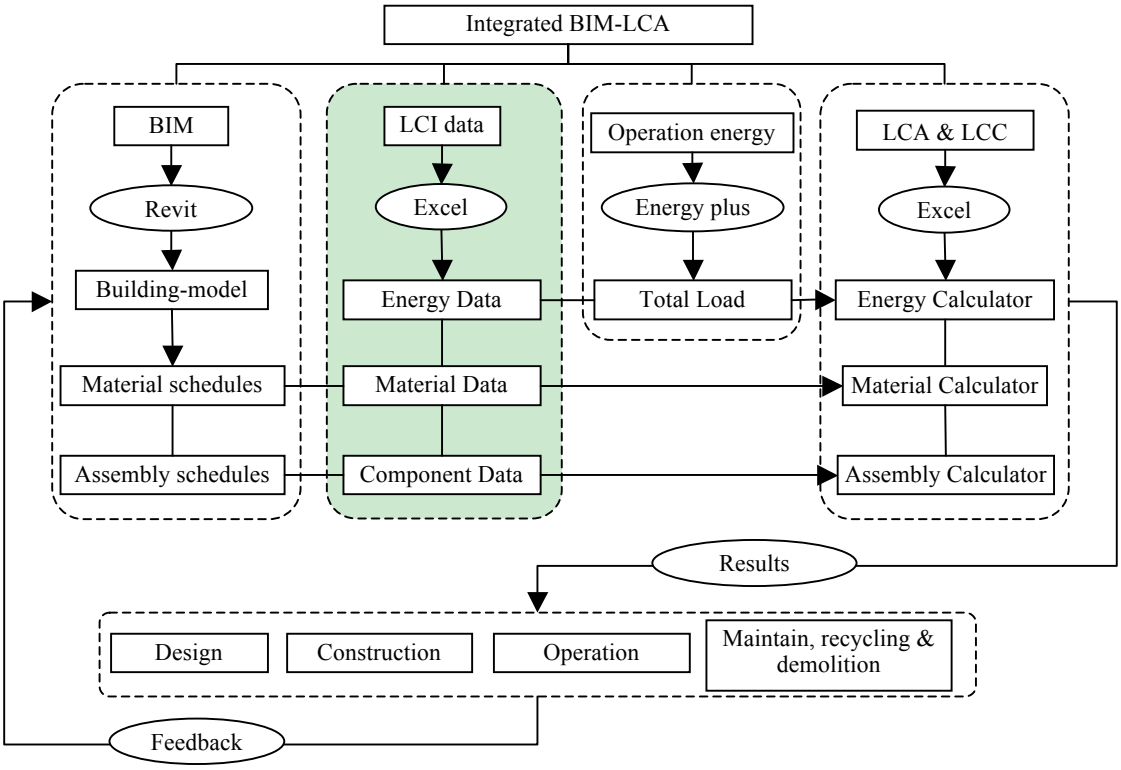

Fig. 1: Framework for integrated BIM-LCA methodology

2.1 Databases and indicators

Necessary databases for integrated LCA methods includes LCI and costs of building material and

assemblies, as well as national category of building assemblies and their life spans. Gong ZQ (2004) presented the LCI data for 6 major building materials in China (Table 1). The Chinese Core Life Cycle Database (CLCD) contains more extensive categories of building material, processes and energy products. Carbon emission for the Chinese electricity grid is reported each year (Table 2). Due to the incompleteness of the Chinese data, Ecoinvent database is referred for specific materials and End-of-life processes. Indicators for energy resource consumption and environmental impacts are selected as shown in Table 3.
China has published standard drawings of building assemblies for each climate zone as common reference of the building industry. The quantity survey of buildings is regulated by the National Cost Engineer qualification system. Local regulation of construction project cost provides the database for costs of all the building materials and assemblies.

Table 1: LCI of 6 major building materials in China

Building Materials	Primary energy Non renewable (MJ/t)	GWP ($kgCO_2eq/a$)	AP ($kgSO_2eq/a$)	NP ($kgNO^-eq/a$)	Solid waste (kg)	Dust (kg)
PVC tube	0.03	1.28	1.29	0.43	12.5	4.84
Glass	0.03	0.44	0.4	0.18	0.06	0.66
Common steel	0.6	2.05	1.86	0.72	268	6.92
P.I.52.5	0.038	0.18	0.039	0.04		0.125
P.O.42.5	0.033	0.159	0.035	0.03		0.112

Table 2: Electricity Carbon emission factor in China

2012 factor	EFgrid, OM, y (tCO_2/MWh)	EFgrid, BM, y (tCO_2/MWh)
North China District grid	1.0021	0.594

Table 2: Impact indicators considered in the paper

Impact indicators	Category	Unit
Primary energy /renewable	cumulative energy demand	MJ-Eq
Primary energy / non renewable	cumulative energy demand	MJ-Eq
Global warming potential (GWP100a)	IPCC 2001	kg CO2-Eq
Acidification (AP)	EDIP	kg SO2-Eq
Nutrient enrichment (NP)	EDIP	kg NO3-
Land filling (Solid waste)	EDIP	kg waste
Stratospheric ozone depletion (OPD100a)	EDIP	kg CFC-11-Eq
Photochemical ozone formation (POPC)	EDIP	kg ethylene-Eq

2.2 Integrated LCA and LCC tools

There had been several building LCA tools developed in the industrialized countries. The LEGEP software for German buildings is an effective tool of integrated LCA and LCC, which combines the calculation of costs, energy simulation and environmental impacts in the same physical framework. The Athena eco-calculator has a user-friendly interface and contains a practical building assembly database for North America, which makes it easy to describe the buildings and to calculate the impacts. However, their methods and databases are highly relevant to specific context, which makes them difficult to be adapted to Chinese buildings. Therefore, we try to build an integrated LCA and LCC model using Chinese data with Excel program, because it conveniently matches to the BIM take-off schedule. In the model, buildings are described as assemblies with the information

of construction details and material composition.

2.3 BIM tool and operation energy software

The application of BIM is developing rapidly in China. Many architectural design institutes have started to use BIM instead of 2D CAD drawings. However, the common standard for BIM database of building elements is not available so far. It will soon be published to regulate the current BIM market.
Autodesk Revit is the most popular BIM tool in the Chinese building industry. As the first step of the BIM-LCA model, major assemblies are chosen from the standard drawings and are described as families of different categories (e.g. walls, windows, doors, floors, roofs) in Revit, which contain the information of material, construction, costs and U values. On this basis, buildings can be described and information for energy calculation and the input data for LCA can be deduced.
The Revit model can be exported in energy simulation tools such as Ecotect, Vasari and Green Building Studio. However, we have chosen Design-builder based on Energyplus software to estimate operational energy demand in order to get more reliable results.

3. Case study in Tianjin, China

The BIM-LCA framework can support the assessment of new constructions as well as retrofit of existing buildings. Case study of a high-rise residential building built in 2010 was presented in Yang W. & Wang SS (2013).
For the renovation project, a teaching and office building in Tianjin University is analyzed. The old building was constructed in 1980. The building is 4 stories with a rectangular plan (72*19m). The gross floor area is 5380 m^2. The renovation aims to adapt to the need of the new faculty, as well as to improve the energy efficiency and the comfort level of the building (Tab.4).

Table 4: The renovation strategies of the building

Renovation strategy	Items
Conserved structure	Solid clay brick with reinforced concrete structure
Envelope & Space Retrofitting	Interior partition and finishing; insulation panels (XPS, stone wool) applied to the external walls supported by additional steel keels; Roof insulation and waterproof; Windows and doors
Designed lifespan	50 years
Solar heated area	4160 m^2
District heated area	1220 m^2
New heating system	Solar heating system with supplementary boiler
Cooling system	Central air conditioning

Information of the building and its elements is defined in the Revit model (Fig. 2), which can be derived for energy simulation and integrated LCA calculation.

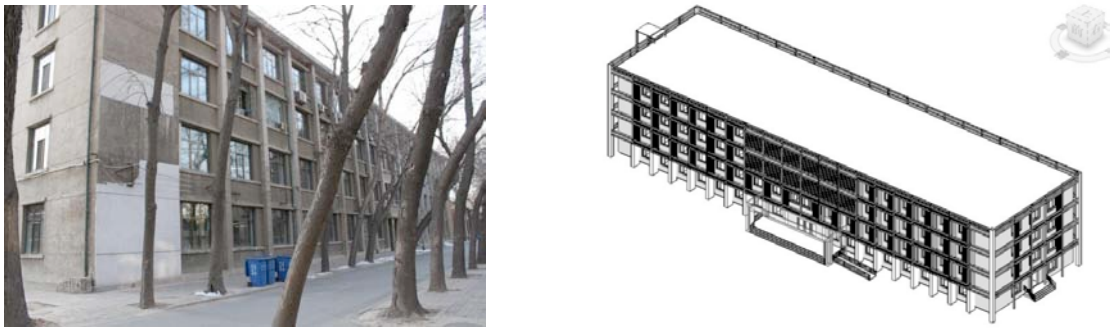

Figure 2: The image of the old building and the BIM model of the renovated building

3.1 Building information modelling with Revit

The Revit model of the retrofitting project consists of three parts: the conserved original structure made of clay brick and concrete, the demolished old elements and newly added elements. The assembly and material schedules are derived from the model. Steel frames are constructed surrounding the façade of the building to support the insulation panels, claddings and blinds. With the 'schedule/quantities' and 'materials take-off' tool in Revit, all the building assemblies are exported with the construction information and physical attributes such as dimensions, U values, and density. Table 5 gives an example of the wall assembly schedule, which can be linked to integrated LCA model.

Table 5: Examples of wall schedule and material take-off in Revit

Element category	Volume (m^3)	Area (m^2)	Width (mm)	Envelope material	Thickness(mm)
Interior wall clay brick	433.83	827.91	524	Emulsion painting	2
				cement lime mortar	20
				clay brick	480
				cement lime mortar	20
				emulsion painting	2
Interior wall, aerated concrete block	20.77	87.27	254	Quarry tile	8
				cement mortar	19
				aerated concrete block	200
				cement mortar	19
				quarry tile	8
Exterior wall, clay brick	675.01	1562.51	432	XPS panels	50
				clay brick	360
				cement lime mortar	20
				emulsion painting	2
Exterior finishing	7.04	251.26	28	Cement mortar	20
				Stone cladding	8

3.2 Operational energy simulation

The energy consumption before and after the energy efficient renovation is calculated with Design builder. The insulation and the heating system are major changes in the retrofit. The solar heating system supplies a use area of 4160 m^2. It consists of the solar collectors (Fig.3), energy storage device, heat pumps, supplementary boiler and radiators.

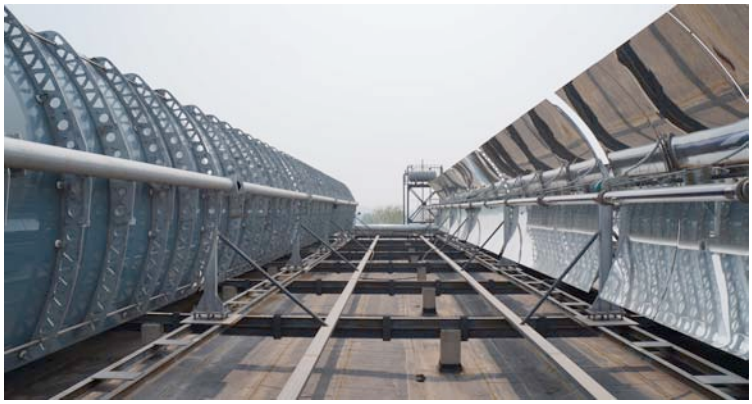

Fig. 3: The solar collectors on the roof

The solar thermal capacity is calculated with two different methods. One is with the energy simulation tool (Design builder). The other is to calculate directly with the heating time, solar radiation data (Tab. 6) and area of the solar collectors (216m^2). The simulation result of the solar

energy capacity in one winter season is 64681.51KWh, while the result from the latter method is 77203.8 KWh. The 10% deviation may be partly due to different estimation of heating time.

Table 6: Weather references in heating seasons in Tianjin

Heating Period	Nov. 15 to Mar. 15
Average temperature (℃)	0.5
Radiation intensity (W/m^2)	454.5
Daily average time (h)	6.5

Table 7 shows that heating energy consumption is reduced by 70% after retrofit. However, if the district heating system were not replaced by solar energy, the energy saving from better insulation would be 27%. The related primary energy, environmental impacts and costs are discussed in 3.3.

Table 7: Comparison of energy consumption before and after renovation (results from Designbuilder; Unit: KWh per year)

Heating system	After renovation (KWh)	Assumption for energy demand with better insulation but without solar heating system (KWh)	Before renovation (KWh)
Auxiliary devices for solar heating (electricity)	84223.5		
Solar (renewable)	64681.5		
District heating (coal)	55834.2	314982.1	432330.3

3.3 LCA and LCC

Through an integrated LCA, the long-term environmental and economical quality of the renovated building is evaluated and compared with its initial status. The system limits and data sources are listed in Table 8. Figure 5 to Figure 8 demonstrate the results of LCA and LCC. The results demonstrate that the energy efficient renovation, especially the solar heating system has a large contribution to improve the environmental performance of the building.

Table 8: General Conditions for integrated LCA of the case building

	LCC	LCA
Observation time span		50
Life cycle phases	Operational energy; Renovation	Dismantling of old components Renovation; Operational energy; Refurbishment; End of life
Discount rate (%)	8	
Annual increase of energy costs (%)	5	
Energy costs	Electricity =0.49 yuan/kWh, district heating=36yuan/m^2	
Service life of building components	Chinese data, Germany Sustainable Building Guideline (BMVBW, 2001a) and VDI (2000)	
Inventories	Construction and decoration project budget in Tianjin, DBD29-101-2008	Chinese LCI data, Ecoinvent
Function unit	1m^2 gross floor area	1m^2 gross floor area

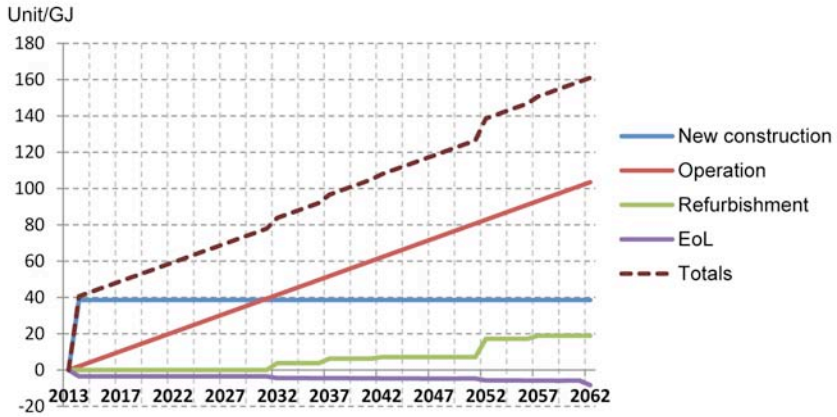

Fig. 5: The accumulative primary energy (non-renewable) consumption in each life cycle stages after renovation

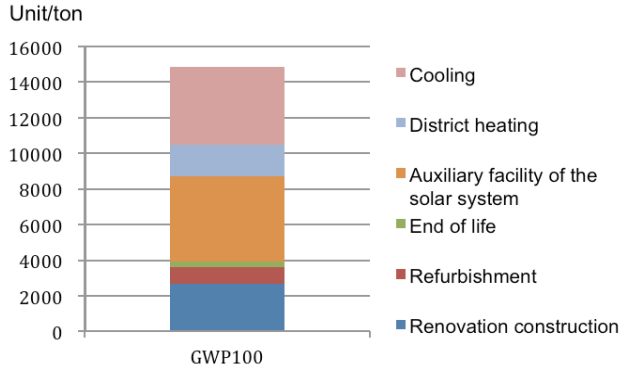

Fig. 6: GWP from each life cycle stages of the renovated building

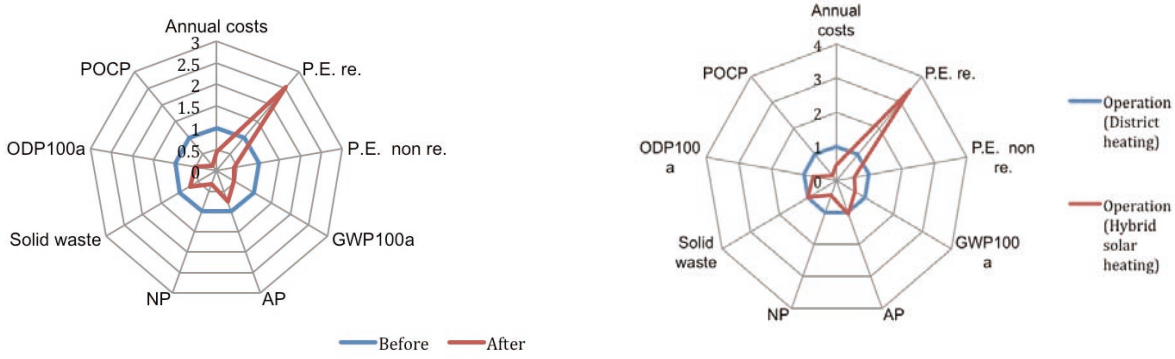

Fig. 7 Comparison of the life cycle environmental impacts between before and after the renovation, and with or without solar heating system

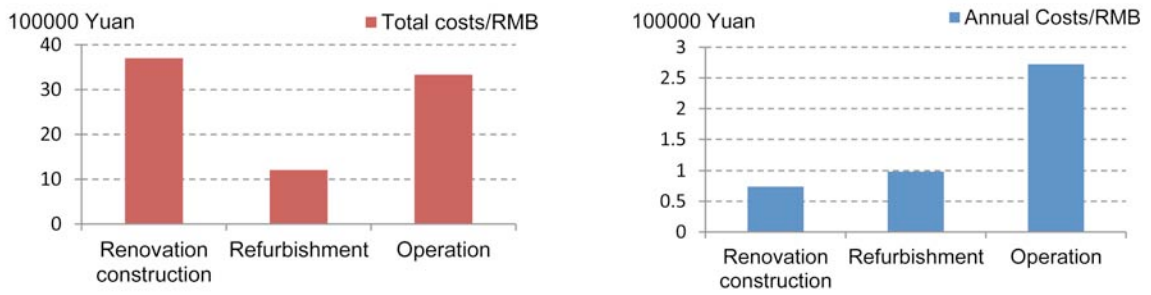

Fig. 8: Costs in each life cycle stages of the renovated building

4. Discussion and Conclusion

This paper introduced an integrated BIM-LCA methodology, which combines several conventional approaches in building design and assessment, including geometrical model, quantity survey, operational energy simulation, LCA and LCC. Through test of the methods and tools with a case study, the following issues can be addressed:
(1) The existing building LCA methods and tools in China are mostly based on quantity survey data and CAD drawings, which is either incomplete or time consuming. There is a need for a BIM-LCA framework to enable an interactive optimization process.
(2) The parametric information databases of building assemblies, LCI data for building materials and their costs are the foundation of Integrated BIM-LCA application in China.
(3) The first results from a case study of a renovation project shows that the BIM-LCA methodology based on Autodesk Revit, energy simulation tools and excel program for LCA and LCC can support the optimization and evaluation of the project.
(4) There exist limits in the interconnection of the Revit model and the energy simulation tool (Design builder for Energyplus). Moreover, the assembly description needs to be improved to include more detailed data of the material composition and construction.
(5) The BIM-LCA framework can be improved by developing the user-friendly interface, completing the building material and components databases, and setting benchmarks for different types of buildings according to national and local standards.

5. Acknowledgement

This contribution is supported by project 51108303 and project 51178292 funded by NSFC, and by the Program of Introducing Talents of Discipline to Universities (B13011). Prof. Niklaus Kohler, Prof. Thomas Luetzkendorf and Prof. Yan Wei gave advices to the contribution. Prof. Liu Conghong and Architectural Design Institute of Tianjin Univ. provided the basic information of the case study project.

Short Summary

The task of assessing the contribution of individual buildings to sustainable development becomes more and more complex. Currently, there is a transition in the sustainability assessment from a previously predominantly qualitative to a predominantly quantitative evaluation. In addition, in the assessment the entire life cycle of a building is included, increasing the need to exchange and adapt data related not only to the technical and functional requirements of the building but also to the sustainability oriented requirements throughout the life cycle. As a result sustainability consultants among others have been added to the traditional building stakeholder groups, like designers and owners. Therefore, as communication, organization and management of information flow becomes of much greater importance, the integration of sustainable building assessment and benchmarking systems with the different stages of BIM is suggested. The BIM (Building Information Model) creates a single information node that simplifies updates and synchronisation mechanisms among the various actors involved in the same construction project. We will present in the paper how the current version of the IFC (the open language supporting the exchange with the BIM) suits the needs to compute and store the various indicators selected or developed in the frame of the SuperBuildings projects.

Keywords: Sustainable Assessment, Sustainable indicators, BIM, IFC, IFC4, Property Sets

1. Introduction to Sustainable Building Assessment

The assessment of the contribution of individual buildings to sustainable development is a complex task. This has to do both with the specifics of the object of assessment and the complexity of the assessment task.
The object of assessment is the building including its plot. In the assessment the entire life cycle of a building is included from the manufacture of building products to the construction of the building on its plot as well as from the stage of operation, management and maintenance to deconstruction and disposal.

To ensure the comparability of the assessment results, the building must be described through its functional equivalent. This task is usually carried out with reference to the functional and technical requirements of the owner of the building, which can be supplemented in accordance with EN 15643-1 [1] with additional demands on the economic, environmental and social performance of the building.
According to the ISO 21929-1:2011 [2] and EN 15643-1 the described requirements for a sustainability assessment of buildings are from an environmental, economic and social viewpoint.

Thus, the impact of manufacturing, construction, use, removal and disposal of the building on the environment, economy (including managerial interests of those involved) and society (including the interests of the community, the participants at the manufacturing and construction, the neighbourhood and the immediate users) is evaluated. Additionally, it needs to be checked and displayed whether and how the building meets all the technical and most importantly the functional requirements in an effective way.
Currently, in the sustainability assessment a shift is taking place. There is a transition from a previously predominantly qualitative (e.g., presence of green roofs) to a predominantly quantitative evaluation (e.g., calculation and evaluation of the GWP). For example, the Life Cycle Analysis is applied, which combines the Life Cycle Assessment (LCA) with the Life Cycle Costing (LCC), while this is often supplemented by a user satisfaction analysis, or a complaint management.
The results of a sustainability assessment can be used to improve the building performance only when they are successfully integrated into the process of planning, construction and management so that they are available at the time of a decision. This requires that the sustainability assessment can be adapted to the achieved state during the planning process and the lifecycle of the building. This state is a consequence of present at that time information about the building, its components and its former or foreseeable future life span as well as of the type of decisions reached at that time.
The impact of a building on the environment, economy and society during its life cycle must not only be described and evaluated, but also manipulated in a targeted way. This is done not only during the formulation of the brief, but as well as during the design, construction, management, deconstruction and disposal. The information on a building over its life cycle must not only be managed but also updated, supplemented and expanded.

2. The need for input data

It is clear that a prerequisite for the sustainability assessment and management in the life cycle of buildings is the identification, update and supplementation of information and data as well as their interpretation and assessment. Thus, the management of data both on the life cycle of buildings (perspective of object of assessment) and in the life cycle of buildings (perspective of a process of the life cycle of the building) becomes essential. For managing the information appropriately issues arise in relation to the identification and updating of data, including the representation of data source, data quality and data history. This includes information on:

- the location, including the forecast of future developments (e.g., climate and climate change, existing infrastructure and infrastructure development)
- the site (e.g. the ground, exposition to sun light)
- the user requirements (including requirements for the technical and functional quality, possibly supplemented by requirements for the economic, environmental and/or social performance of the building)
- the functional equivalent on the basis of user requirements including scenarios of for the nature, scale and intensity of use
- the geometry of the building and its components
- the physical composition of the building at the time of its construction – among others as a prerequisite for the application of the LCA (from cradle to handover) - including verifying the completeness of its description (possibly including the costs incurred during the construction of divergence and breakage losses of construction products in consequence of the construction activities)
- the cost of manufacture and construction of the building - possibly expressed as the construction price at the time of delivery, if calculated using the element method
- the actual or the forecast of the consumption of services (energy, water) and the occurrence of wastewater and waste, if necessary separately for the user related and the building related activities
- the actual or the forecast of the material consumption due to cleaning, repair and replacement investments on the basis of scenarios, including where necessary the possibility of checking of the coverage completeness of the data collection

The demand of data with a direct as well as indirect relationship with sustainability assessment needs to be specified. This is the subset of data that arise during the life cycle of buildings and has to be managed.
The determination of data for a sustainability assessment can be based on a documentation of requirements, a prediction (e.g., planning, calculation or evaluation), the representation of current conditions or facts and the acquisition of consumption data or survey results. On the one hand, the assessment has to be guided by the available data in relation to the various stages of planning and thereby the first generic or average data to be replaced gradually by manufacturer- and product-specific information. On the other hand, in the course of the construction process and the life cycle planned data have to be replaced by actual data. Possibly the actual values have also to be compared with the planned ones. In this case, the respective perspectives (geometrical, physical, functional, technical, environmental, economic, and social) are considered and managed. In particular, the ecological assessment requires further calculations. Both data from the area of physical composition of the building, including the scenarios for maintenance and replacement cycles as well as in the field of supply and disposal must be linked to data that allow the creation of an LCA. Usually, these are available on the basis of environmental product declarations (EPD's).

3. The need for harmonised indicators

In the frame of the SuperBuildings project, a number of European and international harmonisation and standardisation activities, i.e. CEN TC 350, ISO TC59 SC17, Sustainable Building Alliance (SBA), UNEP SBCI, LEnSE and Perfection, has been reviewed for the current availability and state of harmonisation of sustainability indicators and their assessment methods for buildings. Based on these analysis [3] and review [4], it can be conclude that both issues and indicators that are not (commonly) covered by the different tools and issues and indicators that are most occurring within the tools have been identified.
For all issues that are covered by more than one tool, the variation in assessment criteria and methods has been looked into in order to draw conclusions on their needs for further development and/or harmonisation.
Furthermore, both missing indicators and indicators that need (further) development and core indicators have been identified and compared to the indicators that are considered by the different tools.

4. Selected indicators

More than 20 key indicators have been either selected, or improved or developed, and documented through a structured format [5]. They cover the 3 pillars of sustainable development, but not all the related issues. Some are of particular interest and include added-value because they have been newly developed, as land use, cultural heritage, aesthetic quality, long term stability of economic value.
These indicators are listed in three tables below. Each table is presenting the indicators sorted by “subject of concerns” under the three “dimensions” of sustainability which are the environmental; societal and economic aspects.
Each of the selected indicators is documented on a textual basis according to the same structured methodology.
The next step is now to identify if and how the integration of these sustainable indicators with the BIM is feasible.

5. Relevance of a BIM based approach

5.1 Definition of BIM

There are several definitions for the notion of BIM. The Acronym BIM is sometimes turned into “Building Information Model” or “Building Information Modelling”, one representing more the concept and the other the approach.

On Wikipedia, the following definition is given to BIM:
"*Building information modelling covers geometry, spatial relationships, light analysis, geographic information, quantities and properties of building components (for example manufacturers' details). BIM can be used to demonstrate the entire building life cycle, including the processes of construction and facility operation. Quantities and shared properties of materials can be extracted easily. Scopes of work can be isolated and defined. Systems, assemblies and sequences can be shown in a relative scale with the entire facility or group of facilities. Dynamic information of the building, such as sensor measurements and control signals from the building systems, can also be incorporated within BIM to support analysis of building operation and maintenance.*"
This definition presents several facets of the notion of BIM, among others, the most important ones are:

- It covers the whole life cycle of a building project;
- It creates a single information node that simplifies updates and synchronisation mechanism among actors of the same construction project.
- It is a structured collection of building and construction objects including physical components, spaces, processes, actors involved, and relationships between these objects. All of these objects may be enriched by shared or specific properties. As a con-sequence, quantities or values stored in these proper-ties can be extracted and reused as the source of in-formation to perform calculations, analysis or simulations.
- It is a mean to enable heterogeneous actors to work together in an efficient way and for better results;

SD pillar	Subject of concern	Issue	Indicator
Environmental	Resources	Depletion of non-renewable energy resources	Consumption of non-renewable primary energy
		Non-renewable and scarce material resources	-
		Sustainable management of renewable resources	-
		Rational use of water	Embodied water use Operational water use Wastewater production
		Land use / Change of land use	Soil sealing Change of land use
	Biodiversity	Loss of biodiversity Respect of the local original species (planting) Preservation / improvement / restoration of local biodiversity	-
	Ecosystems	Protection of atmosphere (GHG)	Global warming potential
		Protection of atmosphere (other pollutants)	-
		Protection of water and soil quality (pollution and waste)	-
			Construction and demolition waste generation - Non-hazardous waste to disposal - Hazardous waste to disposal - Nuclear waste to disposal Solid waste separation
	Climatic systems	Climatic systems (risk of extreme climatic events) Adaptation to climate change	-

SD pillar	Subject of concern	Issue	Indicator
Societal	Health	Indoor air quality	Concentration of various pollutants
	Comfort	Thermal comfort	PMV (Predicted Mean Vote) PPD (Predicted Percentage Dissatisfied) Operative temperature Air temperature Relative Humidity Air velocity
		Visual comfort	Illuminance Daylight factor
		Acoustic comfort	-
	Safety / security		-
	Human interactions / relationships		-
	Culture and architecture	Architectural quality	Aesthetic quality
		Cultural heritage	Monument or monumental value / Historical value

SD pillar	Subject of concern	Issue	Indicator
Economic	Economic value	Economic value of 'goods' on the long term versus obsolescence	Life cycle costs - Capital cost - Costs in the operational phase *(Whole life costs)* *(External costs)*
	Economic risks	Prosperity versus risks	Long term stability of value *(Cost/value ratio at point of hand-over)*

Fig. 1: SuperBuildings key indicators

5.2 Advantages from a Sustainable Building Assessment point of view

From the user side, relying on a BIM centred approach presents several benefits from a sustainable assessment point of view. Among others, the following ones can be mentioned:

- BIM contains already most of the data listed above to perform a Sustainability assessment (building location, geometry, detailed composition) of a building that can be analysed from different environmental analysis point of views with different analysis tools (even if the data only was general geometries, quantities and qualities).

- BIM can include also data about the environmental properties of the building parts and building products (there are links with EPD's).
- BIM is the place where the results of the analyses could be stored back to ease comparison between different options or approaches.

The concept of BIM is easy to understand but hard to turn into a tangible reality in a current working environment as there is a strong need for an interoperable exchange format, rich enough to allow ALL users / stakeholders working simultaneously around the same digital model to enrich and retrieve data from the same single model.
BuildingSMART International (neutral, international and non for profit organisation coordinating technical and standardisation work around the BIM) is supporting the notion of OPEN BIM and thus promoting the use of a unique exchange language to dialogue with the BIM. This language is the IFC.

5.3 IFC4, the open language for an Open BIM

The building sector's Industry Foundation Classes IFC represent an open specification for Building Information Modeling BIM data that is exchanged and shared among the various participants in a building construction or facility management project. IFC's are the international openBIM standard.
The IFCs were originally developed to describe building components in an objectified way [6]. Based on STEP principles, the IFC data model is an object oriented model that separates the object identification and the associated properties, including potential different geometric representations and materials association. Since the beginning a lot of improvement has been made but the integration of sustainable/environmental notions is quite new as it has been done in the last release.
Now the IFC counts approximately 800 entities.

5.3.1 The "Property Sets" mechanisms

In the IFC4 documentation, a Property set is presented as "any specialization of object can be related to multiple property set occurrences. A property set contains multiple property occurrences. The data type of property occurrence are single value, enumerated value, bounded value, table value, reference value, list value, and combination of property occurrences. "
In the construction domain, for instance, IFC-based implementation of product libraries has a good prospect for meeting the industry requirements. Indeed, while IFC classes represent generic categories of elements (e.g. wall, beam, space) with very few attributes associated with a class to transfer information relevant to a manufacturer, IFCs incorporate a mechanism called Property Sets (PSets) which allow information publishers to dynamically allocate new properties to an object they wish to describe. Since there are numerous alphanumeric attribute definitions depending on discipline, life-cycle stage, building regulation and region, there will never be a complete set of internationally standardized attributes. Therefore, IFC defined property sets intent to standardize a basic set of properties, whereas other property sets can be regionally defined, or agreed upon in projects. The current drawback, however, is that there is no specification of the semantics of PSet information outside that published in the IFC distribution (PSD - Property Set Definition - Schema for the definition of property sets and properties).
It is important to stress the assets of such mechanism. IFC objects can have properties attached to them. The IFC model differentiates between attributes that are directly attached to the object as attribute of the entity, and properties, group in a property set and assigned to the object by a relationship. The latter is the more flexible way to extent applicable properties.
Furthermore these properties may be specific to particular regions, projects or process. The IFC schema supports storing and transmitting these properties in named sets (so called "IfcPropertySet"). Therefore, a property set is a collection of properties that can be declared outside of the IFC schema but that can be assigned to all objects defined within the IFC schema.

In the case of a BIM way of working and a process lead approach, it is worth defining well-suited property sets commonly agreed by parties as the right structure to convey the domain specific information between BIM and this specific activity.
In the current version IFC4, there are more than 400 property sets already defined.

5.3.2 Environmental Property sets and their connections with Building elements

In the scope of this paper it is worth mentioning two property sets that have just been introduced in this IFC4 version.
The first one is the property set “Pset_EnvironmentalImpactIndicators” which official definition is “Environmental impact indicators are related to a given “functional unit” (ISO 14040 concept). An Example of functional unit is a "Double glazing window with PVC frame" and the unit to consider is "one square meter of opening elements filled by this product”. Indicators values are valid for the whole life cycle or only a specific phase (see LifeCyclePhase property). Values of all the indicators are expressed per year according to the expected service life. The first five properties capture the characteristics of the functional unit. The following properties are related to environmental indicators. There is an international consensus agreement for the five one. Last ones are not yet fully and formally agreed at the international level”.
The second one is the property set “Pset_EnvironmentalImpactValues” which official definition is “the following properties capture environmental impact values of an element. They correspond to the indicators defined into Pset_EnvironmentalImpactIndicators. Environmental impact values are obtained multiplying indicator value per unit by the relevant quantity of the element”.
These two property sets are strongly interrelated as the first one is dedicated to the definition of the considered indicator(s) along with its unit(s) and validity domain(s).
They are commonly attached to the notion of IfcElement which is an abstract concept in the IFC ontology that can be further described as a generalization of all components that make up an Architecture, Engineering and Construction product. Those elements can be logically contained by a spatial structure element that constitutes a certain level within a project structure hierarchy (site, building, storey or space).

5.4 IFC elements addressed in a Sustainable Building Assessment

Actually, most of BIM/CAD tools propose export function to IFC. The resulting IFC exported files then contain IFC objects with their properties that can be used to perform Sustainable Building Assessment. A report for the Sustainable Building Alliance [7] shows a list of different devices and appliances that are concerned by different indicators and it makes the link from these devices to the corresponding IFC objects, expressing thus the ability of the IFC language to support the representation of various objects that are concerned by sustainable assessments. Of course, the inputs listed in the chapter “Need for Input Data” are present in the IFC model (building location, building structure and composition).
Sustainable analysis tools require the input of geometry to define the simulation model. This is mostly done by either importing the geometry or manually rebuilding it. Importing and exporting of building geometry is error-prone and tedious, especially as geometry models established in CAD-software are often not suitable as simulation models. The main asset of the BIM is to facilitate the reuse of existing data without retyping them. Even the environmental data produced by manufacturers (EPD’s on construction products) are now available via the BIM [8].

5.5 Sustainability indicators and corresponding IFC objects

In the frame of the SuperBuildings project a survey has been conducted in order to identify if the IFC model already contains the concepts able to support the 20 indicators listed previously.
This survey shows clearly that in its recent update (IFC4), the IFC have made a significant step forward in the integration of sustainable indicators into the BIM.
In the tables below, for each of these indicators, the corresponding IFC property set and element is indicated when existing.

Table 1 : List of SuperBuildings environmental indicators and corresponding IFC structures

Issue	Pset & Related property	Comment / definition attached to the property	IFC related element
Consumption of non-renewable primary energy	Pset_EnvironmentalImpactIndicators/NonRenewableEnergyConsumptionPerUnit	Quantity of non-renewable energy used as defined in ISO21930:2007	IfcEnergyMeasure
• **Embodied Water use** • **Operational water use** • **Wastewater production**	Pset_EnvironmentalImpactIndicators/ WaterConsumptionPerUnit	Quantity of water used	IfcVolumeMeasure
Soil sealing **Change of land use**	Pset_SiteCommon/SiteCoverageRatio	The ratio of the utilization, Total Area/Buildable Area, expressed as a maximal value	IfcAreaMeasure
Global warming potential	Pset_EnvironmentalImpactIndicators/ ClimateChangePerUnit	Quantity of greenhouse gases emitted calculated in equivalent CO2	IfcMassMeasure
Protection of atmosphere (other pollutants)	Pset_EnvironmentalImpactIndicators/ • PhotochemicalOzoneFormationPerUnit • StratosphericOzoneLayerDestructionPerUnit • AtmosphericAcidificationPerUnit	• Quantity of gases creating the photochemical ozone calculated in equivalent ethylene • Quantity of gases destroying the stratospheric ozone layer calculated in equivalent CFC-R11 • Quantity of gases responsible for the atmospheric acidification calculated in equivalent SO2	IfcMassMeasure
Construction and demolition waste generation • **Non-hazardous waste to disposal** • **Hazardous waste to diposal** • **Nuclear waste to disposal** • **Solid waste separation**	Pset_EnvironmentalImpactIndicators/ • NonHazardousWastePerUnit • HazardousWastePerUnit • RadioactiveWastePerUnit	• Quantity of non hazardous waste generated • Quantity of hazardous waste generated • Quantity of radioactive waste generated	IfcMassMeasure

Table 2 : List of SuperBuildings Societal indicators and corresponding IFC structures

Issue	Pset & Related property	Comment / definition attached to the property	IFC related element
Concentration of various pollutant			
Thermal comfort • **PMV** • **PPD** • **Operative temperature** • **Air Temperature** • **Relative humidity** • **Air velocity**	Pset_SpaceThermalRequirements • NaturalVentilation • NaturalVentilationRate • SpaceTemperature • MechanicalVentilationRate • SpaceHumidity	Properties related to the comfort requirements for thermal and other thermal related performance properties of spaces. This includes the required design temperature, humidity, ventilation, and air conditioning.	IfcThermodynamicTemperatureMeasure IfcRatioMeasure IfcCountMeasure
Illuminance **Daylight factor**	Pset_SpaceLightingRequirements Illuminance	Properties related to the lighting requirements that apply to the occurrences of IfcSpace or IfcZone. This includes the required artificial lighting, illuminance, etc.	IfcIlluminanceMeasure

Table 3 : List of SuperBuildings Economic indicators and corresponding IFC structures

Issue	Pset & Related property	Comment / definition attached to the property	IFC related element
Life cycle cost • **Capital cost** • **Cost in the operational phase**			IfcCostItem
LongTerm stability of value			

The property set mechanism demonstrates its ability to provide a semantic layer above the IFC elements. For instance, in the Table 1 above, the same IFC element “IfcMassMeasure” is used four times to store four different notions (Quantity of greenhouse gases emitted calculated in equivalent CO2, Quantity of gases creating the photochemical ozone calculated in equivalent ethylene, Quantity of gases destroying the stratospheric ozone layer calculated in equivalent CFC-R11, Quantity of gases responsible for the atmospheric acidification calculated in equivalent CO2). It is only because the property set has a well-defined and documented structure enabling the fact that the semantic attached to the four occurrences of this “IfcMassMeasure” element differs.

5.6 Gaps between the Indicators and their support in IFC

There is room for enhancement. Among others, one of the main assets of the BIM is to provide a unique repository of data along the whole life cycle of a construction project. In order to facilitate the understanding among the various actors, the exchange model and corresponding language (IFC) is structured and documented to ensure a semantic continuity about the information exchanged and stored at the various phases.
Three levels of trust for this semantic continuity can be defined:

- Level 0: There is not support from the IFC language and thus there is not guarantee at all that other actors or software platforms will be able to reuse it
- Level 1: There is a support from the IFC language. But there is no dedicated specific object or property to explicitly qualify the value of the indicator. The best example for that are the different notions of costs. There are few IFC entities dedicated to the cost and the notion of "cost per phase" can be determined and its value stored thanks to the "IfcCostItem" element but this specific meaning cannot be explicitly defined in current version. It relies for the moment on a possible agreement among concerned actors.
- Level2: There is a direct and explicit support from the IFC. In that case a common understanding in ensured.

The tables below recap for all indicators the semantic quality of its support in the IFC model.

Table 4 : List of SuperBuildings Environmental indicators and corresponding IFC structures

Issue	IFC related element	Quality of the IFC support	Comment
Consumption of non-renewable primary energy	IfcEnergyMeasure	**Level 2**	There is a direct support with the dedicated Property Set
Embodied Water use	IfcVolumeMeasure	**Level 1**	There is a support of the Water use via the WaterConsumptionPerUnit property. The notion of Embodied Water is not explicit.
Operational water use	IfcVolumeMeasure	**Level 2**	Direct support with the dedicated Property Set
Wastewater production	IfcVolumeMeasure	**Level 2**	There is a direct support with the dedicated Property Set
Soil sealing	IfcAreaMeasure	**Level 2**	Direct support with the dedicated Property Set
Change of land use		**Level 0**	No support
Global warming potential	IfcMassMeasure	**Level 2**	Direct support with the dedicated Property Set
Protection of atmosphere (other pollutants)	IfcMassMeasure	**Level 2**	Direct support with the dedicated Property Set Pset_EnvironmentalImpactIndicators/ • PhotochemicalOzoneFormationPerUnit • StratosphericOzoneLayerDestructionPerUnit AtmosphericAcidificationPerUnit
Construction and demolition waste generation • Non-hazardous waste to disposal • Hazardous waste to diposal • Nuclear waste to disposal Solid waste separation	IfcMassMeasure	**Level 2**	Direct support with the dedicated Property Set Pset_EnvironmentalImpactIndicators/ • NonHazardousWastePerUnit • HazardousWastePerUnit RadioactiveWastePerUnit

Table 5 : List of SuperBuildings Societal indicators and corresponding IFC structures

Issue	IFC related element	Quality of the IFC support	Comment
Concentration of various pollutant		**Level 0**	
Thermal comfort • PMV • PPD • Operative temperature • Air Temperature • Relative humidity Air velocity	IfcThermodynamicTemperatureMeasure IfcRatioMeasure IfcCountMeasure	**Level 2**	Direct support with the dedicated Property Set Pset_SpaceThermalRequirements • NaturalVentilation • NaturalVentilationRate • SpaceTemperature • MechanicalVentilationRate • SpaceHumidity
Illuminance	IfcIlluminanceMeasure	**Level 2**	Direct support with the dedicated Property Set Pset_SpaceLightingRequirements/ Illuminance
Daylight factor		**Level 0**	

Table 6 : List of SuperBuildings Economic indicators and corresponding IFC structures

Issue	IFC related element	Quality of the IFC support	Comment
Life cycle cost • Capital cost • Cost in the operational phase	IfcCostItem	**Level 1**	There is a support of the notion of Cost, via the IfcCost item and there possibilities to qualify this cost item via the “IfcCostValue” which is an enumeration of cost categories. But only the “whole life” category sounds related to the needs expressed here. The rest is not mentioned
LongTerm stability of value		**Level 0**	

It appears that:

- For the Environmental indicators 10 (among the12 studied) have a direct equivalent in IFC, one has an indirect support and one is not supported;
- For the Societal indicators 7 (among the 9 studied) have a direct equivalent in IFC and 2 are not supported;
- For the Economic indicators none (among 2) have a direct equivalent in IFC, one has an indirect support and one is not supported.

6. Conclusion

This paper presented part of the work performed in the frame of the SuperBuildings project.

Among the noticeable outcomes, the indicators developed represent the corner stone of a sustainable assessment process that becomes now more quantitative than qualitative. As environmental issues and sustainability increasingly have become hot topics in the building industry, there is a real need to perform sophisticated simulations and analysis based on detailed initial data and the analyses should be introduced as early as possible to allow for early collaboration between the design and assessment teams.

To perform such assessments it necessary to have an easy and quick access to input information such as the construction characteristics (dimensions of the building elements, composition and material used, physical and environmental characteristics, etc...). This is typically where the open BIM approach makes sense. The IFC model has proven its ability to convey necessary information to perform these assessments.

This paper has demonstrated also the ability of this language, especially in its latest version to support sustainable assessment results. Even if there are still some gaps most of the indicators developed or selected in the frame of the SuperBuildings project are already supported by the IFC4.

7. Acknowledgement

The results presented in this paper are based upon the work done during the SuperBuildings project (http://cic.vtt.fi/superbuildings/) led by Tarja Hakinen from VTT and supported by the European Commission under the Seventh Framework Programme (FP7).

Short Summary

Temporary buildings are generally considered to be unsustainable due to a short life span of the materials applied in the building. The construction materials typically have a longer use life than the required use life of the building, thus functioning building materials are often discarded after the demolition. In an attempt to improve the sustainability of temporary buildings, a Product/Service-System (PSS) strategy is here applied to a case project. The case project concerns a temporary building made of leased materials and building components such as shipping containers, scaffolding materials and lifts. The major research question for the case is how the supplier's continued ownership of the building materials influences the sustainability of such buildings.

By using a PSS design approach in the early design stages, the architects involved in the case project were able to make design decisions based on the whole life cycle of the building components, e.g. design-for-disassembly and design-for-reuse. The lease of materials will ensure that the building materials are re-used at the end-of-life stage. This is expected to prevent production of waste and improve the overall environmental sustainability of the temporary building.

The validation of the improved sustainability of the PSS-based building solution is achieved by comparing the PSS with a corresponding conventional approach for the temporary building through a comparative Life Cycle Assessment (LCA). The results show that over the entire life cycle, the aggregated environmental impact score for the PSS solution is 27% lower than the conventional solution when including operational energy and 37% lower when operational energy is excluded.

Keywords: Product/Service-Systems; temporary buildings; Life Cycle Assessment; closed loop systems; circular economy; life cycle design; waste prevention.

1. Introduction

The manifesto for a circular European Economy was published by the European Commission on the 17th of December 2012. It declares that:

"In a world with growing pressures on resources and the environment, the EU has no choice but to go for the transition to a resource-efficient and ultimately regenerative circular economy. Our future jobs and competitiveness, as a major importer of resources, are dependent on our ability to get

more added value, and achieve overall decoupling, through a systemic change in the use and recovery of resources in the economy". [1]

The building sector creates one third of the total waste production in Denmark [2] and in Europe [3] and represents a challenge in terms of resource consumption and waste handling. At the same time, there is an increasing need for temporary and affordable buildings which can adapt to the changing needs and sizes of companies, municipalities, schools and universities. However, impermanent buildings are generally unsustainable, as the amount of material required is comparable to permanent buildings, though with a much shorter lifespan. As the European Commission declared above, this calls for systemic change in the use of resources. Product/Service-Systems offer such a systemic change, which has the potential to radically reduce the environmental impacts of traditional products. Several studies ([4], [5] and [6]) performing LCAs on various Product/Service-Systems have shown a 30-75% reduction of the environmental impact of Product/Service-Systems compared to the conventional solutions.

This paper presents the business potential for using Product/Service-Systems (PSS) in the building sector and explains how the suppliers extended ownership and responsibility in a PSS can facilitate multiple use cycles of building materials, thereby avoiding useful materials going to waste.

Thereafter, the sustainability effects of a Product/Service-System will be quantified using LCA. An LCA has been carried out on a case study in order to investigate how a PSS solution can alter the environmental profile of temporary buildings.

2. Product/Service-Systems in the building sector

2.1 Introduction to Product/Service-Systems

Product/Service-Systems (PSS) have already entered the building sector through lighting services (e.g. Philips), furniture services (e.g. Gispen, the Netherlands) and carpet leasing programmes (such as Interface Inc, USA) [7]. Here, the customer pays for the function, e.g. square meter carpet per year, rather than for the product which delivers the function, e.g. the carpet itself. The company installs, monitors, maintains and replaces the carpets whenever necessary, making it convenient for the customer.

Product/Service-Systems have similarities with circular economy, where resources are kept and restored in closed loops, belonging to either the technosphere or ecosphere. They also have parallels with approaches such as Service Economy and Functional Economy, where the object of sale is a performance, customer satisfaction or result, in contrast to industrial economy, where the object of sale is a product [8].

Here we will offer two general definitions of PSS, the first relating to what it is, and the second to how it can be achieved.

"A marketable set of products and services capable of jointly fulfilling a users/customers need in an economical and sustainable manner." [9]

"PSS strategy is to shift from business based on the value of the exchange of ownership and responsibility, to business based on the value of supporting and enhancing the utility of products throughout their entire life cycle." [10]

This paper will apply both definitions to construction materials and quantitatively as well as qualitatively assess the sustainability of Product/Service-Systems in the building industry.

2.2 PSS business case for construction materials

Currently, most construction material suppliers work with a simple point-of-sale model, where the ownership and responsibilities are transferred to the customer. A Product/Service-System extends the ownership and responsibility of the supplier to the entire life cycle [8], i.e. in our case to the entire life cycle of the temporary building. Thereby, the supplier sells the right to use the material, rather than the material itself, typically through a lease agreement. The PSS may also include servicing and repair of the construction components during use. After use, the manufacturer will take back the product and re-use or recycle it. The customer gets what he wants; the ability to use materials in the form of a building for a certain amount of time, and avoids the usual hassle of being in charge when something breaks down as well as having to cover the expenses for disposal of materials at the end-of-life.

Product/Service-Systems thus provide opportunities for entirely new business models in the construction industry. Lease agreements give economic benefits for both the supplier and the contractor; they give a sustained income for the supplier and improve the cash flow of the developer. The supplier keeps a 'material bank' at his customers, which later can be used as feedstock in the production, making him more resilient to fluctuating market prices and resource scarcity.

There are thus strong economic incentives on both the supply and demand side for Product/Service-Systems. However, it should be considered whether PSS solutions also are environmentally beneficial.

2.3 Product/Service-Systems and sustainability

Mark Goedkoop et. al. [9] found that although a shift from a product to a service is, on average, environmentally sound, there are exceptions with high variability. Therefore they recommend assessing the sustainability of Product/Service-Systems case by case.

Several studies on the sustainability effects of various Product/Service-Systems have previously been carried out. A study of a bicycle sharing system [4] found that the total environmental impacts could be reduced by 30% through improved robustness of the bicycles and that a 45% reduction could be achieved through improved maintenance service. A similar study [5] comparing a PSS self-service laundry system with household washing machines found that the carbon emissions could be reduced by more than 50% through optimised utility of the washing machines. Another study of the leasing of water filtration devices [6] concluded that a reduction of 75% of the total environmental impact over a 4 year lifespan could be obtained through maintenance, increased lifespan and improved end-of-life treatment.

In these studies, several features of Product/Service-Systems were identified as factors to improve sustainability:

- Longer lifetimes through robustness and maintenance
- Optimised utility of products through leasing and sharing
- Improved end-of-life treatment.

All of these features can be relevant in a Product/Service-System of construction materials. However, this case project has focused on optimised utility through leasing and improved end-of-life treatment. In order to achieve optimised utility and improved end-of-life treatment of construction materials, the Product/Service-System design may take its starting point in a cyclic material model, as first suggested by the Swiss architect Walter R. Stahel in 1982 [11]. His self-replenishing model recommends choosing reuse over repair, repair over reconditioning and reconditioning over recycling. Incineration and landfill are not at all included in his model, and should be excluded from PSS models since recycling is generally preferable to these options [12].

Whether a given PSS is sustainable is thus a question of its design. As PSSs focus on the value of use rather than the value of ownership, they render planned obsolescence obsolete and instead promote durable design. They extend the responsibilities of the producer and thereby align the producer interests with the interests of the consumer. Product/Service-Systems may thus be an important step in the transition from a 'buy-and-throw-away' consumption culture, to a system where the utility of products is optimised, equitably distributed and environmental resources carefully managed.

3. Case study and environmental impacts

3.1 Measuring the environmental effect of PSS through LCA

This paper seeks to go beyond conventional eco-design, and focus on the sustainability effects of the Product/Service-System. Thus, the focus is not so much put on choice of materials, but on the effect of making re-use an intrinsic part of the system surrounding the building.

LCA is suitable for assessing the environmental impacts of both products and services, as these can be compared on the basis of the same functional unit [13]. That allows us to compare leased and bought materials in this case. The LCA was carried out according to the ILCD recommendations and EN15978:2011 standards for environmental assessment of buildings.

3.2 Introduction to the case study

This study is based on a temporary building designed by Lendager Arkitekter, a Danish architect studio which is specialised within sustainable design. The building consists of components and materials that are either leased or bought on take-back contracts between the developer and suppliers. In these contracts, the suppliers guarantee taking back the materials after use, which ensures re-use of functional materials.

The building itself is designed for assembly, disassembly and re-use of the materials. The dimensions of the leased materials determine the dimensions of the construction, rather than fitting the materials to the design. Thereby construction waste is reduced significantly, and the materials can be re-used directly after the use phase. The materials chosen for the building are materials which are traditionally leased for other purposes. They include shipping containers, scaffolding materials, lifts and pre-fitted bathroom containers. The containers are used as building blocks to form the outer wall of the building. The resulting modular design makes it possible to modify the layout and size of the building during operation, according to the changing needs of the tenants.

Fig. 1: The case study building 'Eco-Box'

This building is seen as a pilot project for use of Product/Service-Systems in the building industry. The concept behind the building is to lease all construction materials, functions and furnishings, thereby avoiding the creation of waste. However, working within the current network of suppliers, it has not been possible to lease the insulation, wall lining, windows and doors. As the building is still in the design phase and planning stage, the PSS solution focuses on the overall leasing of construction materials, and not on functions such as lighting and furnishing.

3.3 Compared scenarios

The Product/Service-System scenario of re-used and re-usable materials is compared to the conventional scenario of applying first-use materials which receive conventional Danish end-of-life treatment, see table 1. In other words, the LCA compares a model with multiple use cycles of materials with a model with only one use cycle of the materials.

3.3.1 The European waste hierarchy

The European hierarchy prioritises five different waste options, see figure 2 [14]. Out of these five options, the preferred one is waste prevention. The waste prevention strategy has been followed in the design phase of the building under study by reducing the amount of materials per square meter office space and choosing environmentally friendly building materials over materials containing hazardous substances.

Fig. 2: European waste hierarchy [14]

The end-of-life of materials are on average placed higher in the waste hierarchy for the PSS solution compared to conventional Danish building waste treatment, as many materials are re-used rather than recycled. Table 1 shows the construction materials divided into the four waste scenarios; prepare for re-use, recycling, recovery and disposal.

Table 1: Comparison of end-of-life treatment for the two scenarios

Waste treatment	PSS	Conventional
Prepare for re-use	Containers Steel foundation Scaffolding HVAC elements Lift	-
Recycling	Plastics Gypsum Wood based materials Windows and doors Fibre cement Staircases and bridges Screws, bolts and nails	Containers Steel foundation Scaffolding Windows and doors Staircases and bridges HVAC elements Wood based materials Plastics Gypsum Screws, bolts and nails Lift
Recovery (energy recovery rate >60%)	Bitumen Cellulose insulation UPM flooring Roof cover	Bitumen Cellulose insulation UPM flooring Roof cover
Disposal (energy recovery rate <60%)	-	-

In 2009, 5 mio tonnes of building waste was produced in Denmark, this equalled more than one third of the total waste production. 96% of the total mass of building waste was recycled. However, most of this recycled material is dirt, stone, concrete and asphalt which is crunched and used as roadfill [1]. This can be considered 'downcycling' rather than 'recycling'. This means that there are still improvements to be made in the treatment and utility of building waste, improvements which are often intrinsic in Product/Service-Systems.

3.4 Goal and Scope

3.4.1 Goal

The goal of this LCA is to quantify the environmental improvement originating from Product/Service-Systems of building materials and components.

3.4.2 Functional unit, reference flow and key parameters

The PSS and conventional solutions are compared on the basis of the functional unit:

Providing 790 m^2 office space in Denmark for 8 years (2013-2021) including heating, ventilation and cooling according to Danish energy requirements for 2015.

The reference flow is one building and its energy consumption during use. The key parameters are the amount of materials per square meter office space and use life of construction materials.

3.4.3 Modelling framework and handling of re-use and recycling of materials

The modelling of the end-of-life is done by system expansion and subtraction using average data according to the ILCD handbook (situation A) [15] and the EN 15978:2011 standards [16].

The recovered energy resulting from incineration of the materials is assumed to substitute average

electricity in the Danish grid.

For recycling, the net impact of the building material is calculated as the impacts related to the recycling process minus the impacts from producing the substituted product. The substituted product is the average market mix, in accordance with the recommendations of the ILCD handbook [15].

The modelling of re-used materials is relevant in this case, as the use life of the materials is longer than the required use life of the building. Reused and reusable materials are however not environmentally 'free' due to wear during use. The total impacts related to the production stage and end-of-life of the component must therefore be allocated to the different use cycles. The allocation is done according to ILCD's recommendations for handling of re-used materials in attributional LCAs, and the chosen allocation factor is based on time.

The allocation factor is the ratio between the required use life of the building (RULB) and the expected use life of the materials (EULM), where RULB < EULM.

For leased materials, the economic and time-based allocation factors are equivalent, as the monthly payment does not depend on the former use period of the materials. In a Product/Service-System, the customer pays according to functionality of the solution, not according to the newness of the materials. At the end of the materials' use life, the entire production and end-of-life processing is accounted for by the sum of use cycles.

3.4.4 System boundaries

The LCA covers the whole life cycle of the building, from raw material extraction to end-of-life or 'end-of-cycle'. The included life cycle stages are shown in table 2.

Table 2: Life cycle stages in the LCA

Stage	Unit process
Production stage	Raw material supply
	Transport to manufacturer
	Manufacturing
Use stage	Replacement of components
	Operational energy use
End-of-life	Waste processing
	Disposal
Next product system	Reuse, recovery or recycling potential

The surrounding outdoor grounds and materials for plumbing, furnishing, electrical installations and lighting are outside the system boundaries.

3.5 Life cycle inventory

In the production stage, primary data from suppliers was used to set up the life cycle inventory of materials. The inventory was modelled in the LCA tool GaBi (version 4.4) with EcoInvent (version 2) datasets using fully parameterised modelling. The production stage of all construction materials were modelled and divided into six building elements to allow a better overview of the building:

1) Building base (including leased containers and point foundations)
2) External walls (no leased materials)
3) Internal walls (no leased materials)
4) Ceilings, floors, stairs and balcony (including leased scaffolding and lift)
5) Roofs (including leased scaffolding and cover)
6) Central energy, heating and cooling units (including leased HVAC elements)

For the replacement stage and for allocation of re-used materials, the expected lifetimes of materials and components were collected directly from suppliers. The operational energy was calculated as a function of floor area using the Danish 2015 energy requirements for office buildings. The import of electricity was modelled using average Danish grid mix. The waste processing and recycling was modelled manually with data from EcoInvent datasets and WRAP 2010 [12] data for plastics. The recycling processes are assumed to be 90% effective. BUWAL datasets were applied for the energy recovery of different materials.

3.6 Life cycle impact assessment methodology

ReCiPe version 1.0 was applied in this case, and all 18 midpoint categories and 3 endpoint categories were calculated using the Hierarchist characterisation and normalisation factors. The characterised impact categories are extracted at midpoint, translated to endpoint, then normalised and weighted at endpoint using average ReCiPe weighting factors [17]. The weighted endpoints are then aggregated to a single score on which the different alternatives are compared.

3.7 Life cycle impact assessment results

3.7.1 Production stage

Quantified in dimensionless weighted endpoint scores, the total impacts related to the production are 27% lower for the PSS solution than for the conventional solution due to the use of re-used materials. The leased materials currently make up 65% of the total mass of the building. Therefore, a greater reduction could potentially be achieved if an even higher ratio of the materials could be leased.

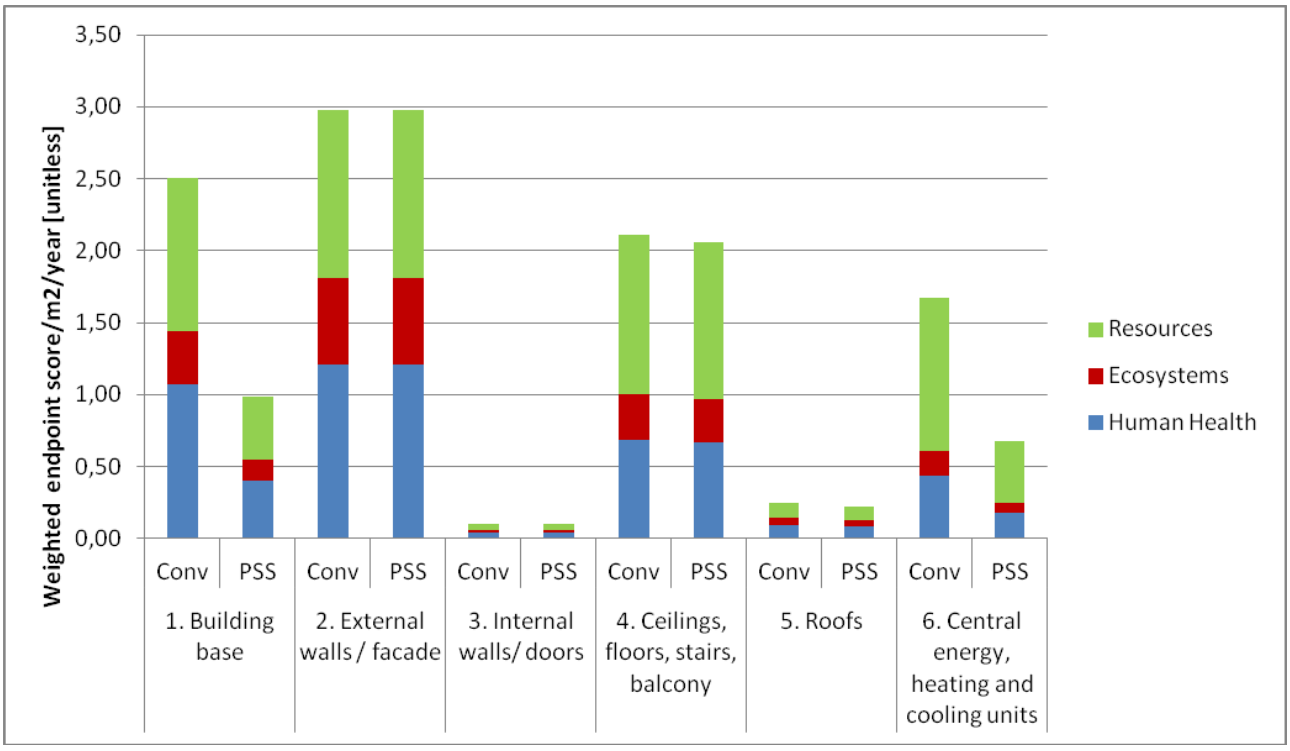

Fig. 2: Weighted endpoint scores for building materials of conventional and Product/Service-System solutions

Figure 2 compares the conventional solution with a Product/Service-System building using the same materials split into six building elements. The largest difference can be found in the building base, which consists of leased containers and leased point foundations. Here, the PSS components only amount to 39 % of the conventional solution quantified in dimensionless weighted endpoint scores - a reduction of 61%. The internal and external walls consist of wood,

plastic, windows and insulation, which are currently not offered by a Product/ Service-System. Therefore, the impact here is the same for the two solutions. Building elements 4, 5 and 6 specified in figure 2 consist of a mix of re-used and new materials; therefore the PSS solution's potential impact is slightly lower than the conventional solution.

3.7.2 Use stage

Figure 3 shows the potential life cycle impacts divided into five stages. The operational energy consumption is the same for the two solutions. This stage corresponds to 26% of the total life cycle impact for the conventional solution, and 36% for the PSS solution which has lower impacts in other stages. This is relatively low due to the short life span of the temporary building. There is however great uncertainty related to the amount of operational energy required, as no energy calculation has yet been performed on the building. The impacts here are also highly dependent on the composition of energy sources in the grid.
In the replacement stage only the roof cover is replaced due to the short life time of the building. Therefore, the replacement stage only contributes with 1% to the total life cycle impacts.

3.7.3 End-of-life

For the end-of-life processing, the environmental impact score of the PSS solution is 52% lower than the conventional solution. This is significantly more than the reduction at the production stage. This is caused by the energy demanding process of smelting steel and aluminium, which also contribute highly to the endpoint impact 'Resources'. The roof cover containing PVC and cellulose insulation containing boric acid are incinerated rather than re-used at end-of-life. These materials contribute highly to eco-toxicity. It can therefore be argued that improvement at end-of-life could be obtained by replacing these materials by non-toxic ones, in an eco-design approach.

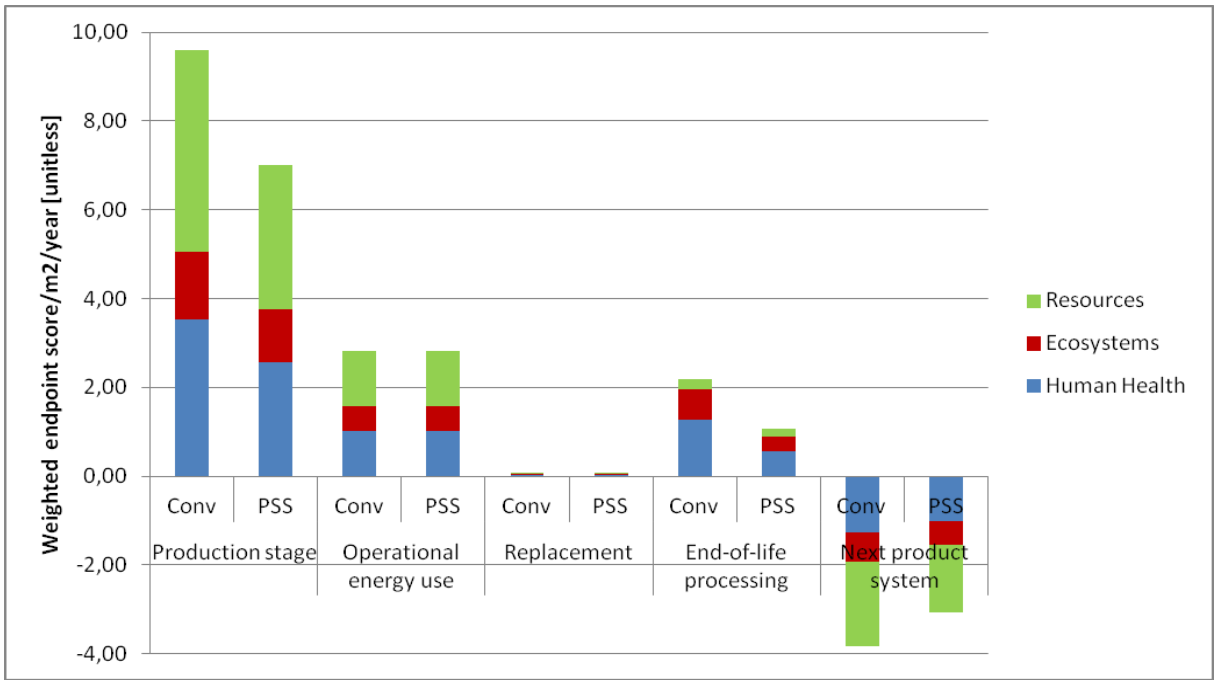

Fig. 3: Weighted endpoint scores for the full life cycle of the conventional solution and PSS

The fact that the end-of-life processing is significantly lower for re-use compared to recycling is another reason to extend the total use life of components through Product/Service-Systems, thereby postponing recycling of the material and lowering the impact per use.

3.7.4 Total life cycle

Over the entire life cycle, the aggregated environmental impact score for the PSS solution is 27% lower than the conventional solution when including operational energy and 37% lower when operational energy is excluded.

3.7.5 Sensitivity analysis

A sensitivity analysis was performed by varying the input parameters by 10% and calculating the corresponding change in total output. The sensitivity analysis showed that all of the input parameters has a sensitivity ratio (percentage change in input divided by percentage change in output) of below 0.01, and can therefore be characterised as having low sensitivity. This means that a change in individual parameters will not have a significant effect on the result.

4. Conclusions

4.1 Discussion

A barrier to using Product/Service-Systems in the building sector today is that the materials cannot be modified. Customisation of leased materials to meet many different needs and building designs represent a challenge for both architects and material suppliers. Also, the limited choice of materials which can be leased today may result in bulkier designs, which eventually use more resources despite re-use. In this case, the shipping containers may be much larger and heavier than alternative materials necessary to create the building structure. Thus, the total material consumption and type of material should be taken into consideration when designing buildings based on Product/Service-Systems.

Furthermore, the rebound effect should be avoided, so that the higher affordability of impermanent buildings through Product/Service-Systems does not lead to increased use of resources on the whole. Although the temporary building can be built and run with 27% less potential environmental impacts through Product/Service-Systems, permanent buildings may on average remain more sustainable than temporary buildings. This is due to the added impacts of transport, construction and deconstruction in temporary buildings. A PSS model may not be suitable for permanent buildings, as the lease period can be too long and therefore the risk too great. Only 65% of materials can be leased in this case example, as materials which are too fragile to be mounted and de-mounted several times cannot be leased. A Product/Service-System based on leasing entire module-based buildings would ensure re-use of all building materials.

4.2 Conclusion

Product/Service-Systems push the benchmark for lifetimes and end-of-life treatment of materials, and thereby reduce the total environmental impact. It was shown that Product/Service-Systems can potentially improve the environmental sustainability of single building components used in temporary buildings radically, in our case example up to 85%. The improvement rate depends on the lifetime of the component versus the lifetime of the building. In general, the shorter the lifespan of the building or the greater the uncertainty of the building's future, the more environmentally beneficial the PSS solution will be.

Since not all the building materials can be leased in this case, the leased materials must be supplemented to form a functioning building, and this affects the total environmental sustainability of the building negatively. Thus over the entire life cycle, the aggregated environmental score for the PSS solution is 27% lower than the conventional solution. The overall reduction of impacts in the production stage is 27% in this case study. The total environmental impact score related to the end-of-life processing is reduced by 52% in the PSS solution, due to avoided energy-heavy recycling of metals. The operational energy only amounts to 26% of the total impacts of the temporary building. This underlines the importance of improving the sustainability of materials used in temporary buildings, by e.g. leasing materials through Product/Service-Systems.

4.3 Further work

Further research on PSS in relation to this case was carried out in this project. A main goal was to compare the environmental life cycle assessment with a life cycle costing model on the same case, in order to find environmental and economic trade-offs and synergies of Product/Service-Systems. Also, further work can be done on how much a PSS and an Eco-design approach respectively can contribute to reducing the environmental impacts in the building sector.

Short Summary

This study aims to define the characteristics of Carbon Dioxide emissions from concrete structures when different compressive strength of concrete applied to structural systems having the same functional unit with different durability. A total of 24Mpa, 40Mpa and 60Mpa cases is analyzed to define the characteristic by Life Cycle Assessment including the stages of production, construction, maintenance and disposal. As results, the amount of cement appears to be a major factor for the emission from the production stage, the amount of concrete from construction and disposal, durability of concrete from use and maintenance. It is recommended to develop optimal mixture designs for sustainable concrete in the consideration of life cycle characteristics of concrete structures to be used.

Keywords: LCA, CO_2 emission, Concrete structure, Compressive strength, Reinforced concrete structural wall system

1. Introduction

As various carbon policies being implemented in order to address climate change and the need for the mitigation of greenhouse gases associated with industrial activities at the national and enterprise level being emerged, efforts are also being made in the construction sector to minimize greenhouse gas emissions. Buildings which are composed of various materials and components, induce enormous environmental pollution throughout the life cycle from construction to disposal and therefore, in order to control environmental impacts from the building, it is necessary to verify the environmental burdens caused by construction material. In particular, since concrete products using cement and aggregates, are the most popular construction material and the proportion of these materials used in a building, is over than 80% among all materials input by weight per unit floor area, it is important to identify the environmental impacts from concrete products[1].
This study is intended to evaluate quantitatively potential impacts of a concrete structure throughout its construction, use and disposal from the perspective of global warming that has been an issue in relation to climate change. It analyses the characteristics of greenhouse gas emissions for concrete structures as there can be the differences in the amount of inputs and durability by the compressive strength of concrete even in the same structure, serving as a basis for the prediction of environmental impacts for the construction of sustainable concrete structures in the future.

2. LCA Implementation

2.1 Overview

The environmental impact assessment which is mainly applied in the field of construction is in accordance with the LCA (Life Cycle Assessment) standards proposed by the International Organization for Standardization[2].
As an evaluation tool for environmental labelling standards, the LCA is intended to compare the full range of effects of products and services on the environment and society in order to provide a sound basis for informed decisions being able to reduce environmental burdens in various aspects of human activity[3]. An LCA is carried out by four main phases including goal and scope definition, life cycle inventory analysis, life cycle impact assessment, life cycle interpretation.

2.2 LCA plan for concrete compressive strength

2.2.1 Comparative assessment plan

Basically, the comparative assessment of environmental impacts for specific concrete compressive strength complies with the LCA techniques as specified in the ISO14040 series but only global warming potential is utilized from the characterization impact categories of the LCA to simplify evaluation processes. For the carbon dioxide emission factor of each material, the National Environmental Information[4] (LCI DB; Life Cycle Inventory Database) which is on the basis of the LCA standards was referenced.
A variety of concrete mixes are chosen with different use of cement. The amount of material inputs varies in each mix and the resulting durability and environmental burdens also can be different. In this assessment, the use and duration of concrete products remain the same, and by assessing them only with varying concrete compressive strength, the life cycle environmental burdens of concrete with general and high compressive strength are analysed. The assessment was carried out by varying the compressive strength of concrete from 24MPa, which is typically required in buildings, to high compressive strengths of 40MPa and 60MPa, and the applied casting area was limited to the walls of reinforced concrete wall structure. Besides, the assessment period of environmental impacts was determined to be a total of 120 years, and the use period of structures was assumed to be 60 years for a structure with 24MPa and 120 years for high compressive strength concrete with 40MPa and 60MPa.

2.2.2 Requirements for assessment

(1) Functions, functional units and reference flows

The comparative assessment in the LCA process must be based on the same function and functional unit. The functional units and reference flows for conducting an LCA on a concrete structure are presented in Table 1.

Table 1: Function, Functional Unit and Reference Flow

Classification	Definition
Function	To form structural wall of reinforced concrete apartment building
Functional Unit	Reinforced concrete walls of 25-story apartment building occupied during 120 years
Reference Flow	Materials and energy input for reinforced concrete walls of 25-story apartment building occupied during 120 years

(2) System boundaries

A system is a collection of series of activities to perform clearly defined functions. In a broad sense, it is associated with all the stages of a product's life from raw material extraction through materials processing, industrial or customer use, and disposal. In the ISO 21930, which embodies the principles and procedures of LCA in the field of construction products, the system boundary of the

life cycle of a construction product is subdivided into production stage, construction stage, use stage and disposal stage, and the environmental impacts due to the flows of material and energy for each stage are designed to be identified. The stage and scope definition of system boundaries associate with the concrete LCA are shown in Table 2.

Table 2: System Boundary for LCA of Concrete

Stage	Scope Definition
Production	all the processes of producing the materials to be inputted into a structure by consuming the resources and energy required for production, manufacture of products
Construction	the process of transporting materials from the production site to the construction site and the stage of completing the structure by inputting building materials, energy, etc
Use & Maintenance	the process wherein a user maintains a structure through additional repair and maintenance while the user resides in the building until the completed building is demolished
End of Life	the process of demolishing a structure using equipment, transporting for reclamation or incineration or recycling

(3) Scope of data collection

The amount of material inputs with respect to the mixture ratio for concrete compressive strength for this study is presented in the following Table 3, which is refered to an actual mixture table from a ready-mixed concrete company. Data on major constituent materials including Portland cement type 1, sand, coarse aggregates and mixing water are collected to perform an LCA.

Table 3: Amount of Input by Concrete Compressive Strength

Strength	Materials (kg/㎥)					
	Aggregate	Sand	Portland Cement Type 1	Water	Admixture	Total
24MPa	931 (40%)	863 (38%)	334 (15%)	170 (7%)	2.34 (0%)	2300.34 (100%)
40MPa	896 (39%)	748 (33%)	459 (20%)	163 (7%)	6.63 (0%)	2272.63 (100%)
60MPa	905 (41%)	705 (32%)	426 (19%)	165 (7%)	6.09 (0%)	2207.09 (100%)

(4) Life cycle assessment scenarios

According to the ISO 21930, all the stages of a product's life cycle (“Cradle to grave") should be subdivided into at least four life-cycle stages and served as basic information modules to present the environmental information on construction products.

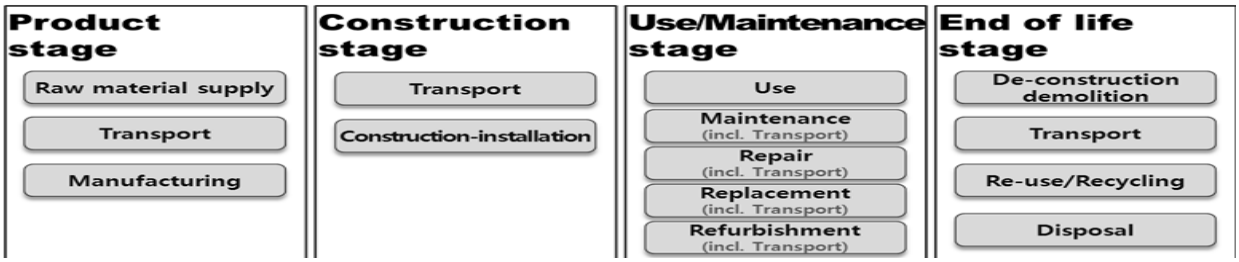

Fig. 1: System Boundary of Materials(ISO 21930 Sustainability in building construction - Environmental declaration of building products)

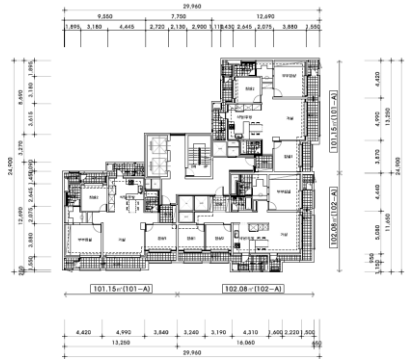
When the principles and procedures of the LCA are applied to this assessment, the scenarios on each stage of the life cycle for a concrete structure with 3 types of compressive strength and corresponding data collection methods are summarized as follows:

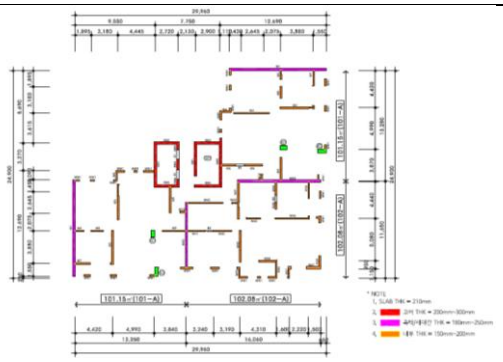
Table 4: Assessment Scenarios for LCA

Stage	Phase	Data Collection	Type of Data	GHG Emission Unit (Source)	Supposition
Production	Material Manufacturing	Aggregate	Field Data	6.65E-03 $kgCO_2$ e/kg (KLCI)	Materials within 95% of the cumulative weight contribution
		Sand		2.42E-03 $kgCO_2$ e/kg (KLCI)	
		OPC Type Ⅰ		9.48E-01 $kgCO_2$ e/kg (KLCI)	
		Water		1.14E-04 $kgCO_2$ e/kg (KLCI)	
	Transportation	Energy Consumption	Transportation Data	(KLCI, Carbon Labelling, IPCC)	Transport data between manufactories
Construction	Construction/ Installation	Oil consumption by Concrete Pump Car	Field Data	2.66E+00 $kgCO_2$ e/L (Carbon Labeling)	Activity data related with construction machinery
	Transportation	Energy Consumption	Transportation Data	(KLCI, Carbon Labelling, IPCC)	Transport data between manufactories and site
Use & Maintenance	Maintenance	Aggregate, Cement, Water Consumption	Field Data	(KLCI, Carbon Labelling, IPCC)	Activity data related with product maintenance
	Transportation	Energy Consumption	Transportation Data	(KLCI, Carbon Labelling, IPCC)	Transport data between manufactories and building
End of Life	Deconstruction	Energy Consumption	Field Data	(KLCI, Carbon Labelling, IPCC)	Activity data related with machinery
	Transportation	Energy Consumption	Transportation Data	(KLCI, Carbon Labelling, IPCC)	Transport data to disposal facility
	Disposal	Waste Concrete Reclamation	Disposal Scenario	(Carbon Labeling)	Activity data related with waste landfill
	Recycle	Waste Concrete Recycling	Recycling Scenario	(Carbon Labeling)	Activity data related with recycling

3. Global warming impacts from the life cycle of a concrete structure

3.1 Production stage





3.1.1 Calculation of the amount of concrete

First, when the concrete compressive strengths of 24, 40 and 60MPa to be assessed are applied to the buildings with the same structure, the following conditions are assumed in order to compare the changes in the amount of concrete inputs with increasing compressive strength.
The structural safety against the lateral load with different wall thickness for concrete compressive strength was examined on the basis of the conditions above, and the amount of concrete inputs in the area of walls was calculated. The results showed the concrete inputs of 3,032.2 ㎥, 2,490 ㎥, and 2,110.7 ㎥ were required to sustain the compressive strengths of 24MPa, 40MPa and 60MPa, respectively. In other words, as the compressive strength of concrete, that is applied to the same structure, increased, the amount of concrete decreased by about 18% at 40MPa, and about 30% at 60MPa, compared to the value at 24MPa.

Table 5: Building Condition for Quantity Survey by Compressive Strength

	Contents			
Building Summary	◦ Structure Type : Reinforced concrete structural wall system ◦ Building Size : 3 stories below and 25 above the ground (305 ㎡/level)			
Wind Load	◦ Basic Wind Velocity : Vo = 30m/sec (Incheon) / Various Roughness Ratios “B” ◦ Power Law Exponent(Kzr) : (Z≤Zb => 0.81) , (Z>Zb => 0.45zα) ◦ Topographic Wind Speed-up Factors(Kzt) : 1.0 ◦ Importance Factor of building use (Iw) : 1.0			
Seismic load	◦ A = 0.176(0.22x0.8), ◦ Ie = 1.2, ◦ R = 4.0, ◦ Ωo = 2.5, ◦ Cd = 4.0, ◦ Ground Type : SC ◦ Earthquake-resistant System : R.C. structural shear wall for X, Y ways ◦ T-value Calculation Formula : X way = 0.049(hn)(3/4) , Y way = 0.049(hn)(3/4)

	External Wall	250mm	200mm	180mm
	Internal Wall	200mm	180mm	150mm

Table 6: Architectural and Structure Plan of Assessment Target

Architectural Plan	Structure Plan
	

3.1.2 Characteristics of carbon emissions at the production stage

Carbon emissions at the production stage can be calculated by summing the amount of the raw material applied for the concrete structure and the multiplication of the material by its carbon dioxide emission factor. The amount of raw material was calculated using the mixture design used earlier for each concrete compressive strength and the carbon dioxide emission factor of each raw material inputs was based on the global warming potential of the environmental information database (LCI DB).

Table 7: Comparison of CO_2 Emission on Production stage

Strength	Concrete Quantity	CO_2 Emission($kgCO_2eq$)				
		Aggregate	Sand	Portland Cement Type 1	Water	Total
24MPa	3,032.2 ㎥	18,765 (1.90%)	6,329 (0.64%)	960,092 (97.45%)	59 (0.01%)	985.244 (324.93 $kgCO_2eq/㎥$)
40MPa	2,490.0 ㎥	14,830 (1.34%)	4,505 (0.41%)	1,083,479 (98.24%)	46 (0.00%)	1.102.860 (442.92 $kgCO_2eq/㎥$)
60MPa	2,110.7 ㎥	12,697 (1.46%)	3,599 (0.41%)	852,402 (98.12%)	40 (0.00%)	868.738 (411.59 $kgCO_2eq/㎥$)

In the case of concrete walls with a compressive strength of 24MPa, the carbon emissions appeared to be total 985,244 $kgCO_2eq$ in which the emission by cement, which was 960,092 $kgCO_2eq$, accounted for 97.45% of the total emissions. In the case of 40MPa, the carbon emissions were shown to have total 1,102,860 $kgCO_2eq$ accounted for 98.24% by cement of the total emissions. For 60MPa, the emissions appeared to be total 868,738 $kgCO_2eq$ accounted for 98.12% by cement of the total emissions.
The total amount of emissions was greater at the compressive strength of 40MPa compared to the compressive strength of 24MPa because the amount of cement inputs was considered to be large.

3.2 Construction stage

Carbon dioxide emissions at the construction stage mainly occur during the processes of transporting materials to the site and using construction equipments.
In this assessment, however, the carbon dioxide emissions generated during the transportation process are excluded, and the carbon dioxide emissions arising from the construction process are limited only to the emissions by the oil energy that is consumed in the casting process on site using a concrete pumping equipment.

Table 8: Comparison of CO_2 Emission on Construction stage

Strength	Concrete Quantity	Pump Car Capacity	Pump Car Working(hr)	Pump Car Diesel Consumption (L)	GHG Emission Unit of Diesel	CO_2 Emission ($kgCO_2eq$)
24MPa	3,032.2 ㎥	80 ㎥/hr	37.9	625.39	2.66E+00 $kgCO_2eq/L$	1,664
40MPa	2,490.0 ㎥	Diesel Consumption	31.13	513.56		1,366
60MPa	2,110.7 ㎥	16.5L/hr	26.38	435.33		1,158

In the calculation results, the carbon emissions by a concrete pumping equipment appeared to be 1,664 $kgCO_2eq$ for the case of concrete walls with a compressive strength of 24MPa, 1,366 $kgCO_2eq$ with 40MPa, and 1,158 $kgCO_2eq$ with 60MPa. Since the increase in the compressive strength of concrete induces the decrease in the total amount of concrete pumped into a structure, the carbon emissions arising in the construction process are also considered to be reduced.

3.3 Use Stage

In this assessment, the use period of structures was assumed to be 60 years for compressive strength concrete with 24MPa and 120 years for high compressive strength concrete with 40MPa and 60MPa. In order to compare the environmental burdens generated during the assessment period, it was assumed that the concrete structure with 24MPa has undergone demolition and reconstruction once during 120 years of the total use period of the structure, and maintenance or demolition has not occurred in the case of the compressive strengths of 40MPa and 60MPa. However, as in the construction stage, scenarios for transportation were excluded.
The comparison results of the environmental burdens of a concrete structure by compressive strength at the use stage are shown in Table 9. Only in the concrete walls with a compressive strength of 24MPa, the carbon emissions due to the reconstruction process was generated additionally by total 986,907 $kgCO_2eq$ during the use period.

Table 9: Comparison of CO_2 Emission on Use & Maintenance stage

Strength	Concrete Quantity	Assessment Period	Rebuilding	CO_2 Emission($kgCO_2eq$)		
				Materials for Rebuilding	Reconstruction	Total
24MPa	3,032.2 ㎥	120 year	1	985,244	1,664	986,907
40MPa	0		N/A	0	0	0
60MPa	0		N/A	0	0	0

3.4 Disposal stage

In principle, the environmental burdens associated with the use of equipments in the deconstruction, and the burdens in the transportation and disposal process of construction wastes, should be considered together. However, for this assessment, only the carbon dioxide emissions occurred during the disposal processes after deconstruction are taken into account.
In the case of recycling or landfilling concrete waste occurred after 120 years of use period, the carbon emissions due to the disposal of walls with 24MPa were 2,776 tonCO_2eq, 1,090 tonCO_2eq with 40MPa, and 897 tonCO_2eq with 60MPa. The carbon emissions arising in the disposal stage appeared to be more than three times higher in general compressive strength concrete with 24MPa, as compared to 60MPa concrete, because the amount of wastes increased due to the reconstruction in the use period.

Table 10: Comparison of CO_2 Emission on End of Life stage

Strength	Concrete Quantity	Assessment Period	Waste Concrete(ton)		CO_2 Emission(kgCO_2eq)		
			Recycling	Reclamation	Recycling	Reclamation	Total
24MPa	6.064.4m^3	120 year	13,490	460	2,684,475	91,611	2,776,086
40MPa	2,490.0m^3		5,472	187	1,088,949	1,307	1,090,256
60MPa	2,110.7m^3		4,505	154	896,450	1,076	897,526

4. Results of the LCA

So far, the life cycle environmental burdens with varying compressive strength of concrete were analyzed from the perspective of carbon emissions. From the assessment results, it was found that in the walls built with a concrete compressive strength of 24MPa, total 6,064.4 m^3 concrete was consumed over 120 years of assessment period and the total amount of carbon emissions was estimated to be 4,749,901 kgCO_2eq. In the case of 40MPa, total 2,490 m^3 concrete was consumed and the total emissions was estimated to be 2,194,482 kgCO_2eq. In the case of 60MPa, total 2,110.7 m^3 concrete was consumed for 120 years and the emissions estimated 1,767,422 kgCO_2eq. Due to the difference of durability by compressive strength, about 54% of carbon reduction over the life cycle of 120 years was shown in the walls with high compressive strength of 40MPa, compared to the walls with general compressive strength of 24MPa, and about 63% carbon reduction appeared in the 60MPa walls.

Table 11: Comparison of Life Cycle CO_2 Emission by Concrete Compressive Strength

Strength	Concrete Quantity	Assessment Period	CO_2 Emission(kgCO_2eq)				
			Production	Construction	Use & Maintenance	End of Life	Total
24MPa	6.064.4m^3	120 year	985,244	1,664	986,907	2,776,086	4,749,901
40MPa	2,490.0m^3		1,102,860	1,366	0	1,090,256	2,194,482
60MPa	2,110.7m^3		868,738	1,158	0	897,526	1,767,422

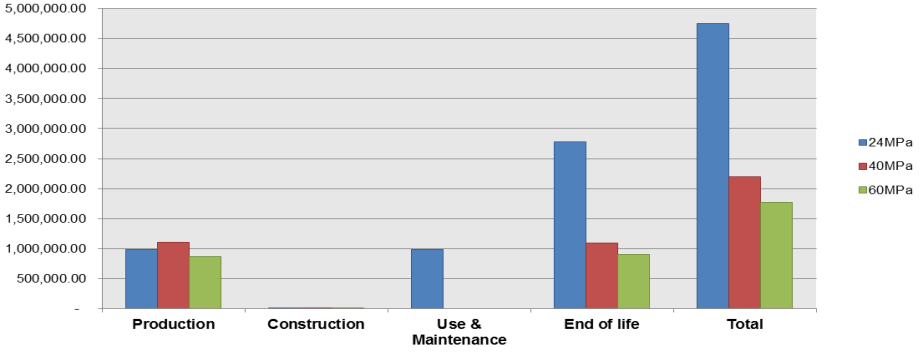

Fig. 2: Comparison of CO_2 emission by Compressive Strength

5. Conclusions and Further Studies

The following procedures and assumptions were applied for analyzing the characteristics of carbon dioxide emissions of concrete structures with varying compressive strength of concrete.

(1) Performance requirements including size, wind load and seismic load were set to maintain the same structural performance in a 25-story apartment housing.
(2) After setting the compressive strength of concrete with three types of 24Mpa, 40Mpa and 60Mpa, and calculating the amount of wall for specific compressive strength required for the same structure performance, the emission factors for each material were applied. At this time, the use period of structures was set to 120 years.

As a result of analyzing the global warming effects of concrete structures for specific compressive strength calculated by the procedures above, the following conclusions were obtained.

(1) At the production stage, the carbon emissions appeared to be higher in the concrete structure with 40MPa, compared to the structures with 24Mpa and 60Mpa, implying that large cement inputs influenced the emissions.
(2) At the construction stage, the carbon emissions appeared to be 1,664 kgCO2eq for the case of concrete walls with a compressive strength of 24MPa, 1,366 kgCO2eq with 40MPa, and 1,158 kgCO2eq with 60MPa. The results indicate the increase in the amount of concrete also increases the carbon emissions.
(3) The concrete structure with 24MPa was assumed to undergo one time reconstruction during the service life of 120 years at the use stage, resulting in increased emissions as in the production stage.
(4) At the disposal stage, the carbon emissions increased with increasing concrete inputs, implying the concrete structure with 24MPa made high environmental impact.
(5) For the carbon dioxide emissions during the life cycle, due to the difference of durability by compressive strength, about 54% of carbon reduction over the life cycle of 120 years was shown in the walls with high compressive strength of 40MPa, compared to the walls with general compressive strength of 24MPa, and about 63% carbon reduction appeared in the 60MPa walls.

As results of analyzing major environmental impact factors at each stage of the life cycle, it is found that the amount of cement input appears to be a major factor for the emission at the production stage, and the total amount of concrete at the construction stage, durability of concrete at the use stage and the amount of concrete waste at the disposal stage.
Based on these results, further studies are needed to present optimum mix designs of concrete structures considering the durability and environmental impacts of concrete.

Short summary

The necessity of assessing and addressing the environmental sustainability of urban systems is becoming increasingly relevant due to growing urbanization across the globe, higher consumption in urban systems and related competition for finite resource stocks. In this study we present how fused urban metabolism (UM) and life cycle assessment (LCA) can be applied to assess the sustainability of urban system, taking into account up- and downstream activities directly or indirectly linked to the metabolism of urban systems. Further we apply the fused UM-LCA approach to assess the absolute environmental sustainability of large urban systems by relating the environmental sustainability performance of urban systems with global environmental burden boundaries quantifying pollution thresholds beyond which performance of global ecosystems services may be detrimentally affected.

Keywords: Urban metabolism, life cycle assessment, UM-LCA, planetary boundaries

1. Introduction

Urban metabolism (UM) has over the last 4 decades served as a credible means to assess the environmental performance of urban systems, however its purest form, 1st generation UM, only provides the magnitudes of non-standardized material and energy flows making it difficult to provide meaningful comparative analysis of the environmental performance of different cities. Independently over the last 3 decades emergy has been implemented as a 2nd generation UM analysis model by systems ecologists. However, due to its complex thermodynamic origin, the emergy based UM models are opaque and are at a disadvantage to communicate results to the public and policy makers alike. In the present study we introduce 3rd generation UM, relying on the coupling of UM and full-scale (i.e. complete indicator set) life cycle assessment (LCA), the UM-LCA fusion approach.

The UM-LCA coupling was tested out on existing UM studies covering 5 major urban areas [1]. The results of this UM-LCA application study clearly underline that the UM-LCA coupling facilitates comparison across cities, mainly due to the ISO standardized LCA framework. Further the study by [1] reveals that the major sustainability burdens of cities are not related to the impacts within the cities but occur up- and downstream of the cities showing that the major impacts are embedded within the provision of energy and goods for consumption in the cities and the waste and goods excreted by the cities. Furthermore, the representation of an urban environmental loading with common indicators (e.g. global warming potential, particulate matter formation, etc)[1] appeared to improve communication of UM-LCA results over earlier UM methods.

Application of LCA for relation of product system impacts and planetary boundaries as suggested by [2] is still in its infancy [3] but the available data suggests that LCA can serve as a means to address the absolute sustainability of product systems and hence urban systems that consume those products. In this presentation we therefore propose a UM-LCA framework to assess the

absolute sustainability of urban systems, relating the climate burdens of the 5 urban systems assessed in [1] to the planetary climate boundaries suggested by [2] as a cursory example.

Cities as they currently function are simply not sustainable into the future. They are heavily reliant on other cities and beyond to provide material and energy resources, and dispose of waste [4]. In the process of this material and energy metabolism, cities interrupt the cyclical material flows of the biosphere and transfer them to the predominantly linear material flows in the technosphere (taking resources from the biosphere and returning them as waste to incompatible receiving areas) [5]. Cities take useful materials and largely relegate them to the landfill or the incinerator, which would not pose an issue if not for the fact that many of the planet's resources are finite, and that humanity is consuming them at an ever increasing rate as both the global economy and population grow [6]. Additionally, cities being the centres of economic growth [7] play an important role in the scale and direction of material flows [8]. Concurrently with their resource consumption cities are also disproportionately large producers of many forms of pollution [9]. Pollution problems in cities vary from the local to the global in their impacts. For instance the industrialization of Manchester 200 years ago has left contaminated soil and waterways that the city is still grappling with today [10]. In a global sense, cities are estimated to contribute upwards of 70% of greenhouse gas (GHG) emissions to the atmosphere [11]. Compounding these issues is the increasingly globalized economy, whereby the consumption of goods in a city in one part of the world can lead to negative local environmental implications across the planet at the point of extraction and processing [12], while at the other end of the consumption train, the exportation of waste to emerging economies, such as electronic waste, has become increasingly common in recent decades [13].

Urban areas are overwhelmingly absorbing population growth around the world through both domestic and international migrations [14]. Urban environmental pressures will increase parallel to the growth of the planet's urban population if current environmental trends continue, with an approximated 70% of the humanity expected to reside in urban environments by 2050, up from roughly 50% in 2008 [15]. The bulk of this rural to urban migration is going to occur in the transition economies, which will place increased pressures on an already stressed planetary ecosystem as new urbanites attempt to attain the same standards of living (and consumption) in line with the developed world [6]. Cities, the hyper-concentrated centres of human activity [16] represent both the problem and solution to global sustainability. Cities not only pose a looming environmental challenge, but they also represent areas where technological innovation and behavioural shifts can be implemented on large populations. In essence, an economy of scale with regards to the effects of sustainable policy can theoretically be achieved, as these policies can target large populations in condensed spaces. The predicted growth in urban population has additional benefits in that it will allow for sustainable urban development (SUD) policy to be implemented from the ground up, as the city grows. This provides the opportunity for planners in the developing world to avoid the difficulties of "technological lock-in" – whereby the socio-techno-economic systems support the use of an unsustainable technology to the point that it is difficult to displace [17]. Because of all of these reasons, SUD is not only important, but imperative, particularly in a world where estimated planetary boundaries for pollution and resource extraction are quickly being met [3]. Cities represent the battleground for the future sustainability of society.

2. Methodology

In this study we, based on the results presented by [1], illustrate how fusion of the Life Cycle Assessment (LCA) framework and the UM methodology can provide a more complete description of the environmental impact profiles of 5 major case cities and how the fused UM-LCA methodology addresses some of the existing issues in UM practices. Further, we illustrate how the results obtained applying the fused UM-LCA methodology can be used to relate the environmental sustainability performance of cities to the planetary boundaries as those presented by [2].

2.1 Case cities

For the application of the fused UM-LCA methodology presented here, 5 case cities were chosen. The case cities are all major capitals and presented in table 1.

Table 1: Characteristics of the 5 case cities to which the fused UM-LCA methodology is applied during the years modelled.

City	Population (millions)	Population Density (inhabitants/km2)	GDP (billions Year 2000 USD)
Beijing (2006)	17.1	1016	85.2
Cape Town (1997)	3.0	1239	18.9
Hong Kong (1997)	6.6	6480	169
London (2000)	7.4	4978	211
Toronto (1999)	5.07	858	160

2.2 Urban metabolism

Urban Metabolism (UM) is becoming an increasingly popular framework, due to its novel aim of providing a complete measure the environmental loading incurred by the total sum of city's activities. Though UM has only come into vogue in the past decade, it is one of the oldest tools for quantifying the environmental impacts of urban areas [18]. UM is gaining greater traction with policy makers around the world and is being considered a serious methodology for municipalities to track their sustainability. UM was developed in the 1960s, whereby a city was viewed as analogous to an organism in that it requires flows of material and energy inputs to sustain functions and grow, while at the same time generating waste as a by-product [19]. Much like an organism, this process of consuming matter and energy to sustain life functions in a city, is termed the city's metabolism. The concept is very much akin to material flow accounting (MFA), but performed on the scale of the urban agglomeration. Astonishingly, the principles of the UM method in the original paper have seen little advancement in the convening 45 years. An enlargement in the number of flows included have been made, and the accounting methods have been updated to reflect agreed upon standard methods [20] but essentially, the method has remained primarily focused accounting the annual direct mass and energy flows through a city. The field of UM has not remained completely static since its development. A second school of UM studies which integrates Odum's thermodynamic concept of emergy (a method that accounts for the embedded solar energy in material and energy flows) emerged in the 1970s [21]. The UM method has waxed and waned in popularity since its introduction, but it has seen a resurgence in popularity, mainly from a school of researchers based in China who primarily use it as a tool for assessing the SUD of Chinese cities. Another indirect development of the UM method has been the birth of the Ecological Footprint (EF) framework. This framework is very similar to UM in that it quantifies the flows of material into a city over a year, however it differs from the MFA method in that it converts these flows from mass to the global hectare [22]. Though originally intended for use on national accounts, it has been routinely applied to cities, and can be considered an unofficial extension of the UM method. Because the core of UM studies are firmly rooted in the concept of capturing only direct mass flows, they remain unable to fully assess SUD.

One failure is that by only accounting for masses directly consumed by the city, current UM studies neglect those masses utilized in processes upstream necessary to provide the direct mass flows consumed [8]. Secondarily, mass flows are incommensurate with environmental loading, and therefore do not form a proper basis for assessing the environmental sustainability of a city [23]. Shortcomings in the current UM framework highlight the need for methodological advancements that can both, capture the upstream flows not being quantified now, and transform the quantified masses into indicators that better represent their environmental loading. Capturing upstream flows has been addressed to an extent by the emergy and EF assessment methods. However, this success remains limited in the amount of upstream flows these methods can account for and the limited number of downstream pollutants they model [22, 24]. Additionally, the esoteric concept of emergy is difficult to convey to both policy makers and the public, limiting its practical application to SUD. Thus, major methodological gaps remain in the UM tool, and complimentary improvements are necessitated to bring it to the level that it can be applied to properly quantify SUD. Moreover, if

the goal of UM is to provide indicators to properly inform SUD policy decisions, then current deficiencies must be addressed, otherwise by providing incomplete or erroneous results UM risks being of little utility to policy makers, or worse, counteractive to SUD. Given the importance of SUD and its potential contribution to overall global sustainable development, it is necessary to quantify the environmental loading of cities [14]. UM can contribute to this end, but as outlined above, the method is currently immature.

Urban metabolism has been described as “the sum total of the technical and socio-economic processes that occur in cities, resulting in growth, production of energy and elimination of waste” [25]. In essence, urban metabolism uses analogies from biology to liken a city to an organism. Thus, cities are perceived as entities requiring resources in the form of metabolic fluxes that are required to maintain human activities and provide for growth [26]. Accordingly, urban metabolism is focused on quantifying flows of materials and energy into cities, and the resulting wastes out of cities. The flows of materials through societies have been an interest of economists and philosophers (eg. Marx and Malthus) since the 19th century [27], the concept was not crystallized to the scale of the city until 1965 by Wolman as outlined in his seminal work that studied a hypothetical American city of 1 million inhabitants [19]. Though crude in its formulation, this study provided the framework of all future urban metabolic studies. In the three decades following the publication of Wolman’s study, only a dozen or so urban metabolism projects were completed, however since the mid-1990s the field has seen a renaissance as a topic of renewed research by a number of engineers, systems ecologists and environmental scientists [8].

2.3 Life Cycle Assessment

‘LCA is a methodology for assessment of the environmental effects of a product or service throughout all stages of its life. Potential impacts are gauged quantitatively, and the perspective can be holistic – from ‘cradle to grave’ – depending on the assessor’s goals [28]. LCA developed over a two-decade period due in part to the economic interest of large corporations to realize greater material efficiencies in production processes [29] or to assist decision making of clearly defined product end goals [28]. It was not until the publication of the Centrum Milieukunde Lieden (CML) LCA handbook in 1992 that a worldwide standardization of the science began to take shape.

By providing quantification of the resource use and release of pollutants to the environment LCA can be applied to [30]:

- Finding where material and energy optimizations can be made along a life cycle
- Identifying phases in a life cycle that are environmentally problematic
- Comparing and choosing between existing and new product/service designs
- Benchmarking the environmental impacts of a product or servces

As the science has become increasingly regimented, it has also proliferated in the scope of its application. LCA is now a popular choice of environmental assessment tool for a wide range of decision makers including academics, private firms, NGOs and policy makers [31]. The framework of LCA remains a work in progress as the field continues to harmonize. A major step in this direction was the establishment of an international standard [32]. Guidelines for the practice of LCA have also been released to compliment the ISO standard, most recently the International Reference Life Cycle Data Reference System [33] or the earlier work of others [30]. Additionally on the international level, projects by the United Nations Environmental Program (UNEP) and the Society of Toxicology and Chemistry (SETAC) aim to further build consensus in the field [31]. LCA consists of four separate phases intended to track the impacts of a product or process from raw material extraction to disposal: Goal and Scope Definition, Life Cycle Inventory Analysis (LCI), Life Cycle Impact Assessment (LCIA) and Interpretation [33]. LCA is an iterative process that relies on communication between the phases and updating of information in accordance with the goals and data requirements set out for the process.

The LCA based comparison of products and services, works by assessing the flows associated with a functional unit. This is the process or service that must be fulfilled (eg. hold 500 mL of liquid, or transport a person 1000 km in a day, etc.). Thus, all calculations are related to the impacts

required to fulfil the functional unit.

2.4 Life Cycle Impact Assessment (LCIA)

Contrary to the UM methodology, the LCA methodology does not stop at the mass, direct material and energy exchanges with the environment. The flow results obtained in the LCI step can via an impact assessment methodology and accompanying characterization models be converted in to potential environmental impacts or damages. Results from a full LCA including the LCIA step are typically provided as predicted/potential environmental impacts resulting from the flows needed to fulfil the functional unit. These flows can be communicated as midpoint impacts which characterize predicted impacts in terms of specific environmental indicators (eg. global warming potential, terrestrial ecotoxicity, etc.). A second option is the use of endpoint indicators that are aggregations of midpoint impacts. Endpoint impacts communicate predicted effects of the system in of more general environmental and health issues (eg. ecosystem quality, damage to human health, etc.) [28].

The conversion of the flows, quantified in the LCI, to potential impacts is impact assessment methodology specific. In present study we apply one of the most recent and widely acknowledged methodologies, the ReCiPe methodology, see fig. 1 and [34]. LCA is a malleable framework in that optional steps can, as presented in fig. 1, be applied. These include converting predicted midpoint impacts to endpoints, normalizing predicted impacts to a reference quantity, or weighting and aggregating impacts to create a single score. As such, LCA can be tailored by practitioners to suit their needs, including providing information to support SUD policy development.

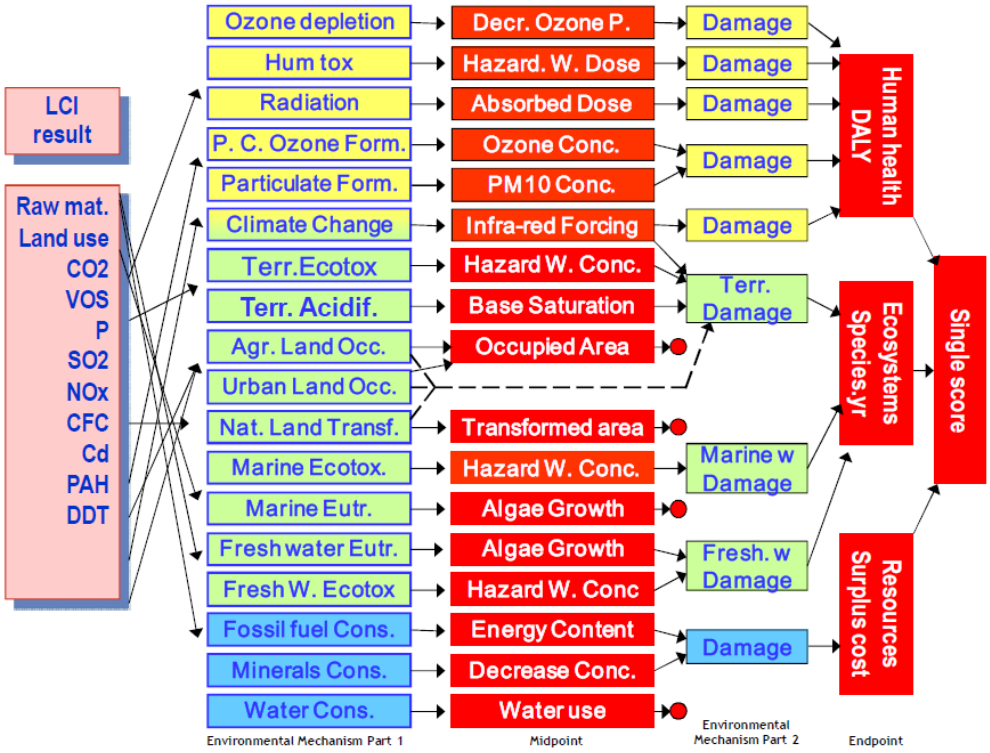

Fig. 1: The ReCiPe framework. From [34].

2.5 Fused urban metabolism and life cycle assessment (UM-LCA)

LCA is a widely applied QSA tool and the coupling of UM and LCA to most LCA practitioners seems obvious, thus, an LCA literature review was done to judge the novelty of the fused UM-LCA approach. Ensuring that LCA practitioners have not already covered this project in another form provides confidence that this study will not only be novel, but also provide an improvement to the field of UM. From reviews of previous LCA literature there appear to be only two papers which

attempted to assess the built environment with a full LCA. A study [36] of high and low density housing in Toronto using an economic input-output LCA, this case was limited in the sense that it only performed a carbon accounting of building materials, transport energy and operational energy inputs. The other study of study interest is the aforementioned 3rd Generation UM by [36] on Finnish cities. Both previous studies depart from the current one at hand in a number of key dimensions. Firstly, in both cases the LCA was was focused on carbon and energy accounting, not applying all of the potential LCIA (i.e. multiple impact categories), as will be done here. Moreover, the Toronto study only looked at hypothetical “built forms”, thus primarily serving as a conceptual model as opposed to an assessment of an existing urban system. Hence the coupling of UM and LCA presented here applying a full set of LCIA impact indicators is new and has never been performed before on existing urban environments.

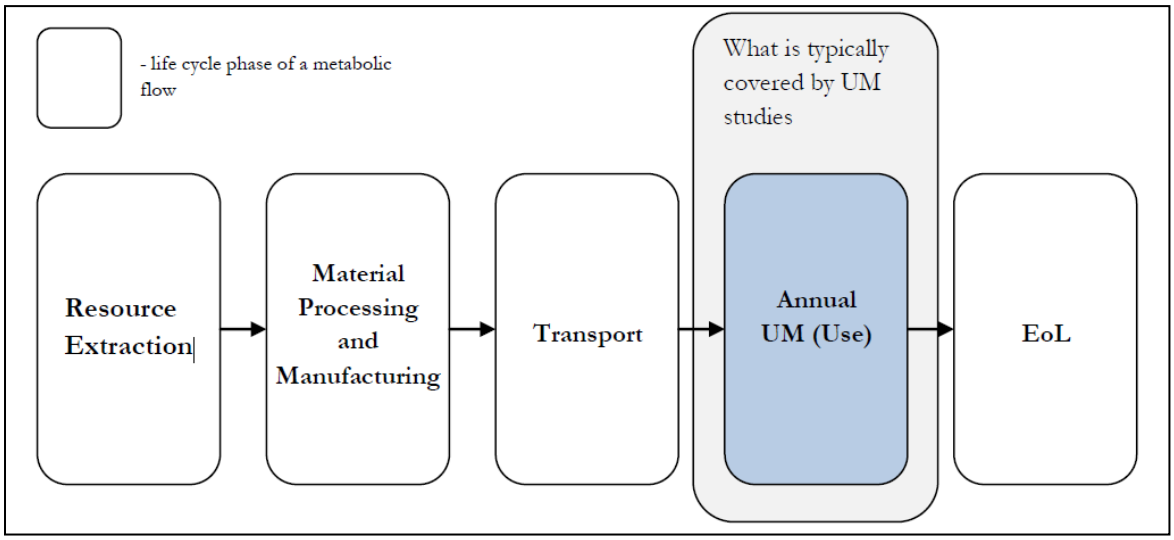

Fig. 2: Comparison of the UM and the UM-LCA coverage. From [1].

2.6 Planetary boundaries

The planetary boundaries as defined by [2] quantifies for a range of earth-system processes/impact categories, thresholds or rather planetary boundaries below which ecosystem services as we know them can be maintained, the boundaries quantified by [2] are listed in table 2. Since many subsystems of the earth react non-linearly or even abruptly, exceeding the planetary boundaries can according to [2] lead to bifurcations of some earth sub-systems such as e.g. the monsoon system shifts permanently into a new state with deleterious or even disastrous consequences for humanity. In the study at hand we solely try to relate the results obtained on the 5 case cities to the planetary boundary for climate change. The planetary boundaries for climate are presented in table 2.
keys are listed in table. 3

Table 2: Planetary boundary for climate change in atmospheric CO_2 concentration and radiative forcing change. From [2].

Earth-system process	Comment	Proposed boundary	2009 status
Climate change	(i) Atmospheric carbon dioxide concentration (parts per million by volume)	350	387
	(ii) Change in radiative forcing (watts per metre squared)	1	1.5

The planetary climate change boundary as presented in table 2 provides an absolute measure for sustainable life on planet earth in terms of global warming. Hence if humanity according to [2] can

maintain atmospheric carbon dioxide concentration below 350 ppm, the Earth should not experience abrupt changes in its sub-systems and hence avoid potential environmental disasters. The issue is that humanity already has transgressed the 350 ppm CO_2-eq. boundary and the question is hence how to get below this boundary again and avoid potential disaster. According to [37], there should be a 75 % chance to get below the climate change boundary again if the predicted 2050 global greenhouse gas (GHG) emissions are cut by 60 % compared to the global 1990 GHG emissions implying an atmospheric peak concentration of GHG gasses in the atmosphere of 470 ppm CO2-eq between 2010 and 2020. According to [37] should the global 2050 GHG emissions amount to app. 4 GtC-eq/year (equalling 14,4 GtCO2-eq/year).

Combining the data from [2] and [37] hence provides us with absolute sustainability measures in the form of global CO_2 "boundary quotas" for sustainable life in 2050. The boundary quotas can be calculated according to various allocation keys and thereby provide political angle specific SUD measure for climate change. In this study we apply two CO_2 quota allocation keys; an egalitarian (E) key allocating the CO_2 quota equally based on population number (i.e. each person receives same share) and an individualist (I) allocation key allocating the CO_2 according to GDP (i.e. the higher the GDP the higher the city quota). For a more thorough introduction to political perspective specific sustainability analysis, please see *[34].* The CO_2 sub-quotas allocated according to the two

Table 3: Planetary boundary based and city specific 2050 CO_2 quotas, allocated according to an egalitarian (E) and individualist (I) allocation key. Allocation keys based on data from table 1, a global population in 2000 of 6.188 billion people [38] and a world GDP in 2000 of 32,334 billion US $ [38].

City	CO_2 quota (E) $MtCO_2$-eq/year	CO_2 quota (I) $MtCO_2$-eq/year
Beijing	40.2	37.9
Cape Town	7.2	8.4
Hong Kong	15.6	75.3
London	17.4	94.0
Toronto	11.9	71.3

3. Results

Applying the fused UM-LCA the impact potentials normalized per capita were initially calculated in order to compare the city performances across a variety of impact categories, thereby facilitating the comparison of the environmental burdens related with the metabolisms (i.e. consumptions and excretions) of each of the cities covered by our study.

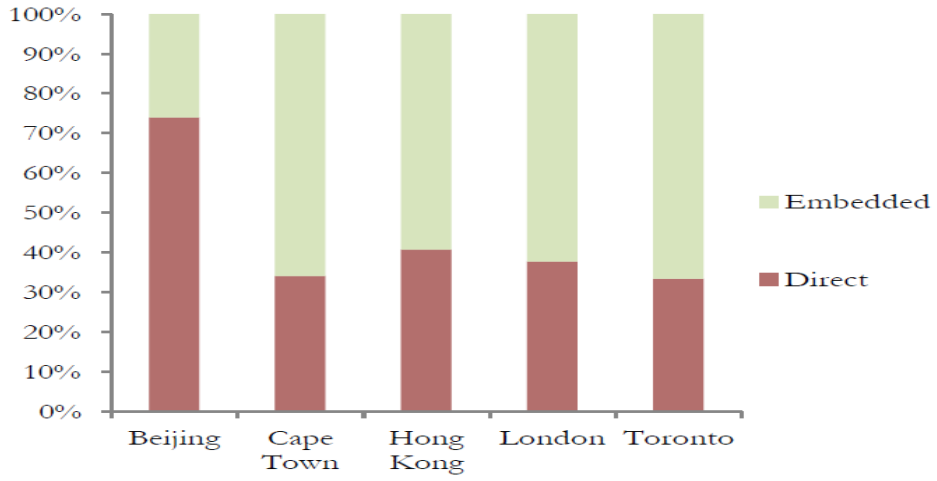

Fig. 3: Proportions of the mass flows covered by conventional UM (direct) as well as the fused UM-

LCA approach and mass flows solely covered by the fused UM-LCA approach (embedded).

The fraction of potential impacts covered by the conventional UM approach compared to the fused approach (please see fig. 2) can by visualized by the fraction of mass flow occurring within the urban area (direct) and up- or downstream of the urban area (embedded) as presented in fig. 3.

Applying the fused UM-LCA methodology allows, due its process based nature, for quite detailed analysis of the origin of potential impacts, fig. 4 illustrates this point by highlight the activities contributing the most to impact profile of the city.

Table 4: Midpoint impacts for the 5 case cities. PMF = Particular Matter Formation, POF = Photochemical Oxidant Formation and pr. = per resident. Highest value within each midpoint impact is marked in bold

Midpoint Impact	Beijing	Cape Town	Hong Kong	London	Toronto
Agricultural land occupation [m2a/pr.]	1700	1500	2200	**3300**	2700
Contribution to GWP [t CO2-eq/pr.]	17.1	11.2	10.2	12.2	**18.0**
Fossil depletion [t oil eq/pr.]	4.8	2.3	3.1	3.6	**4.9**
Freshwater ecotoxicity [kg 1,4-DB eq/pr.]	**170**	62	31	36	43
Freshwater eutrophication [kg P eq/pr.]	**0.88**	0.33	0.35	0.29	0.51
Human toxicity [t 1,4-DB eq/pr.]	**1.9**	1.0	0.8	0.4	0.6
Marine ecotoxicity [kg 1,4-DB eq/pr.]	134	42	**672**	19	22
Marine eutrophication [kg N-Equiv./pr.]	**26**	13	20	12	18
Metal depletion [t Fe eq/pr.]	**8.2**	0.4	0.7	0.7	0.8
Natural land transformation [m2/pr.]	2.33	1.42	2.83	2.02	**2.86**
Ozone depletion [g CFC-11 eq/pr.]	0.83	0.36	0.42	**2.78**	1.39
PMF [kg PM10 eq/pr.]	**42**	18	18	11	16
POF [kg NMVOC/pr.]	**60**	29	42	25	34
Terrestrial acidification [kg SO2 eq/pr.]	**106**	56	54	34	54
Terrestrial ecotoxicity [kg 1,4-DB eq/pr.]	**5.2**	5.0	5.3	2.3	4.5
Urban land occupation [m2a/pr.]	355	206	349	217	**408**
Water depletion [m3/pr.]	22900	9400	8400	10600	**114900**

Based on the annual GHG emissions from the 5 cities and the planetary boundary determined CO2 quotas presented in table 3, the GHG emission reductions needed by 2050 can be calculated.

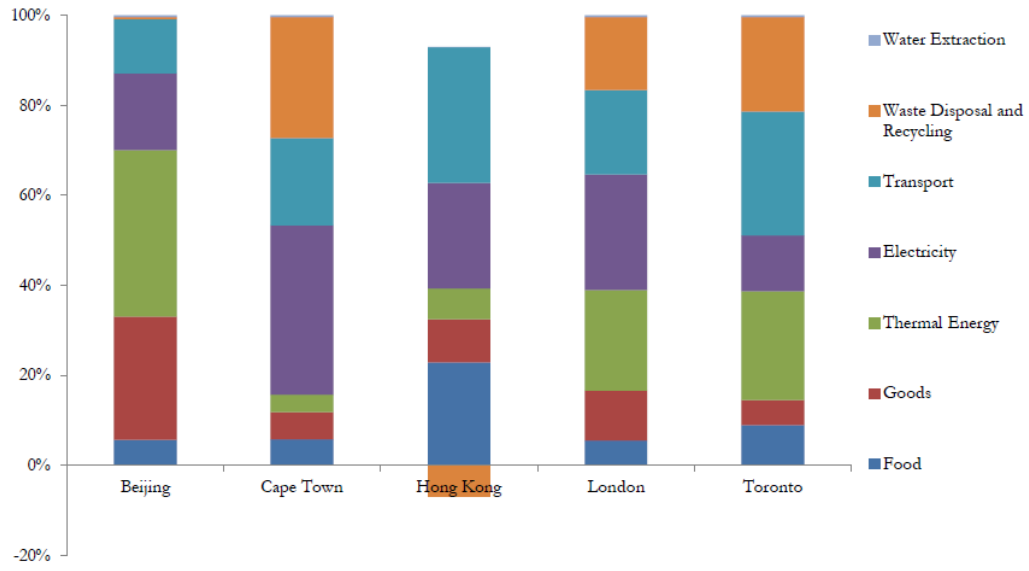

Fig. 4: GHG emission hot spot analysis of the 5 case cities.
The annual GHG emissions and needed emission reduction for the 5 case cities are presented in table 5.

Table 5: GHG emissions reductions quantified by the planetary boundary for climate change quantified by [2] applying the fused UM-LCA approach and two sets of political perspective determined CO_2 emission quotas allocation.

	Beijing	Cape Town	Hong Kong	London	Toronto
Contribution to GWP [Mt CO2-eq/year]	291.9	34.1	67.5	90.3	91.3
Emission reduction needed by 2050 - egalitarian allocation of CO2 boudary quotas (%)	86.2	79.0	76.9	80.7	86.9
Emission reduction needed by 2050 - individualist allocation of CO2 boudary quotas (%)	87.0	75.3	-11.5	-4.1	21.9

4. Discussion

The application of UM and LCA in combination to assess and quantify the environmental burdens of urban systems appears, as presented above, promising. One major issue relating to the comparison of urban environments is the question of whether the comparison is following the basic LCA requirements and hence if the assessment is based on comparison of the same functional unit. The services provided by the 5 cities compared in this study are basically seen as the same since the essential services the cities delivers to the citizens are the same (i.e. provision of an urban system), the quality of this service however differs tremendously across the compared the cities, which cannot be accounted for by the UM nor the UM-LCA approach.

Comparing UM studies is difficult due to the non-standardized manner in which UM studies are performed. The lack of an “UM standard” clearly introduces a considerable source of comparison error, since the UM assessors are given a large “artistic freedom” to e.g. include and exclude flows contributing to an urban metabolism. A similar problem has been encountered in LCA. In order to ensure that LCA studies are comparable an ISO standard on the general LCA framework was published in 1996 [39], thereby laying the basic validation criteria for the any LCA, and thereby providing standardized guidance on e.g. goal and scope definition, inventory analysis (i.e. analysis of exchanges between technosphere and ecosphere), impact assessment and interpretation of assessment results.

Fusing the UM and the LCA methodology may seem as a further complication of the assessment of urban systems. The midpoint results presented in table 4 on the other hand reveals that by combining the two methodologies, midpoint impact indicators facilitate comparison of assessment results across the cities. Since one of the major deficiencies of the MFA based UM approach is the problems relating to the comparison of various forms of mass flows (e.g. comparison of steel and concrete flows). At the same time we find that the midpoint impact indicators presented in table 4, are generally easier to communicate than emergy based UM results since it is possible for people, with some guidance to relate to the individual impact categories. Hence fusing UM and LCA facilitates inter-city and inter-study comparisons of results and further enhances the communication of the assessment results compared to emergy based UM results.

Applying the fused UM-LCA approach ensures a holistic approach, by taking into account the up- and downstream exchanges between the urban system and the ecosphere, and hence facilitates the coverage of the complete system. This approach decreases the likelihood of burden shifting by shifting, whereby environmental burdens from direct to embedded flows (i.e. moving environmental burdensome processes up- or downstream as illustrated in fig. 2, by e.g. moving concrete production upstream and hence out of the urban system). As presented in fig. 3 are the majority of ecosphere-technosphere exchanges related to cities metabolisms located up or downstream of the urban system and hence outside the scope the conventional UM framework.

The process nature of the LCA part of the fused approach facilitates, as presented in fig. 4, easy in-depth analysis of the assessment results and streamlined identification of the activities contributing most to the pallet of impact categories included in any given study applying a LCIA methodology. As presented in fig. 4 can the varying importance of problematic processes such as e.g. energy provision be tracked across the impact profiles of the cities.

Accounting for the environmental burdens of large complex socio-technical systems such as nations, cities or large companies may in some instances require discounting/cut-off of impacts being passed on up- or downstream to the final consumers who may reside in geographically disparate regions. The problem relating to the standardization of accounting for “trading of environmental burdens” has, primarily based on the carbon accounting trends, is not new and has been dealt with in LCA, most recently by the European Commission [40]. Hence standardized approaches for allocating environmental burden trading are already implementable in LCA context and hence these standard approaches could easily be applied to the fused UM-LCA approach, thereby providing guidance with how to deal with this difficulty.

In the present study it was chosen to assess the cities applying mid-point indicators. Comparing cities across the 17 impact indicators is as is evident from table 4 a complex task. Absolute ranking of cities based on the 17 impact categories included in present study is impossible, without weighing the individual impact categories. The ReCiPe methodology includes, as presented in fig. 2, two additional impact assessment steps, endpoint assessment (i.e. quantifying the damage caused by the exchanges between the technosphere and ecosphere) and single score assessment (i.e. aggregating the mid-point impacts via the end-points to single scores), see fig. 1 and [34]. Despite the fact that single scores are related to some subjective interpretation of impact category prioritisation (and related uncertainty), it does allow for comparative ranking of cities in terms of environmental sustainability.

On the other hand, single-score based assessments allow for comparison of the impact assessment result with absolute sustainability measures such as the planetary boundaries presented by [2]. Comparison of the UM-LCA results of the cities with absolute sustainability indicators provides an initial quantification of the sustainability of the case cities relative to environmental tipping points, and hence, the limits of the environmental loads that these urban areas can place on the ecosystem before they become incommensurate with the populations or economic activity they support. However, as presented in table 5, it remains to be seen whether the allocation of absolute sustainability measures allow for various more or less true/objective depictions of the environmental sustainability performance of urban systems. Judging from the egalitarian perspective, the data in table 5 indicates that, for the case cites, avoiding crossing the planetary boundary is related with considerable effort (77-87 % reduction of GHG emissions) however also that this goal in term of CO2 emission reduction seems plausible for all cities. Moreover, the need for some cities (Beijing, Cape Town and Toronto) to reduce GHG emissions based on the Individualist approach, shows that their economies are sub-optimized for environmental performance.

5. Conclusions and comments

The UM methodology has a number of research needs that until now have been largely discussed but not addressed; a narrow scope not addressing up- and downstream impacts of a cities metabolism and inter-city and inter-study incomparability of different mass and energy flows. Combining UM and LCA seems to attenuate these weaknesses by introducing a holistic scope and ensuring inter-city and inter-study via standardized sets of impact indicators.

The fused UM-LCA approach further allows for comparison with planetary boundaries and evaluation of cities performance relative to the earth carrying capacity in terms of environmental deterioration/pollution.

Present study had to be based on more or less fragmented data sets and the fused UM-LCA approach hence needs further validation.

Short Summary

In Northern European countries, the transformation of prevailing systems to supply and use energy for heating residential buildings is considered a major challenge in urban development. Ongoing renewal and growth in the residential building stock allows increasing energy efficiency by introducing new buildings standards. By additionally encouraging alternative sources for heat supply such as geothermal and solar energy, a significant reduction of greenhouse gas emissions seems feasible. To evaluate options and conditions favourable for such a development, we developed a spatial explicit, dynamic model for the transformation of the residential building stock. This model was used to assess energy demand and greenhouse gas emissions for heating the residential buildings in the City of St. Gall and analyse alternative scenarios for future development. The model incorporates the communal energy plan as well as empirical data of 50 refurbishment projects (estimates for construction costs and gains in energy efficiency). Model-based scenario calculations show that the City of St. Gall can reach its ambitious goals in energy policy within the next 50 years. However, the municipality and private property owners have to provide substantial funding and make a great effort in refurbishing their old building stock.

1. Introduction

In Switzerland, the operation of buildings built between 1950 and 1980 is of growing importance in the overall urban energy demand. While new constructions become more and more efficient in heat demand and supply – encouraged by regulations as well as technological development – refurbishment of older buildings is often limited to minor improvements in energy standards (see [1], [2] and [3]).

In recent years, however, many municipalities have set themselves ambitious goals in energy policy. One example is the «2000-Watt-Society» which has become a guiding principle for a number of cities in Switzerland such as Zurich, Bale, Geneva, Winterthur or St. Gall aiming at a reduction of individual energy demand to approximately one third of today's demand. The Swiss Association of Engineers and Architects (SIA) has introduced guidelines and tools for planning in the so called «Energy Efficiency path» [4].

[5] and [6] accentuate the need for urban renewal determined to significantly increase energy efficiency in heat consumption if such ambitious goals are to be reached. In addition, [7] claims the necessity to increase the use of renewable energies. He introduces a concept called «Zero-

Emission Low-Ex Architecture» combining the use of stationary available heat (e.g. ground heat) with optimizing energy efficiency in heat transport, storage and use ([8]). Stationary available heat, thus, becomes an important parameter for planning processes in urban renewal. It can be defined in energy plans on communal level as described in [9] and combined with common instruments in spatial planning.
The challenge in urban renewal oriented towards a «2000-Watt-Society» lies in a pragmatic and goal-oriented combination of such tools and concepts. The development and application of empirically based, numerical models can help to encourage this development. To this aim, models have been developed in Germany (see [10] and [11]) and have also been applied in Switzerland (see [12]). Yet, they are not sufficiently adapted to data available on communal level in Switzerland and to common planning tools. A spatial explicit analysis of heat demand of residential buildings, for example, can be derived by combing data from official statistics with standard estimates from literature (see [13]). Information from communal energy plans can be used in modeling and results from model calculations can be fed into Geographic Information Systems (GIS) to generate spatially explicit representations of scenarios in future development.

In this paper, we introduce a model combing heat demand for residential buildings and the use of stationary heat in a settlement area that is adapted to data available on communal level in Switzerland and common planning tools. The model is applied for the city of St. Gall and used for a scenario analysis for urban renewal combing refurbishment and structural modification of residential buildings with the introduction of renewal energies for heat supply.

2. Method

The development of the built environment can be described in stock-flow-models (see e.g. [14]). The building stock is captured in floor area, built volume or settlement area. Its development causes costs and revenues as well as demand for energy, materials and waste management services. Such variables determined by the building stock development are described as flows of money, energy or material (in monetary or physical units). Their development depends on activities in construction, refurbishment, structural modification and demolition, comprised in the overall model of the buildings stock dynamics.

Stock-flow-models have been used to analyze a wide range of different questions ranging from development in real estate markets ([15], [16] and [17]), modelling heat demand for residential buildings ([18], [19], [20] and [21]) to modelling future demand for construction minerals ([22], [23], and [24]) and services for construction waste management [25], [26] and [27]).

In this paper, we introduce a stock-flow model for cumulative energy demand for non-renewable energies ($CED_{non\text{-}renewable}$) and greenhouse gas emissions (GWP) related to the heat demand of residential buildings. The cumulative energy demand of building materials, however, is not taken into account as recent studies revealed its minor importance in the overall energy demand of the building stocks current development (e.g. [6], [28] and [29]).

We assume that future heat demand of residential buildings depends on the development of heated area in buildings stock of specific construction and refurbishment periods and their energy standards given by the heat demand coefficient for each period. For spatial explicit representation of the model, each square meter of heated area is allocated to square cells of a 100 x 100 meter (hectare) creating a grid covering the entire study regions.

$$\mathrm{HWV}_t^j = \sum_{i=1}^{n} \mathrm{HA}_t^{ij} * \mathrm{HDC}^{ij} \quad (1)$$

HWV_t^j: Total heat energy at point t in cell j

HDC^{ij}: Heat demand coefficient for construction and refurbishment period i in cell j

HA_t^{ij} Heated area for the construction and refurbishment period i in cell j at point t

n Number of construction and refurbishment periods

To calculate $CED_{non\text{-}renewable}$, the heat demand of each cell j is multiplied with the weighted average of specific $CED_{non\text{-}renewable}$-coefficients for each energy carrier s used to provide heat in buildings allocated to cell j.

$$\mathrm{CED}_t^j = \mathrm{HWV}_t^j * \sum_{s=1}^{m} \mathrm{AN}_s^{jt} * \mathrm{CED_CE}_s \quad (2)$$

$\mathrm{CED_CE}_s$: $CED_{non\text{-}renewable}$-coefficients for each energy carrier s

AN_s^{jt}: Percentage of the energy carrier s to provide heat in cell j at point t

m Number of the energy carriers

GWP is calculated the same way, both using coefficients from [30].

[31] differentiate between two types of models. The first type assesses the development of the building stock – mostly based on either assumptions about the service life of buildings or building components ([34], [3] and [6]) or empirical evidence for construction and demolition activities ([31] and [33]). The second type describes the development of construction, refurbishment and demolition rates ([23] and [11]).

In our model, we use the first type of model to describe the development of heated area. We distinguish between periods of construction and refurbishment and assume that the building stock in this period is given by two inputs - new construction in this period as well as refurbishment activities transferring heated area from older buildings into this period – minus one output – heated area transferred from this period to an even more recent period by refurbishment activities.

$$\mathrm{HA}_t^{ij} = \mathrm{HA}_{t-1}^{ij} + \mathrm{NHA}_t^{ij} + \mathrm{CRA}_t^{ij} - \mathrm{HACR}_t^{ij} \quad (3)$$

HA_{t-1}^{ij} Heated area for construction and refurbishment period i in cell j at point t-1

NHA_t^{ij}: New built heated area for construction and refurbishment period i in cell j at point t

CRA_t^{ij}: In construction and refurbishment period i refurbished heated area of older construction periods in cell j at point t

HACR_t^{ij}: Heated area for the construction and refurbishment period i which are refurbished at point t in cell j

Refurbishment activities in each period are a function of the amount of heat area in the specific period, the average persistence time of heated area in this period and the time needed for transferring the building to more recent periods (by refurbishment).

$$\mathrm{HACR}_t^{ij} = f\left(\mathrm{HA}_{max}^{ij}, \tau_i, \kappa_i\right) \quad (4)$$

HA_{max}^{ij}: Maximum of total heated area in the construction and refurbishment period i in cell j

κ_i: Time period of the construction and refurbishment period i, within the buildings of the construction and refurbishment period are not refurbished

τ_i: Time period after the time period κ_i, within the buildings of the construction and refurbishment period are refurbished

A high degree of uncertainty is a common feature in all building stock models ([35]) because there is yet little empirical evidence of processes of urban renewal on a higher level of aggregation. Some models address this problem incorporating stochastic models for the distribution of key parameters (see e.g.[24] and [25]). Most models, however, use deterministic model approaches and discuss uncertainties in the interpretation results derived from model applications (e.g. [3]).

In our model, we use a deterministic model approach. It is shown in *Fig. 1* taking one period of construction and refurbishment as an example. In this example, the heated area is built up between 1940 and 1960 and remains untouched by refurbishment activities relevant of heat demand until 1990 (persistence time (κ_i): 30 years). Starting 1990, buildings containing this heated area improve their energy standards due to refurbishment activities. Step by step their heated area is transferred to more recent periods of construction and refurbishment characterized by energy standards corresponding to technological standard of the period in which the refurbishment takes place. In these periods, the building stock grows accordingly. By 2030 almost the entire building stock is transferred from the period 1920-30 to more recent periods of construction and refurbishment (transformation time (τ_i): 40 years).

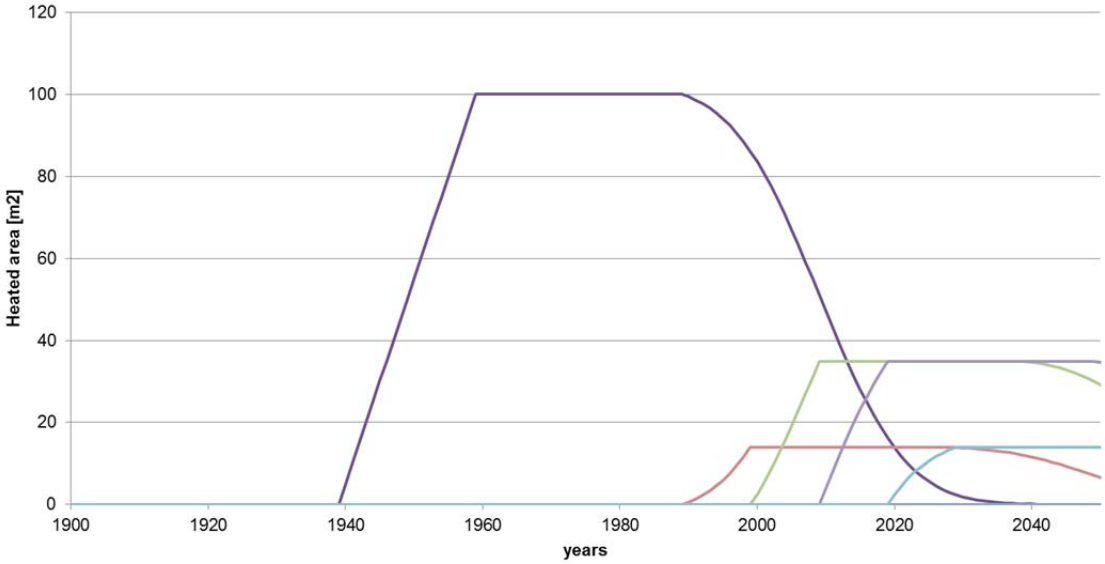

Fig. 1: Demonstration of the model on an example of a building with 100 m2 heated area (Source: own analyses)

One major challenge is the assessment of future technological development in heat supply. Technological development in general can be described with assumption about the diffusion process of innovations (see e.g. [5], [36] and [31]).
We use a similar approach describing the diffusion process with an s-curve presenting the substitution of one system to provide heat for residential buildings (e.g. combustion of fossil fuels) with an alternative system (e.g. geothermal energy). This s-curve is defined by a starting point of the substitution process α_{sj} and the time needed until 50% of the substitution has been completed (half-life period β_{sj}).

$$AN_s^{jt} = f(\alpha_{sj}, \beta_{sj}) \quad (5)$$

with

$$\sum_{s=1}^{m} AN_s^{jt} = 1 \quad (6)$$

α_{sj}: Time from t=0 to the beginning of spreading the energy carrier s in cell j

β_{sj}: Half-life period for the energy carrier s in cell j

In addition, we calculate the expected costs for refurbishment activities in each period by multiplying our results for heated area refurbished in this period with estimates for the related construction costs.

$$SK^l = SNF^l * Ssk \quad (7)$$

SNF^l: In time period l refurbished heated area

Ssk: Specific costs for refurbishment per m^2 heated area

3. Case study: city of St. Gall

The city of St. Gall is located in the east of Switzerland south of the Lake Constance. With a population of around 73'000 it is Switzerland's eighth largest city. The city's population density is comparatively low: St.Gall covers 40 km², of which around 50 percent is green space. 6 km2 of buildings and infrastructures are located in a valley. The valley bottom, situated 700 meters above sea level, is densely populated with the city's oldest buildings originating from medieval times as well as the 19th century when the city prospered due to texile manufacturing. Today, commerce and industry are mostly located at both entry points of the valley providing work for around 66'000 people, many of them commuting into the city from suburban areas. Municipal utilities provide for electricity and gas. District heating is supplied by the local waste incineration plant. Most buildings are heated by decentralized combustion of either gas or oil.

Yet, the city has set itself ambitious goals in energy policy: By 2050 authorities aim at reducing the demand of fossil fuels for heating by two-third of today's demand. They developed an energy plan to better coordinate activities in construction and the transformation of energy supply systems. The most important project is a geothermal power station providing heat for almost 40% of all buildings in St. Gall as well as electricity. In addition, the municipality encourages construction activities aiming at a significant increase of efficiency in production and use of heat in residential buildings by public consulting as well as public funding.

In our paper, we choose this case study to analyze how the introduction of new energy systems focusing of stationary available heat can be combined with promotion of construction activities to increase energy efficiency.
The city of St. Gall also provides an excellent data base to apply the model introduced in the previous section. The most important data base for model application is data on floor area or volume of buildings described in the model. Most models require a data set differentiating between important building characteristics such as construction period, building size or type of use. In Switzerland, the National Register of Buildings and Dwellings provides an appropriate set of geo-referenced data that is frequently used to assess heat demand for residential buildings (see [13], [5] and [37]). The following table shows how this data is incorporated in our model.

Table 1: Overview of the used data (Source: own analyses). GWR : german abbreviation for the National Register of Buildings and Dwellings.

Source	Data	Explanations	Use in the model
GWR	Swiss building identity (EGID)	For the explicit identity of the buildings in switzerland.	Key for correlation of the building's specifications
GWR	X- Coordinate (GKODX)		Cell structure
GWR	Y- Coordinate (GKODX)		Cell structure
GWR	Construction period (GBAUP)	Time period given in the registry given time period i.e. 1971- 1980	Parameter value for number of new buildings per period of construction and refurbishing
GWR	Building category (GKAT)	single detached family houses, apartment buildings or buildings with/without secondary use	Attribution of the heat demand coefficient
GWR	Energy carrier used for heating (GENHZ)	i.e. oil, gas, electricity	Share of energy carrier in each cell needed to calculate the weighted average
GWR	Floor area used for living (WAERA)	In m^2	Parameter value for heated area
ERP	Energy system used to provide heat for residential buildungs in future	Setting is given by the municipal energy plan	Parameter values for assessing the diffusion processes for new energy systems
ERP	Time until the intended substitution of energy systems	Refers to the develpment of the planned distribution network for long distant heating	Parameter values for assessing the diffusion processes for new energy systems

Data for heat demand coefficients and refurbishment costs are taken from a survey of the the effecs of refurbishment acitvities in the city of St. Gall in 2012 ([39]). It analysed planing documents attached to applications for public funding by the municiplity for 52 buildings (21 single detached family houses and 31 apartment buildings) and data on heat demand from the energy data base of the city of St. Gall.
The following table shows the heat demand coefficients derived from this study differentiated in single detached family houses (german abbreviation: EFH) and apartment buildings (german abbreviation: MFH). These values are between 10 and 50% below coefficients presented in [37] and [5] indicating that most older buildings in our survey have already been refurbished in an earlier period.

Table 2: Heat demand coefficients for the construction and refurbishment periods HDC^{ij} (The heat demand coeffiencients from 1980 to 2010 derived and interpolated on the heat demand coeffienct decrease of 20% from 1960 to 1979)

Construction and refurbishment period i	HDC_{EFH}	HDC_{MFH}	HDC^{ij}
	MJ heat per m^2 heated area		
1900-1919	701	512	Weighted average from HDC_{MFH} and HDC_{EFH} calculated with the percentage of the heated area in cell i, obtained for each building category (GWR)
1920-1939	624	455	
1940-1959	547	480	
1960-1969	566	468	
1970-1979	525	456	
1980-1989	499	431	
1990-1999	473	406	
2000- 2010	448	380	

For modelling the development of the building stock we need data on future refurbishment activities. Yet, according to [38] there is no empirical evidence for typical refurbishment cycles in Switzerland. The Swiss building stock is still rather young and up to now only moderate refurbishments can be observed in large numbers whereas complete refurbisment or reconstruction is still an exception in urban renewals. Therefore, our estimation of parameter values for the persistence time (κ_i) and transformation time (τ_i) can not be based on emiprical evidence. We decided to use best estimates in accordance to [3] and [5]. [3] estimates the time until a building is refurbished with moderate improvements in heat efficiency as 25 year in average. A complete refurbishment, however, is to be expected in between 50 and 70 years. As our model does not differentiate between different types of refurbishment, we assume that an average building is not refurbished with improvements in energy efficiency until 30 years after it was built (persistence time κ_i = 30). After these 30 years, however, it takes further 40 years to refurbish all buildings built at that time (transformation time $\tau_i = 40$).

Parameters for improvements in energy efficiency obtained by refurbishment and the related costs are taken from the before mentoined survey [39]. We differentiate between refurbishment with moderate improvements in heat efficiency and complete refurbishment aiming at a significant increase of energy efficiency.

Table 3: Heat demand coefficient for scenario calculation for the years 2011 to 2050

Construction and refurbishing period i	HDC_{EFH}		HDC_{MFH}	
	MJ heat demand per m^2 heated area			
	Complete refurbishment	Moderate refurbishment	Complete refurbishment	Moderate refurbishment
2011- 2050	234	358	217	351

Estimates of refurbishment costs are also taken from [39]. For model calculations we use an average values covering all periods of construction and refurbishment and types of buildings. For complete refurbishment we assume building costs of 537 Swiss Francs per square meter of floor area (CHF per m^2), for refurbishment with moderate improvements in heat efficiency building costs

amount to 211 CHF per m^2.

In addition, we use the communal energy plan – german abbreviation: ERP - for information about planned transformation of energy supply. In contains information on the intended system to provide heat in future differentiated between different areas within the settlement. This information can, thus, be georeferenced easily and matched with the GWR building stock data. For future community heating the ERP also indicates the intended time frame for phasing out the prevailing systems of heat supply. This information is used to estimate parameters for the diffusion processes described in equation (5). As the municipality strongly encourages the use of long-distance heat from the planned geothermal power plant, we assume that phasing out the existing heat supply systems in areas to be connected to the distribution system will be completed within 20 years. For district heating or other more decentralized future heat supply systems parameter values have been defined in expert interviews with the municipality. We assume that the diffusion processes begin in 2010 and it will take sixty years until all prevailing systems have been substituted.

4. Results

In 2010, the city of St. Gall need 1.8 PJ or 500 GWh of non-renewable energies to provide heat for operating all residential buildings in the settlement area (including all processes to produce and transport of energy carriers for final use). An average building in St. Gall needs 492.42 MJ of energy per year for each square meter floor area. Apartment buildings are major consumers with 70% of total consumption. Efficiency in heat supply increases significantly in more recent construction periods. Energy coefficients don't vary much for buildings constructed before 1980. Since then, their values decline continuously due to improved building standards and the increasing use of renewable energies in heat supply. Yet, the majority of all buildings in the city of St. Gall were built before 1980. Older buildings are mostly located in the densely populated valley bottom in the city centre whereas recent construction is located at the periphery.

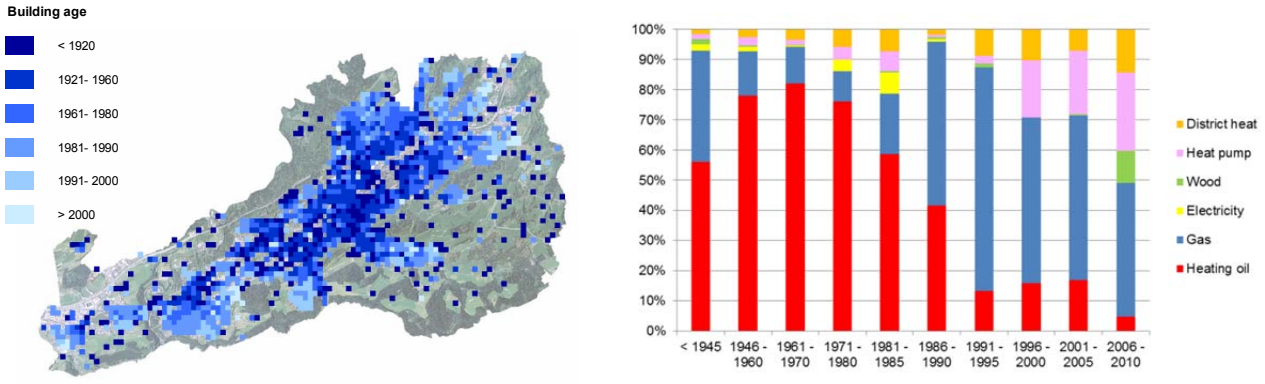

Fig. 2: Left: Age distribution of building of the city of St.Gall presented in the hectare grid used; Right: Share of different energy system providing heat for residential buildings per construction period (Source: own analyses)

Therefore, the density of heat demand is highest in the historic city center at the valley bottom and the surounding areas. In these areas refurbishment and structural modifications are most challenging because of conflicting interests the with protection of sites of historic interest. Density of heat demand is significantly lower on the slopes of the valley where a lot of single detached family houses are located. In the periphery, the density of the settlement decreases and so does heat demand per area unit. Even in areas where older buildings are located, density of heat demand remains low.

Most buildings constructed before 1985 are heated with oil. In 1986, the municipalities starts building a gas supply network and gas becomes an important energy carrier for heat supply in buildings constructed since then. Geothermal heat is increasingly used for new buildings since 1996. District heating is has been used for many years, but it only covers a minor share of heat demand focusing of the settlement area near the municipal waste incineration plant. In 2006-2010

50% of all heated floor area in newly constructed buildings is heated with renewable energies.
Fig. *3* presents the spatial distribution of heat supply in St. Gall today. Is shows the location of distribution networks for heat and gas. The majority of all residential buildings, however, are still heated with oil.

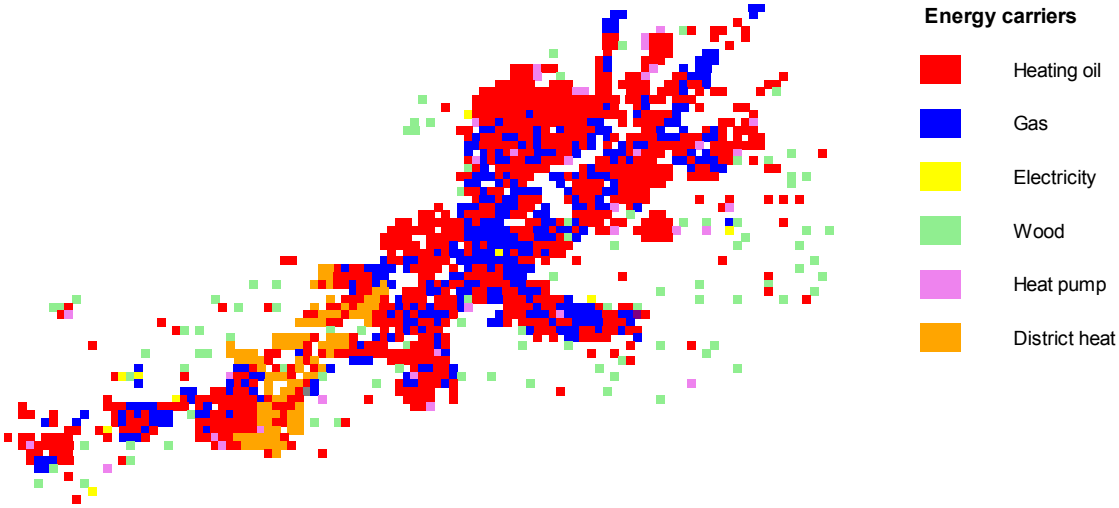

Fig. 3: Distribution of heat supply per hectare in the city of St. Gall today (Source: own analyses)

To analyze the future development of demand and supply of heat for operating residential builds in St. Gall, we use our model for scenario calculations. Four different scenarios for future development are calculated (parameter values for these scenarios are presented in section 3 of this paper):

- Scenario 1 «complete refurbishment with transformation of heat supply systems»: In this scenario, every residential building is completly refurbished until 2050 and its heat demand per square meter heated floor area has been significantly reduced. In addition, a new system of long-distant heat supply has been installed using heat from a geothermal power plant.

- Scenario 2 «complete refurbishment without transformation of heat supply systems»: This scenario is defined as scenario 1 except for its assumptions on provision of heat for operating residential buildings. In scenario 2 we assume, that current heat supply systems are still in place and no substitution has taken place.

- Scenario 3 «moderate refurbishment with transformation of heat supply systems»: This scenario is defined as scenario 1 except for its assumptions on refurbishment activities. In scenario 3 we assume, that buildings are only moderately refurbished and their heat efficiency is not significantly reduced.

- Scenario 4 «moderate refurbishment without transformation of heat supply systems»: This scenario combines assumptions on refurbishment activities from scenario 3 with assumptions on provision of heat for operating residential buildings from scenario 2.

In all scenarios, we assume that building stock will not grow between 2010 and 2050.

The following figures show the results of the scenario calculations for the developments of cumulative energy demand from non-renewable resources ($CED_{non\text{-}renewable}$), greenhouse gas emissions (GWP) (see *Fig. 4*) and construction costs related to refurbishment activities (see *Fig. 5*).

$CED_{non\text{-}renewable}$ declines in all four scenarios. This reduction is caused by two effects: (a) refurbishment activities leading to increased energy efficiency and (b) the on-going substitution of

heat supply systems replacing non-renewable by renewable energies. Scenario 1 combines both effects and assumes a maximal impact from both. It results in a reduction of $CED_{non\text{-}renewable}$ by almost 80% until 2050. A comparison between the results of all scenarios reveals that assumptions on provision of heat for operating residential buildings have significantly higher impact compared to assumptions on refurbishment activities. The introduction of long-distance heating supplied by a geothermal power plant leads to a reduction of $CED_{non\text{-}renewable\ by}$ 70% even if we assume only moderate gains in energy efficiency due to refurbishment activities. Without changes in heat supply systems only 41% reduction can be obtained by complete refurbishment until 2050.

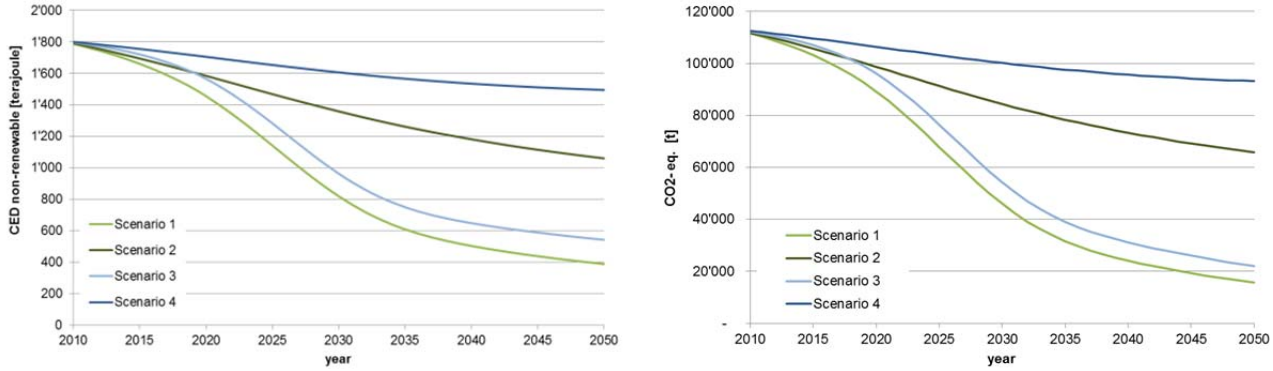

Fig. 4: Left: $CED_{non\text{-}renewable}$ development for all four scenarios; Right: GWP development for all four scenarios (Source: own analyses)

We get very similar results for greenhouse gas emissions. The potential to reduce GWP by combining complete refurbishment with heat supply by a geothermal power station amounts to 86%. Even if refurbishment activities remain moderate, 80% of today's GWP can be reduced with heat supply from a geothermal power station until 2050.

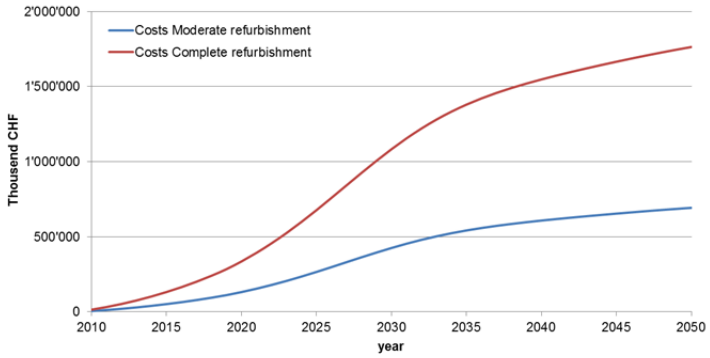

Fig. 5: Cumulated costs for complete and moderate refurbishment of the buildings in the city of St.Gall (Source: own analyses)

Fig. 5 shows a comparison of cumulative construction costs for scenario 1 and 3 (complete refurbishment) and scenario 2 and 4 (moderate refurbishment). It reveals that the costs of complete refurbishment are significantly higher. Real estate owners have to spend approximately 700 million Swiss Francs (CHF) until 2050 if we go for moderate refurbishment and around 1'700 million CHF if we choose complete refurbishment.

5. Discussion

In combination with increasing refurbishment activities, the city of St. Gall has defined a very promising strategy to reduce energy demand for heating residential buildings in the settlement area by two-third of today's demand – according to the target proclaimed in the city's energy policies. Scenario calculations show a reduction of more than 70% if all measures described in the communal energy plan are implemented.

This reduction represents the gross energy savings not taking into account the energy invested in the refurbishment or structural modifications. This additional energy consumption can be represented by the estimates for the $CED_{non\text{-}renewable}$ of building materials used in these building processes. A rough estimate based on benchmarks from [4] shows that approximately 250'000 terrajoule $CED_{non\text{-}renewable}$ per year will be invested on average between 2010 and 2050. It confirms results from recent studies that showed the minor importance of the cumulative energy demand from building materials in the overall energy demand (e.g. [6], [28] and [29]). $CED_{non\text{-}renewable}$ of building materials will, however, become more and more important in the transformation of the building stock with major increases in energy efficiency – as represented in scenario 1 in our study. In this scenario the average cumulative energy demand for building material amounts to over 50% in the overall energy demand in 2050.

Our results emphasize the importance of the geothermal power station currently planned in the city of St. Gall. As shown in *Fig. 4*, it will supply a major part of the settlement area with heat from renewable sources without producing significant amounts of greenhouse gases. The historic city center where heat density is highest will be entirely supplied with long distance heat. This is favorable for the efficiency of the planned community heating. It also helps solving conflicts with goals of protecting historically sites because a complete refurbishment of buildings in the historic city center is no longer necessary to reach the city's ambitious targets in energy policy.

Fig. 6: Distribution of heat supply per hectare in year 2050 (Source: own analyses)

Yet, this strategy requires substantial funds from real estate owners as well as the municipality itself. If the city encourages complete refurbishment of residential buildings aiming at a significant efficiency increase in heat supply, real estate owners will invest a total amount of 1.7 billion Swiss Francs until 2050 – an average of 40 million per year. A part of this huge amount of money can be accounted to the on-going process of urban renewal independent from energy policies. Yet, the financial burden for real estate owners remains significant and increased energy efficiency of residential buildings will have minor effects on future revenues in real estate. In addition, the municipality plans to invest around 160 million Swiss Francs to build the geothermal power station. With this infrastructure, the city will reduce its dependency on future prices for fossil fuels. Thus, the economic and environmental benefits from increased heat efficiency of buildings supplied with long distance heat seem small.
Expected costs for real estate owners could be reduced significantly with a more differentiated approach for increasing energy efficiency in the building stock. In areas connected to the distribution system for long-distance heat moderate refurbishment should be encouraged with significantly lower construction costs. Public funding to encourage extensive refurbishment activities, however, should focus on areas not connected to the distribution system.

The results of model calculations, however, should be interpreted carefully. Some parameters

values could not be based in empirical evidence (e.g. parameters for the building stock dynamics) and for others the dispersion of values is significant (e.g. heat demand coefficients). Yet, our results for the four scenarios differ considerably (by more than factor 2 between scenario 1 and 4) indicating that our findings are robust in spite of data and model uncertainties.

6. Conclusions

Based on our case study results we conclude that buildings supplied by long distance heating can refrain from extensive refurbishment aiming at significant efficiency gains in heating if three conditions are fulfilled:

- Long distance heating is provided by low emission processes based on renewable resources,
- Renewable resources used for heat production are available abundantly at all times,
- Renewable resources used for heat production cannot be used for other purposes relevant in sustainable urban renewal (e.g. to produce electricity).

The geothermal power station planned in the city of St. Gall seems a promising option. Yet, at the current planning state we cannot be certain that these three conditions will be met in future. The municipality, therefore, is well advised to keep its current strategy in promoting both energy efficiency and the transformation of energy systems. Yet, it should carefully keep track on the ongoing development and be ready to adapt its strategy.

The application of the model introduced in this paper, could help to monitor the ongoing development and evaluate alternative strategies if necessary. It supports prioritization of measures and adaption of existing concepts in energy policies. By using data from official statistics as well as commonly used planning instruments, it can be easily updated. It provides a consistent data pool of expert knowledge which can be improved continuously within the learning process on sustainable urban renewal.

Short Summary

The parallel commissioning process in the Brøset project made it clear that physical measures can only reduce GHG emissions to 5-7 tonnes per person per year [1]. This paper assesses the potential of Smart Cities methods and solutions to reduce emissions further towards 3 tonnes per person per year (which is the overall goal of the Brøset neighbourhood), based on the progress made in the EERA Joint Programme Smart Cities within the European Smart Cities and Communities Initiative. The main aspects of Smart Cities discussed in this paper are cross-scale energy-efficient networks integrating people, buildings, urban planning, energy infrastructure and supply, and the ICT-based tools and solutions needed to model and manage these cross-cutting networks.

In order to really achieve integrated energy planning at neighbourhood scale and avoid sub optimisation, the paper recommends key indicators and assessment methods that can be included in Brøset regulations and quality programme. These are related to: urban structure with optimal orientation related to solar access, wind and precipitation; optimisation of energy efficiency at neighbourhood scale based on diversity, proximity, distribution, accessibility and density; energy-efficient interactive buildings with integrated RES; robust bioclimatic solutions resilient to climate change impact.

Keywords: Smart cities, Sustainable neighbourhoods, urban planning, CO2

1. Introduction

“Cities of the Future” is collaboration between the Norwegian Government and the 13 largest cities in Norway to reduce greenhouse gas emissions and make the cities better places to live. The new suburb of Trondheim, Brøset, will be carbon neutral. Built from healthy materials and using little energy, Brøset will make an integrated and future-oriented suburb. The work in Brøset will be given full priority in Cities of the Future and should become a model for future urban development.

The results of the Brøset parallel commissioning process showed that through planning and design of traditional technological issues such as building standards, energy supply and motorised transport, it is possible to directly reduce carbon footprint with 3 to 5 ton of CO_{2eq} per capita from 12 to 7-9 tons CO_{2eq} (Norwegian conditions) [1]. This indicates that careful design of buildings and infrastructure alone will not lead to carbon-neutral, resilient neighbourhoods, although such neighbourhoods are an absolute necessity in order to facilitate transition to a more sustainable future. Staying below 550 ppm CO_2 in the atmosphere (IPCCs 2-degree limit) requires far-reaching changes in built environment, energy systems, and people’s lifestyles, and particularly in the interfaces between them.

Design solutions in urban strategic planning, infrastructure and buildings, and the interfaces

between them, will have a direct impact on the stationary energy performance of the Brøset neighbourhood, and it is therefore important to create a set of energy indicators able to incorporate these distinct physical scales and their interfaces. Successful planning and implementation of the Brøset neighbourhood and its long-term integration in Trondheim municipality's political priorities, legislation and planning practice require several steps:

- Creating a holistic vision for integrated energy design of the Brøset neighbourhood;
- Establishing well-defined Key Performance Indicators (KPI) and benchmarks that allow the city to plan Brøset neighbourhood design and monitor its performance;
- Ensuring support by measurements, simulations and qualitative methods, in co-operation with knowledge institutions;
- Devising an implementation plan for translating the design into practice;
- Exploring synergy effects with other municipal priorities such as climate change adaptation (resilience, capacity to respond to crises), health, mobility and commercial development;
- Setting up governance structures to support planning, implementation, monitoring and transferring of experiences to other projects, both within the municipality and to others [2]

The development of the Brøset neighbourhood offers a unique innovation potential in terms of integrated energy design of urban environment, buildings, infrastructure networks and supply systems, combined with high quality of life. In order to achieve this, a common vision was developed early on in the project, which resulted in a holistic planning programme for the neighbourhood, and a parallel commissioning process in which four interdisciplinary teams developed a master plan for the site.

2. Strategic energy planning: interfaces between urban form, infrastructure, and buildings

Energy efficiency is a core issue in the global effort towards tackling climate change and resource scarcity [3], and its effect is even increased when combined with other resource efficiency measures [3]. Simultaneously, however, one of the main challenges to be addressed is managing potential synergies and conflicts between strategic urban planning topics as diverse as energy-efficiency, carbon-neutrality, climate change adaptation, aesthetics, functionality, socio-economic benefits, health, well-being, comfort, productivity, culture and heritage [4].

In addition, resilience of energy system design and management has become of increasing concern for cities during the past years. While originally used to express resistance against natural disasters such as earthquakes, resiliency has come to be linked to the robustness of a neighborhood, city or country to withstand climate and climate change and the ability to cope with the consequences of their impact, including local adaptation of the built environment, social well-being, ecosystem services, accessibility and safety [5]. For Trondheim, for example, potential climate change scenarios include amongst others more intensive extreme weather conditions, less snow, a higher yearly average temperature, sea level rise, more and more intensive rain, and increased danger of erosion and landslides, stressing amongst others the importance of integrating green and blue infrastructures into urban zones for storm water management [6]. As a consequence, principles for climate change adaptation of energy systems need to be integrated at various scales including urban form, infrastructure, and buildings.

Integrated urban energy planning and transformation processes require thorough understanding of how aspects such as urban morphologies and typologies influence the neighbourhood's overall energy performance characteristics. However, few methods currently analyze what happens in between the building and urban level (i.e., building clusters, neighborhoods). Most simulations are centered on buildings, users or grids, and experts are educated and trained correspondingly. It is therefore difficult to model and optimise synergy effects for energy efficient buildings that interact with the grid, their users and the environment in real-time, and to integrate flexible, general and elastic solutions that can adapt over time [7, 8 and 9].

Furthermore, energy efficiency can be promoted by fully integrating individual buildings as active hubs in the neighbourhood energy grid, using information and communication technology (ICT) to gather and exchange relevant information, and to facilitate robust, yet flexible design and demand

side management:

- Building design for optimised interactivity with surrounding site, microclimate, people and cultural heritage, in order to optimise energy efficiency, enable generation of renewable energy, and support energy efficient lifestyles;
- Building envelope materials and technologies that can optimise the interface between buildings and their surroundings;
- Energy interface between buildings and the grid;
- Interface between buildings and users: how to include users and user behaviour in designing and monitoring energy measures;
- Buildings as disseminators, which can create awareness and a multiplier effect [10].

In order to promote integrated energy design in urban form, infrastructure, buildings and supply systems, it is important that this type of design is being perceived as relevant and attractive for all residents and stakeholders in general – not only those with a particular interest in the subject. This type of challenge is the topic of a branch of behavioural science called choice architecture, extensively explored amongst others by [11], arguing that the manner in which people make decisions depends a lot on the manner in which the problem is framed. The authors claim that people, when given a choice, in most cases just choose the default option, unless they are especially engaged in the subject. This phenomenon, called the Status Quo Bias, is often used in Tversky and Kahneman [11 and 12] and is implemented amongst others in product placement in supermarkets: putting groceries at eye level increases their sale in a predictable, easy and cheap manner, regardless of the type of product placed in this position. What would be the equivalent for environmental issues in architecture? In order to answer this question, several rules of thumb for the factors on which people base their decisions can be applied [12]. Particularly highlighted are the concepts of anchoring, availability and representativeness:

- Anchoring relates to the fact that, when making a decision, people start from something they know, and adjust this “anchor” in a direction they think is appropriate in the given context.
- A second factor that guides people’s choices is representativeness: is the situation and context representative of what one oneself has experienced or thinks is relevant?
- The third factor, availability, is related to the ease with which people come up with relevant examples. The more readily available relevant examples are, the more likely it is that these will influence people’s decision making – for better or worse.

These three issues can be applied to increase the probability that people will make more energy-efficient choices. For example, when a household is given information on the energy consumption of their neighbours, they will in most cases adjust their own consumption correspondingly [11]. Such connections or patterns have also been explored extensively in the past [13, 14 and 15], and particularly in contemporary eco-villages and the traditional garden city principles on which they are based: “an attractive and green neighbourhood which is safe, pollution-free and uncongested; a sense of local community and excellent access to friends and facilities both locally and regionally. People hope through telecommunications to participate in wide flung networks and activities while (in many cases) living a less frenetic and more locally-based life” [16]. In fact, we found suggestions related to anchoring, representativeness and availability in the parallel commissioning teams’ master plan proposals for Brøset, which will be one of the topics discussed in the next section

3. Cross-scale energy measures and indicators for Brøset

There are several assessment and certification standards for buildings and urban areas which include relevant measures and indicators for integrated energy design. Common for these are that they are mostly using indirect and qualitative indicators for the assessment, rather than quantitative and measurable indicators. They are also mainly dealing with improving and optimizing existing characteristics, rather than seeking synergies and new solutions.

The Brøset project took a different approach by seeking new solutions and synergies between technologies and consumption patterns (lifestyle) and scales. The tender for the parallel

commissioning process called for “new technological and social perspectives on energy and resource consumption are to be tested and to show a more climate benign manner in which to live” [17], and, correspondingly, a wide range of measures was proposed by the four parallel commissioning teams to support a holistic master plan for the Brøset area. The measures could generally be divided into two main categories: urban design strategies creating the architectural and technical framework for the Brøset area, and facilitation of an attractive social network spurring citizens to a more environment-friendly lifestyle [18]. Regarding energy in buildings, the tender asked for proposals that can contribute to:

- Show various types of settlement structures that facilitate development of energy efficient buildings during a later, more detailed stage of the process;
- Low greenhouse gas emissions related to energy in buildings; this requires extensive use of renewable energy sources such as solar energy, biomass, and heat pumps. Shared energy solutions can be considered for building clusters;
- Explore housing typologies that reduce land use per person;
- Illustrate new buildings in the area with at least passive house standard or better, or other solutions that result in minimal greenhouse gas emissions;
- Assess flexibility and adaptability of the proposed urban structure and building typologies;
- Assess collective versus individual heating system solutions;
- Draft potential choice of materials (…)
- Use of green infrastructure to reduce heating need in buildings [17]

In the next stage, these proposed measures will have to be transformed into a detailed quality programme for the planning, construction and management of the neighbourhood. The challenge lies in describing and validating these potential synergies, translating the measures to an assessment scheme with measurable indicators, and weighting of indicators in order to enable comparison of various scenarios, benchmarking, and monitoring.

This section summarises and discusses the measures proposed by the tender for the parallel commissioning process, the proposals from the four participating teams, and the evaluation report [19]. Where relevant, additional measures and indicators are suggested by the authors of this paper is based on state of the art development within the European Energy Research Alliance Joint Programme on Smart Cities (EERA JP Smart Cities), and the European Environmental Agency’s report on urban adaptation to climate change in European cities [20]. The EEA report provides an excellent state of the art summary of climate change adaptation challenges and measures in European cities, including those related to energy infrastructure. EERA JP Smart Cities was chosen for comparison because it is the largest research programme looking dealing with innovative energy efficiency measures in cities across urban, infrastructure and building scale.

Table 1 Overview of the steps in BREEAM Communities 2012 and the scales approach in the Brøset project

	Scale 1: Integrated urban energy planning and transformation processes	**Scale 2: Infrastructure networks**	**Scale 4: Energy-efficient buildings as interactive elements of the urban energy system**
Step 1: Establishing the principle of development			
Step 2: Determining the layout of the development			
Step 3: Designing the details			
Innovation			

The analysis is of course influenced by the fact that different levels of detail are of importance for various design and development phases; a parallel commissioning process to procure a master plan for the Brøset site will thus not go into detail on the specific building details needed to obtain good energy efficiency. However, it is important to remember that the development of the Brøset site and its energy system in any case requires high levels of investment regardless of whether the design optimised complementarities between urban form, infrastructure, buildings and supply. Planning for integrated energy design from the very start, using a range of 'no regret', flexible options, is therefore an appropriate scenario, in order to avoid the neighbourhood's energy consumption and corresponding emissions from being locked for decades.

3.1 Scale 1: Integrated urban energy planning and transformation processes

Make best possible use of local climate and site conditions to optimise energy efficiency and create an attractive outdoor space

During the parallel commissioning process, teams suggested that working with local climate in terms of urban morphology, infrastructure and vegetation, and thorough understanding of the nature of the site and its connection to the surrounding environment builds a solid foundation for good comfort conditions combined with resource conservation; this includes microclimatic conditions such as wind, sun and humidity, remote and local view, and shelter from noise and dust from the neighbouring road. A high ratio of solar-oriented buildings provides good access to daylight and sun for human well-being as well as for energy production; these conditions are optimised by careful planning of neighbourhood densities, building heights and depths, and roofscapes.

The evaluation committee remarked that while solar and daylight access seem to be met in a fair manner by the four teams' proposals (though not always for ground floor housing units), it is questionable whether the form and location of the built structures on the Brøset site will provide a comfortable outdoor microclimate [21], an issue that is also extremely important in terms of climate change adaptation [20].

3.1.1 Robust energy solutions that can tackle impact by climate change

The teams propose green infrastructure on site, including green roofs and facades, to mitigate the urban heat island effect; even distribution across the neighbourhood is to be preferred above a few large parks. In addition, it is specified that outdoor surfaces on buildings and public spaces should have high albedo to mitigate the heat island effect and reduce need for mechanical ventilation indoors. Development of infrastructure and buildings at the Brøset site will require a large investment and the opportunity needs to be used to make them resilient to future climate change. In the upcoming detailed design stage, high albedo and green roofs and facades as measures to cope with heat in buildings and public spaces will need to be extended to better insulation in buildings, solar control measures such as shading, orientation and building morphology, and passive cooling measures to reduce need for air conditioning in housing but particularly workplaces and public buildings on the Brøset site [22]. These are typically no or low regret measures that either are reversible or provide a range of co-benefits such as storm water management, increased contact with nature, and, possibly the largest driver for climate change adaptation, more attractive living environments [20].

3.1.2 Making energy efficient solutions the most accessible and attractive alternative

Within ambitious energy standards for the whole neighbourhood, the teams propose a variety of housing types with different energy, technology and cost profiles to cater to a broad potential target group, ensure accessibility for various user groups. In addition, they are aiming to create a built environment that facilitates a new, low-carbon way of living, hopefully influencing the manner in which people think and act, and to create a reinforcing cycle by making low-carbon alternatives more available, and high-carbon alternatives less available, in the entire Brøset neighbourhood.

An Environmental Centre is proposed established on-site that can serve as innovation hub and showroom for residents and visitors, providing stakeholder support during planning, construction

and monitoring of the neighbourhood's performance; helping residents when needed; showcasing methods and solutions that support the vision of the area; and facilitate selling and renting housing units and commercial units on the Brøset site.

3.1.3 Reducing embodied energy and transport by providing local products, services and service agreements

The teams propose cradle to cradle [23] design of goods and services, including support for small businesses and facilities for recycling, re-use, re-design and sharing, such as an object library, second-hand stores, garage sale facilities, and shared workshops with high quality equipment with long lifetime.

Environment-friendly service agreements, including the best available technology at all times, are to be preferred above ownership agreements. A range of these services combine individual comfort and time-saving with potentially commercially viable activities. For example, local-food delivery, cleaning services, repair-services for household appliances, furniture and other items can be provided to residents or even located on-site. Brøset can provide a framework for quality control, start-up facilities for businesses for trading, organizing and scaling this practice for Brøset, Trondheim and the entire region. Stores located at the Brøset site should be encouraged to review their packaging and storage routines to reduce the amount of waste.

In order to increase the chance that people want to spend more time in the area, the municipality should facilitate local shops and market places, cafés and restaurants, sports and leisure, schools, workplaces, library, organic food and allotment gardens with energy efficient greenhouses; slow food restaurants on attractive street corners, a high-end, luxurious yet environment-friendly spa, concert hall and cultural centre, engaging Brøset inhabitants as well as neighbours and visitors – "a place so sublime (and expensive) it becomes addictive" [24]. In order to secure these facilities from the start, lower rent and/or other incentives are advised.

3.1.4 Finding synergies between integrated urban energy planning and other municipal priorities

The teams state that an integrated, long-term land use plan for activities, functions and urban structure is needed to support the overall vision of the Brøset area. The plan should be adaptable over time, according to changing use, users, and available technology and knowledge. Active use of existing built environment should be encouraged when developing the new Brøset identity. Historic buildings, landscape and built environment can be used as story-tellers to give the neighbourhood an identity and a soul, using them as anchors for the new neighbourhood.
Qualified density should be provided to ensure well-functioning, cost-efficient infrastructure and services, but with high-quality living environment. Reduced area for motorised transport, combined with mixed use in different parts of the neighbourhood, can support this policy. Mixed use is proposed by the teams to support good accessibility of shared and/or public facilities. In fact, this type of structure could be extended to become a smart energy district [2] or synergy zone [8], allowing for smart coupling of different buildings with complementary energy requirement, such as schools, industry, shopping centres, homes, and workplaces.

3.2 Scale 2: Infrastructure networks

3.2.1 Smart coupling of energy generation, consumption and storage

Several teams propose a smart grid for the neighbourhood, with plug-and-play system and central smart management. The evaluation committee comments that while some teams propose smart grid solutions, it is not specified how this can be solved on the Brøset site or how this will contribute to lower energy consumption and corresponding greenhouse gas emissions. This is particularly important since smart grid solutions are not yet "best practice" and may appear to be somewhat uncertain [19]; within a few years' time, however, when the Brøset area will be constructed, these conditions will most likely have changed, with experience from demonstration projects in other areas.

3.2.2 Promoting renewable supply technologies integrated into urban infrastructure

Shared low-carbon energy supply for the area is suggested by most teams, ready when the first residents move in, with diversity and flexibility for future development. A mixture of renewable energy sources is proposed, for example district heating based on biomass or waste incineration, combined with on-site generation of local renewables (mainly solar thermal and PV, but also wind turbines, geothermal, biomass CHP, potentially combined with seasonal storage). These should be integrated in large-surface buildings and structures such as the Brøset energy hub, the environmental centre, schools and noise-reduction screens towards highly-trafficked roads. The system should be able to adapt to more energy-efficient, carbon-neutral energy sources should these arise in the future. In addition, solar thermal and photovoltaic systems can be installed in individual housing units when economically viable; buildings should at least be designed to allow this option in the future. The system can be coupled to electric cars gathered in a central underground garage in the future.

In order to make this development economically viable, the teams recommend that a stepwise development and investment plan is provided for local renewable energy supply in co-operation with a private energy company, in return for temporary monopoly on energy supply to the area.
According to the evaluation committee, however, with low energy demand by Brøset buildings, it will not be cost efficient to develop a multitude of renewable energy systems in parallel. In addition, cost efficiency and usability of a district heating system on-site have to be evaluated against large-scale local renewable energy system development [21].

3.2.3 Increased energy efficiency through synergies with water and waste management systems

The teams didn't deal with energy efficiency of infrastructure systems; blue-green infrastructures are mainly mentioned in the context of climate change adaptation for the purpose of storm water management, urban heat island mitigation and so forth.

However, several co-benefits of coupling energy efficiency and infrastructures could be highlighted, amongst others using water systems for pumping and storage to balance the energy system; using waste water systems in the energy system, e.g., for cooling water, or as heat source for local heat pumps; using waste incineration plants for power and district heat production in connection with cities; and using organic waste for biogas used either for heat and power or in transport [25].

3.3 Scale 3: Energy-efficient buildings as interactive elements of the urban energy system

3.3.1 Set minimum standards for individual building energy performance

All teams propose that Brøset buildings should have at least passive house standard or better, and, at any time the buildings should perform better than national regulations. New as well as existing buildings need to comply with these rules, though with lower ambitions for the historic, protected buildings on-site.

The evaluation committee remarks that while almost all proposals include passive house or similar standards, this does not necessarily indicate low energy consumption during the buildings' lifetime, only low operational energy consumption per square meter. Total lifetime energy demand can only be reduced if the built area is restricted as well, and embodied energy of materials and technologies is taken into account. In some cases for example steel and concrete are used while advocating use of materials with low embodied emissions [21].

3.3.2 Robust bioclimatic design

According to the teams, passive design strategies should be used extensively, such as compact building, orientation and adaptation to local climate and site, passive solar heating and use of solar rooms and basements for insulation, thermal mass, good airtightness and insulation of building envelope including windows. Ample potential for public-private interface should be provided, for example in the form of balconies and roof terraces.

The teams recommend that buildings be designed for future integration of solar thermal and photovoltaic panels when economically viable; this requires design able to combine current passive energy saving strategies with potential future integration of renewable energy systems. It is, however, not sure how this measure will be combined with the extensive use of green roofs and facades described in the teams' proposals.

In the upcoming detailed design stage, the proposed urban textures need to be optimised according to their bioclimatic potential, by means of urban shape factors such as volume to surface ratio (the enclosed built volume to envelope surface area ratio), passive volume (the building's potential for use of passive systems such as natural light and ventilation, and passive solar gains), the degree of occlusion of the sky (variation with the height of the surfaces and perimeters of horizontal sections), vertical sections and directionality (influencing incident solar radiation and wind direction) [9].

3.3.3 Diversity, flexibility, generality, elasticity

The teams recommend that buildings be designed with innate flexibility to adapt to changes in use and users when required, on a daily, seasonal or long-term basis. Housing units should have potential for expanding and shrinking, also in terms of room height. It is also suggested that design regulations should open for a diversity of plot sizes and shapes, ownership structures, contractors, developers, and design teams. Housing should have in-built potential for lifelong living, preferably combined with contact with outdoors and ground floor, to create housing units with the feeling of single housing with own entrances and access to private or semi-private outdoor space. The evaluation committee remarks, however, that the teams' claims as to these solutions leading to a lower-emission lifestyle are not supported by state of the art references. In addition, the evaluation committee remarked that while diversity has definitely been taken into account, the teams offer few assessments of how the diverse housing types will perform energetically [21].

Several teams suggest it is desirable to allow for do-it-yourself (DIY) building practices while maintaining high energy efficiency standards. Therefore it is necessary to establish professional consulting on-site or connected to the Brøset neighbourhood to assist DIY builders in their practices. In addition, a catalogue can be provided containing prefabricated, mass-customised options, using energy-efficient, low-carbon design, materials and equipment.

3.3.4 Reduce energy needs per person through reduction of built area per person

The teams suggest that individual core facilities should be included in each housing unit, while rooms that are not essential for daily use can be moved to shared facilities, for example laundry rooms, storage sheds and workshops, boats and cabins. In order for shared facilities to be attractive, they have to be located close to the private residence – therefore clustering of housing units that share facilities are preferably located around a courtyard, or similar types of clustering. Well-designed, space-efficient floor plans with attractive facilities in the neighbourhood should further support reducing individual housing units.

The evaluation committee remarks that this is a vital issue for reducing energy consumption and corresponding greenhouse gas emissions. kWh/m^2 only relates to energy efficiency, but if the built area is not restricted, this will have no effect on total energy consumption [21].

3.3.5 Creating awareness about energy efficiency and renewable energy systems

Diverse solutions are proposed to make the residents more aware of their energy consumption, amongst others in the form of competition among residents, or with other low-carbon neighbourhoods. Visible and smart metering allow for user-controlled demand side management of operation of electrical household appliances and heat pumps, and recharging of electric cars and car batteries. Visibility of energy efficiency measures and renewable energy systems (RES) can also be used to support dissemination purposes.

4. Discussion

In order to transform the vision for Brøset as low-carbon neighbourhood and potential lighthouse

project for Smart City Trondheim into reality, it has to be firmly anchored and detailed in co-operation among Trondheim politicians and policy-makers, commercial actors, knowledge institutions, media and citizens. Scenario analysis and testing of alternative transition pathways should be performed, and potential synergies and conflicts with other municipal goals investigated to ensure that the development, implementation and monitoring of the Brøset vision does not happen 'on top of' conventional urban practice in Trondheim municipality, but rather is embedded in Trondheim's transition towards a more energy-efficient and low-carbon city.

The Brøset projects is different from other assessment methods in that the project tries to limit the overall emissions from the development at by 3tons CO_{2eq}/capita*year, including embodied energy and end of life. Thus the Brøset projects are the first project worldwide that tries to limit the overall emissions from an area. This in turn influences the choice of indicators, and how they are used.

In assessment schemes, stationary energy is measured as kwh/m^2 or kg CO_{2eg}/m2, giving points to how much better the proposed building is when compared to current building code. The embodied energy is also rated a similar way, but there is no limit to the "allowed" total energy used or emissions from a project over its lifespan.

At Brøset, a different approach is chosen. First of all, all buildings should comply with the passive house standard or better (15 to 25 kwh/m^2) in terms of in-use energy consumption (or emissions). Second, the total emissions from the development should not exceed by 3tons CO_{2eq}/capita*year. This in return leads to an optimization of material consumption (embodied energy/emissions) and area per capita. Area efficiency is crucial in order to achieve the goals set for Brøset.

Also, on-site energy productions, energy storage, smart integrated grids and the areas albedo is taken into account in the design and development of the area. The idea here is to create excess energy that can be exported back to the grid, or be used for other purposes such as transport etc. Also the change in the albedo from the area will create a net "reduction" of CO_{2eq} from the area.
So where other assessment schemes look at stationary energy consumption, embodied energy and transport systems in relation to each other, but independent of each other, the Brøset projects limits the whole development with a final emission cap. This will in turn force an integrated design and search for synergies and energy design across different scales and disciplines.

5. Conclusions

The measures proposed by the parallel commissioning teams provide a plethora of robust, diverse and adaptable solutions and methods for integrated energy design at Brøset that can avoid lock-ins, provide adaptability to uncertain challenges, and create an attractive built environment.

The next phase will be the creation of an environmental programme, including development of standardized and clear criteria by which project proposals can be judged in a uniform manner. This environmental programme will provide a basis for monitoring all stages of development of the Brøset project, including design and selection of proposals, construction phase, and long-term management of the area. The parallel commissioning process clearly showed the importance of being able to describe correct and measurable goals, and exposed the lack of science-based, planning-friendly decision-making tools for the early design phases of a neighbourhood project.

In particular, there was a lack of design, assessment and management tools to examine synergies and conflicts between building and energy network performance. In the parallel commissioning process relatively few solutions were proposed for interaction between buildings and networks, including any smart or ICT systems, responsive building facades, or seasonal bioclimatic solutions. This type of interaction should be further developed to create energy efficient, integrated energy planning (building-grid-user) for the entire neighbourhood, and avoid potential redundancy or incompatibility among the various systems.

Summary

The topic of “Smart City” gradually becomes more important, especially because of the growing world's population. Considering this situation, experts recognize the potential values of cities with long-term sustainability. For buildings, the establishment of an energy certificate is mandatory, with considerations of the building environment, locality, infrastructure provision and other issues that have not been taken into account.
In this study, using a real community in Vorarlberg, Austria, various factors were investigated and their impacts were analyzed. The “Energy Certification of Communities” software, co-developed and provided by the Lower Austrian Land Government, Department of Spatial Planning and Regional Policy, was used for the calculations and analyses. The focus of this program is not only on the quality of the location but is more on the utilizations of various areas. Essentially, concerns of this development were mainly costs in Euro per living unit and year; it means the more built in an area the less the cost. The last part concerns the effects of developments on the CO_2 emission, which is affected by traffic emission. First, the present situation was calculated, including the following factors:

- Indicators;
- Partial areas;
- Development;
- Quality of open spaces;
- Connectivity and transportation;
- Locations and buildings.

Considering these factors, different variants could be worked out. Initially, the existing green spaces would be partially removed to reduce the developmental costs. Another factor is to build a central school or shopping center. In this case, the individual transportation routes would be shorter and the CO_2 emissions would decrease. Other variants were also investigated and evaluated. Results show that we can achieve a lot, but more than two efficiency levels cannot be reached. An energy-efficient use of resources can be achieved in all cases.

Keywords: Smart city; Development costs; Building environment; Locality; Infrastructure provision

1. Introduction

One of the key instruments of the EU for accelerating the development of large scale use of low carbon technologies is the European Strategic Energy Technology Plan (SET Plan) [1]. It proposes systemic approaches and organizational innovation about the energy efficiency, low carbon technologies and the smart management of energy supply and demand (SEC 1295, 2009) [2]. Technology roadmaps serve as a basis for strategic planning and decision making applying a collective approach in research, development and demonstration planning and implementation with a clear focus on large scale programs, such as the European Industrial Initiatives (EII) [3]. Together with other industrial initiatives, the “Smart Cities” initiative highlights the importance of intelligent energy management systems in cities in order to achieve a 40% reduction of greenhouse gas emissions by 2020. For the design and planning of smart energy systems, the detailed

understanding of the energy performance characteristics in urban areas is of crucial importance. The future energy management of “Smart Cities” is a very complex interdisciplinary problem that requires a new research approach, as the research aims of individual fields concentrated on progress in the technological issues of those fields, sometimes even at the cost of the whole system.

A “Smart City” can generally be defined as a sustainable urban community, with importance of mobility, environment, economy, life and people. The sustainable development of cities has long been in prospect, but there are many concepts currently discussed: Sustainable Cities, Green Cities, ecocities, climate neutral cities and also cities of the future [4]. However, clear distinctions between these concepts are rather difficult [5].

Due to the thematic diversity in the field of “Smart Cities”, it is more difficult to define future research strategies in this area. But there are some substantial core themes that characterize a Smart City.

Typically, a “Smart City” meets specific quality features that are composed of various factors or axes. On the one hand, every cities infrastructure is taken into account, but also the existence of innovative ecological/environmental concepts. A smart city as well is a city with a high quality of living [6].

In this study, using a real community of Dornbirn in Vorarlberg, Austria, various factors were investigated and their effects were analyzed. The “Energy Certification of Communities” software [7], co-developed and provided by Lower Austrian Land Government, Department of Spatial Planning and Regional Policy, was used for the calculations and analyses.

Following aspects were taken into account:

- Key figures
- Subareas
- Development
- Quality of open space
- Accessibility and traffic
- Location and development

The key figures included on the one hand building land areas and on the other hand living units (LU). The building areas were divided into subareas. It was important that those areas to have the same topography and not separated by streets, paths, rivers or greenways, so the alignment, the art of development as well as the types of buildings are always the same. Those subareas are then filled with residential units.

The factor “improvement” is concerned with developmental costs. There are interior and exterior developmental costs. Interior costs only include the length of the pipeline for supply and disposal, whereas the exterior costs include traffic development, water supply, wastewater and rain water management, street lighting, gas pipeline and also local and district heating system. So, generally speaking, we can assume that the longer the required pipelines bring the larger costs.

The subareas, already explained, carry great weight in consideration of the factor “quality of open space”. They provide information about existing sources of disturbance and if there are recreational areas nearby. This means that every subarea receives its own evaluation.

The aspect of “Accessibility and Traffic” considers every subarea separately and focuses on the distance to certain facilities and authorities, for instance, the subarea located in close vicinity of the town center, local amenities and kindergarten and primary schools, the evaluation increases towards energy efficiency. Almost all kinds of distances are taken into account, excluding the trip to work, since it differs too much from resident to resident.

Under the point “Location and development” we found data regarding topography and buildings types in every single subarea. It should also state the subarea’s alignment, where the alignment’s direction is heading away from the street.

The evaluation was conducted in three sections:

a) Development costs in □ per living unit and year;
b) CO_2-Emission affected by the traffic of the art of development per living unit and year;
c) Quality of location and development.

There is an individual outlay between the classes “A” and “G” that follows those points in which “A” is for the most energy efficient use and “G” is the weakest rating. Before this final classification, each of those 3 parts has to be weighed differently while part a) weighs 0.40, part b) weighs 0.25 and part c) weighs 0.35.

2. Energy pass of the actual state

The study area is located in Austria, Vorarlberg province, as one of the largest cities in the state. For this study, all of Dornbirn is too large of an area so the survey was narrowed down to only one part of the city. This part is located in the west of Dornbirn and is bounded by Josef Ganahl Straße, Lustenauer Straße, by the Dornbirner Ach and the railroad tracks. The region has a total area of 828,630.18 m² and an auxiliary of housing construction of 100,000 m² (left part in Figure 1).
After defining the area, we divide it into subareas. Here, it is important that the topography and the alignment characters of the majority of the buildings are the same. The subareas should not be divided by streets but the area was too large to avoid that. Hence there were 25 arrangements with different areas and living units (right part in Figure 1). The existing transport routes have a total length of approximately 9,045.24 m with an average width of 6 m. The arrangements and related information are presented in Table 1.

Fig. 1. Left: blue line denotes the investigated area; green line denotes the green area. Right: red line denotes the subareas with numeration.

Table 1. Subareas: number, area and the living units.

Number	area [m²]	LU	number	area [m²]	LU
1	13,558.53	5	14	38,754.16	32
2	12,286.44	4	15	19,711.56	19
3	14,385.85	12	16	24,115.90	35
4	13,385.73	8	17	16,174.01	30
5	8,614.08	7	18	23,471.45	22
6	11,672.08	2	19	26,665.13	25
7	28,001.01	14	20	20,926.58	16
8	15,859.10	35	21	15,655.63	15
9	27,376.71	27	22	57,638.62	61
10	14,918.31	16	23	28,490.56	36
11	23,707.36	20	24	25,471.53	28
12	18,226.37	15	25	7,564.69	18
13	34,625.68	37			

The exterior and interior developments include the length of the supplying pipelines, traffic development, water supply, electricity supply and gas pipelines. In this housing estate, the rating of the energy efficiency class regarding to development is “G”, which is the lowest level in the rating system. Regarding to the quality of open space, this estate is rated “C” due to the existence of private green spaces and a low source of noise within 150 m. Even though this rating is not taken into account for the classification of this housing estate, it gives a roughly evaluation of the area on the comfort of the residents.

The next section of b) includes an exact description of each of the subareas and how far they are apart from various reference points. Then, it calculates a sum of CO_2 emission of traffic/LU/year of 0.26 t /LU/year, which is a satisfying rating of “D” level.

The last section of c), which weighs 0.35 in the overall calculation, is the quality of location and development. As the definition already tells us, the topographic location of every single subarea provides an influence. Those are all on one level. The type of building is also important, dividing into 4 different varieties: single family house attached or detached, row house and apartment complex. The last part for the overall evaluation is the alignment of the subareas. To define those houses closer, the direction was considered averted to the side of the street. In our housing estate this section is rated “B” and therefore the best rating in the weighting of classification. With those 3 calculated points of evaluation we have a total classification of the actual state in class “E”, meaning that it is in the lower level of the classification system.

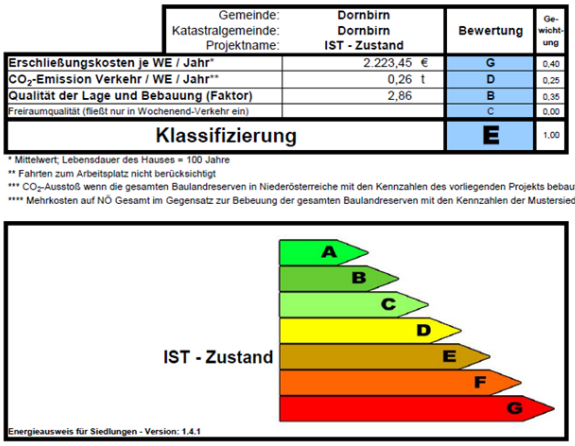

Fig. 2. Energy passes of the actual state.

3. Research of alternatives

After the evaluation of the energy pass in the actual state, we attempted to increase the energy usage efficiency. In this process, it was important to avoid a big alteration of the area; a total resituating of houses or a modification already existed in the street courses. Two different alternatives were elaborated, as explained below.

3.1 Alternative 1

Firstly, various parts of classification were closely considered and was found that the development costs per year are the largest in weight. Considering the energy pass of this housing estate, the factor has a relatively bad rating. To change this, the interior and exterior developments should be reviewed and edited or more building land has to be added.
The first point includes length of pipelines, traffic development, water and electricity supply, street lighting and length of gas pipelines. The problem is that the alteration of the area is not desirable. This means that in order to change those developments, the lengths have to be shortened. But, that is possible only if the whole streets are altered or houses are relocated. Because that is not the best option, maybe more lands for buildings could be added.

The investigated area has a total of 100,000 m² of auxiliary housing constructions, so this section will be extended. Two new subareas, one with 17,886.89 m² and 16 living units and the other with 27,969.23 m² and 28 living units are added, reducing the auxiliary to approximately 57,000 m². The new building areas certainly need accessibility to the transport system leading to the construction of a new street. This street causes an increase in the length of transportation routes of 567 m. Consequently, there is still a green area and an ideal expansion of the housing estate that causes almost no modification in the cityscape and the small increase of living units has no influence on the improvement of the energy level of the development.
Our chosen area in Dornbirn-Schoren has approximately 539 living units, with the expansion the number increases to 583. But, as there is a constant growth of population, the area is calculated with a triple expansion. This decreases the development costs per living unit from 88,376 to 25,000 euro per year and the energy efficiency increases by three levels and is now at the level of “D”.
The remaining calculations did not reveal any increase so the end classification for a) is class “D”, factor b) is also at level “D” and the last factor c) reaches the level “B”. As a result of the increase the number of living units, a better classification arises and is now at level “C”, which is an acceptable result.

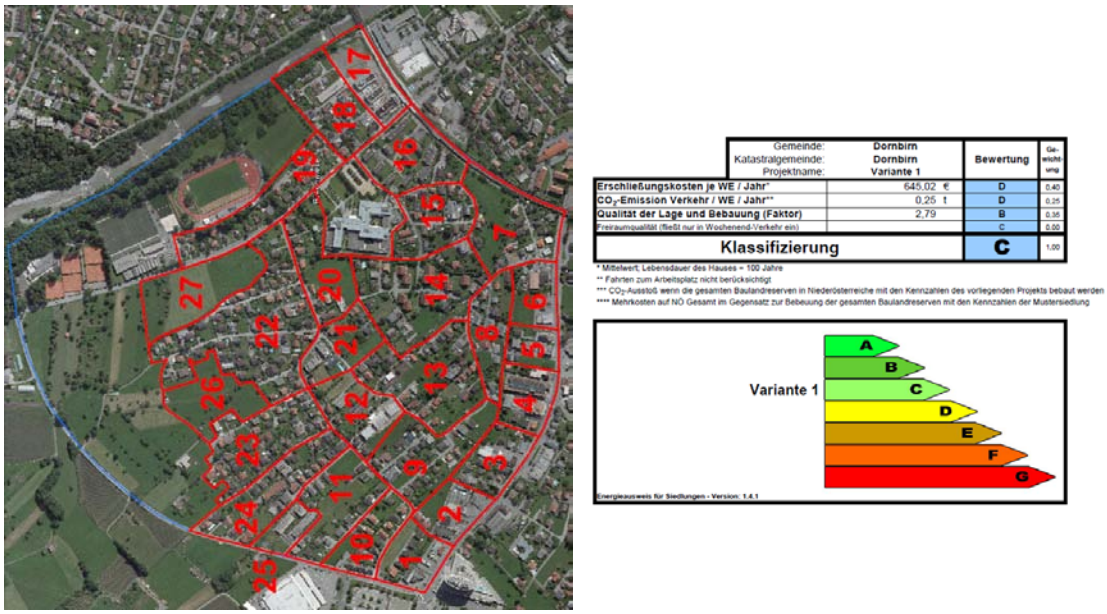

Fig. 3. Left: blue line denotes the investigated area, red line denotes the subareas with numerations right: energy passes alternative 1.

3.2 Alternative 2

Another alternative to improve the energy usage efficiency is to change the CO_2 emission and the quality of location and development. The latter is quite difficult to readapt, because it would be difficult to relocate the estate from a flat topography into a mountain range. Equally impossible would be to consider a new development since the area already exists and is not newly constructed. For building the future estates, those factors should be taken into consideration in advance because it might be impossible or really difficult and costly to change it afterwards. That means, for the second alternative, the CO_2 emission is going to be influenced to get to a higher level of classification. Currently, the rating is at the level of “D”. To change this, the following factors can be changed, involving a length specification of different subareas.
Weekday

- To town center
- To closest local amenity
- To playground/green area
- To kindergarten
- To primary school

- To closest public transport station

Saturday, Sunday and holiday

- To green area > 1500 m²
- To recreational or cultural facility
- To sports area or playground > 500 m²

In this housing estate almost every subarea is at least 1500 m away from the town center, thus a reduction of 500 m is assumed. This could be realized through assuming that the existing peripheral area with the same development is close to the city area. Using this method, an improvement of every subarea of 1 to 2 levels can be induced.

The other factor of improvement is the distance to the closest local amenity. The investigated area is part of a larger city and the local amenities are usually 1500 m away. Another increase of the outcome could be achieved through making sure they are only 1000 m apart.

With those two improvements in the performance of Dornbirn, Area Schoren, can be improved from level “D” to “B”. That means, two levels of enhancement, meaning improvement from a satisfying efficient energy usage level to an almost very good level. So, with a certain consideration of the structure of a housing estate, a significantly good usage can be gained.

The remaining calculations did not bring any increase, so the end classification can be calculated with the respective weighting.

- Development costs per LU/year: level “G”
- CO_2 emission of traffic per LU/year: level “B”
- Quality of location and development: level “B”

With the improvement of CO_2 emission of traffic the area increases to level “D” which means that there is a satisfying energy efficient usage of resources.

Alois Kraussler, 4ward Energy Research GmbH, Austria, alois.kraussler@4wardenenergy.at

Short Summary

The small city of Hartberg wants to demonstrate a smart city within the Austrian promotion program “smart energy Demo”. By establishing a zero emission district at downtown of Hartberg with outstanding showcases of “green” technologies Hartberg turns the conditions of a small city into advantages to support an expansion to the surrounding. Based on a comprehensive bottom-up approach and a scientific / technical monitoring a balanced bundle of demonstrations are being implemented, that are linked to each other interdisciplinary (smart… buildings, municipal disposal, energy, communication, mobility, business-models). „SMART CITY Hartberg“ has already overcome several challenges to establish a small city of the future. Thus small cities show a significant potential for realizing a climate-protecting and sustainable environment.

Keywords: Smart city; demonstration; zero emission district; sustainability; energy.

1. Introduction

Cities cause currently 80% of the global greenhouse gas emissions, even though they account for only 2% of the global surface. In addition, the current world population development shows an increasing urbanization [1]. This fact is also true for Austria, whose cities will grow significantly until 2030 [2]. In the interdisciplinary and complex field of tension between quality of life, competitiveness and environmental protection therefore new, holistic approaches to the CITY OF THE FUTURE are required.
The small city of Hartberg (inhabitants: 11,000; area: 10 km²) faces the challenges as one of 6 Austrian SMART CITIES within the promotion program “smart energy Demo – fit for set”. [3] The district capital is a small sized town and by the the use of "green" technologies it wants to become CO_2 neutral. The urban area of and around Hartberg accumulates a mature, cohesive and compact area. Its characteristics are comparable with thousands of cities across Europe. By a comprehensive package of measures tailored and adapted to a small town a reproducible model region (small Smart City) should be established with a national impact. In particular, Hartbergers buildings provide innovative, meaningful demonstration possibilities of future urban development.
In opposition to major cities Hartberg has significantly different conditions to demonstrate a Smart City. There are differences in terms of sustainable transport solutions, energy policy for decentralized generation, the scale and complexity of demonstration opportunities, available resources (human, energy, financial, time, building, infrastructure, resources etc.), the process of participation of residents and stakeholders, the economic structures and the philosophy etc.. Additionally the vision of the city of Hartberg is is inspired and influenced by the cultural trend "Città Slow". This motion wants to improve the urban quality of life, while globalization and homogenization, which exist especially in larger cities, should be avoided. Thus other actions are necessary to encourage demonstrations and investments.

2. Objectives to establish a SMART CITY on small-town scale

The main objective of the project is the development and demonstration of a zero emission district at downtown of Hartberg (historic core zone) as highly frequented "heart" of small towns by outstanding showcases of “green” technologies. Thus Hartberg turns the conditions of a small city into advantages to support an expansion to the surrounding. Following demonstrations should be implemented:

- Smart Buildings / Smart Municipal Disposal:
  - (A) Establishment of an ideal new smart building complex for commercial & residential issues in a historical downtown area: highest efficiency, PV-integration (landmarked area), electricity storage, energy management, (re)utilisation of gray & rain water, e-mobility-infrastructure, city information system & carpooling.
  - (B) Renovation of the landmarked town-hall of Hartberg: Building automation, e-mobility-infrastructure to an ideal historical smart city building.
- Smart Energy(grids) - Establishment of a smart biomass-based district heating network in the project core zone:
  - (A) Load management / optimization / shifting to avoid grid enforcements.
  - (B) Providing of a smart monitoring for consumers.
  - (C) Optimization of consumption at the consumers (based on the monitoring data).
- Smart Communication and Information: Several information outdoor & indoor-terminals in the project core zone: Touch-screen-function, real-time-information (e. g. traffic & city news), integrated feedback-possibility, free WLAN, additional public utilization via internet & mobile phones, routing and communication, traffic guide to provide real-time information (e. g. congestions or news).
- Smart Mobility:
  - (A) Establishment of car sharing: At the new basement garage of project “Alleegasse”.
  - (B) Providing of an e-mobility infrastructure for bikes, scooters and cars: At the new basement garage and at the main square.
  - (C) Establishment of 3 Shared Spaces: Main-square, Alleegasse & pedestrian zone-end.
  - (D) Real-time-traffic information & optimization of carless transport chain from/to Hartberg.
  - (F) Demonstration of an ideal e-mobility-package for single-buildings (typical characteristic of small towns): e-mobility-garage with PV-roof, charging unit, electricity storage, energy management tool.
- Smart business-models for consumption & supply as well as a package for carpooling together with flat-sale.

3. Approach to establish a SMART CITY on small-town scale

(1) Technical feasibility study (incl. roadmaps and action plans) according to Hartberg’s vision have been established on a comprehensive bottom-up- & interdisciplinary approach with focus on all smart city topics (interdivisional: energy, building, mobility, communication, society):

- Basis for the project is a comprehensive participatory process to link local stakeholders, experts, the population, companies (more than 50) and organizations with the initative.
- By a holistic approach (> 200 exploratory and coordination meetings) numerous demonstration opportunities and activities in the areas of buildings, energy networks, mobility, and communication and information were identified.
- From more than 200 demonstration facilities a priority with regard to feasibility, ecological relevance, financing possibilities and relevance of the vision of the city have been evaluated. The highest ranked measures, that have a chance of being implemented within the next 3 years, were included in the Smart City project. By a multidisciplinary integrative orientation with respect to ALL Smart City themes (across divisions: energy, buildings,

mobility, economy, society, ...) a coordinated and balanced package of measures have been worked out. The projects intents to implement integrated demonstration (no individual solutions), which are particularly suitable for the small town of Hartberg.

(2) Implementation of more than 10 smart city relevant and connected demonstrations (incl. business models), that are very suitable / reproducible for small / comparable cities by addressing an integrated, balanced and adjusted bundle of realizable measurements (no single solutions);

On the basis of experience of the project team [4, 5, 6] an appropriate approach to the development / demonstration a Smart City project was developed (see figure 1):

- A revision loop was built, which consists of 5 steps, so that a steady but consistent optimization of the entire urban system can be guaranteed.
- All 5 steps, which are interrelated, are with a diverse and inclusive stakeholder process crossed (complete involvement / participation of residents and stakeholders).
- Steady monitoring, evaluation and improving measures (incl. repeating loop, steady optimization measures and heterogeneous & integrated stakeholder-process): With the aim to provide reproducible results for small towns a monitoring and evaluation are accompanying the demonstration project.
- Accompanying research activities (technical, social and economic orientated);
- A comprehensive communication / dissemination of multipliable results / findings is performed.
- Finally, also preparations are made for the continuation of the Smart City activities after the project end. The goal of a CO_2-neutral Smart City will be followed after the project period.

The approach of Smart City Hartberg does not aim to develop components and individual solutions, but the high degree of innovation is given by the intelligent, holistic and complex linkage of almost mature technologies and systems.

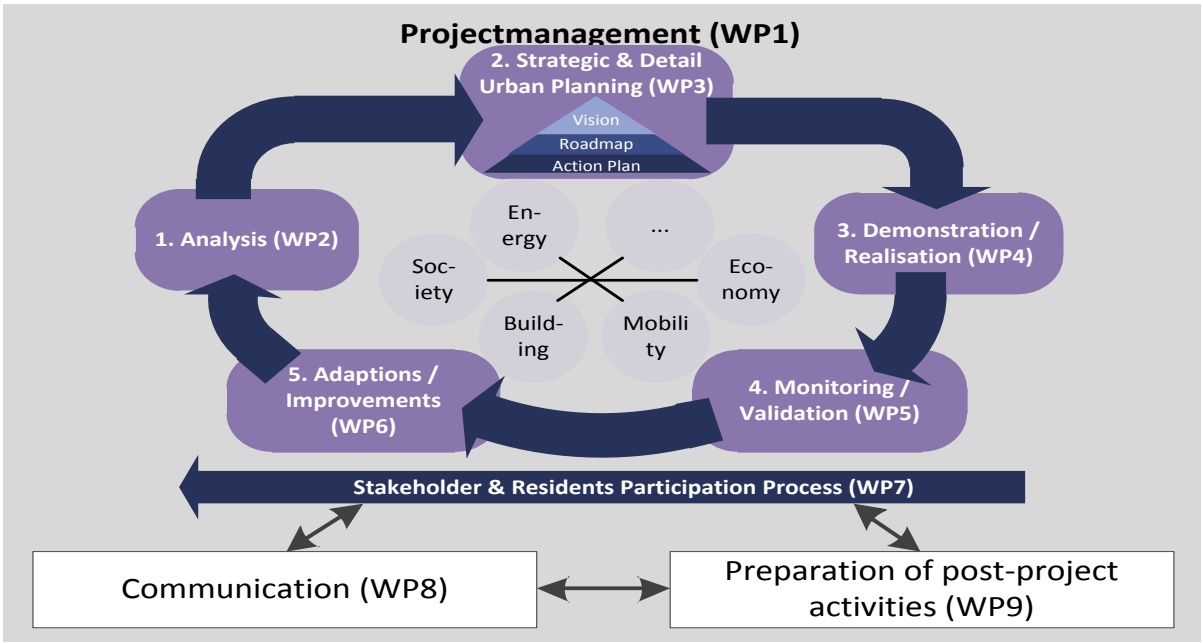

Fig. 1: Methodological approach for demonstrating the SMART CITY Hartberg

4. Factors of success to establish a SMART CITY on small-town scale

4.1 Project development: Creating Hartberg`s vision

Starting point for all Smart City activities was the "Città Slow" vision of Hartberg, which was developed through a comprehensive participation process with the full integration of the population, experts and politicians to build Hartberg`s vision of 2050 (see figure 2). [7]

Fig. 2: Vision of SMART CITY Hartberg 2050

The vision building process of Hartberg can be identified as one of the key factors of success, because it supported the comprehensive "Smart City" project (public, politicians, decision makers, stakeholders, associations, government agencies, business, and especially by a unanimous vote of the Municipal Council for the vision), and it was the basis for a successful Living Lab approach.

4.2 The Living Lab approach of SMART CITY HARTBERG

Behind the concept of Living Lab SMART CITY HARTBERG there is an innovative approach that shifts the development of innovative products from the laboratory to the real world. In particular, the (potential) users can express their opinions on new ideas as early as possible or try out first test applications in their everyday life. But also representatives of other groups (energy suppliers, component suppliers, planners, municipality / agencies, R&D facilities etc.) play a role. They are involved actively in the development process and give a feedback about the product quality, equipment and conditions. In this way, costly mistakes could be prevented and the user friendliness of products is increased. The innovativeness of the project Smart City Hartberg need not only be provided from the consortium, but the innovation aspect is generated through the creation of a diverse and inclusive environment from the interaction of people with different interests, perspectives and knowledge. These conditions are guaranteed by the Living Lab SMART CITY HARTBERG and thus increase the probability of the emergence of new, application-oriented solutions. Living Lab SMART CITY HARTBERG therefore promotes an intensive participation (especially for ongoing feedback), which can be used in addition to the participation in workshops and the new ICT media (internet, apps, Facebook etc.) to allow the inclusion of different actors and to bundle the communication (through e-participation).

4.3 Convert small-town features / challenge into advantages

As mentioned in section 1, in small towns exist differences for sustainable urban policy as in bigger cities. Small-town characteristics should therefore be transformed into a success factor:

- The close to the people provide an intensive participation process, leading to a broad support and project-related volunteer work. The available human resources have to be activated in other ways.
- The combination of ALL Smart City topics due to lower complexity and less effort is easier possible. A holistic view of the urban and (energy) system is supported.
- Project management is more efficient and flexible.
- In relation to the city size a large / wide consortia is possible through personal contacts. Optimally coordinated expertise and project partners can be implemented more easily.
- A decentralized energy supply policy is easier to implement, because there are more "open spaces" for solar use available in relation to the energy demand. Further a close relationship with the surrounding region for the biomass supply can be provided.
- Through the buttom-up approach appropriate targets for the region and measures can be defined. Mistakes can be avoided. This also affects the awareness positive.
- The economic structures have a significant impact on urban development and must be optimally integrated into a smart city theme. Therefore Smart City Hartberg binds several regional local companies in the project. At the same time a regional value is achieved.
- Small towns are financially weaker than bigger cities. In order for a secure financing partnerships are necessary. This was realized in Hartberg for the capital-intensive investment (EUR> 14 million), in particular through a public-private partnership (PPP) model.
- In small towns customized business models need to be implemented that address the specifics (e.g.: How the return of investment can be achieved with fewer inhabitants?). Therefore, different business models are developed and implemented within Smart City Hartberg, which are ideally suited for this city sizes.
- Pre-commercial Procurement: The project does not address the entire city area of Hartberg. Thus it is intended that the sustainable urban development goals are carried out in the downtown area through selected demonstrations (see Figure 3). This should support the spread to the surrounding region. This is achieved through pre-commercial procurement by the public sector that operates in the downtown area as a climate-and energy-conscious seller / investor of green / innovative technologies.

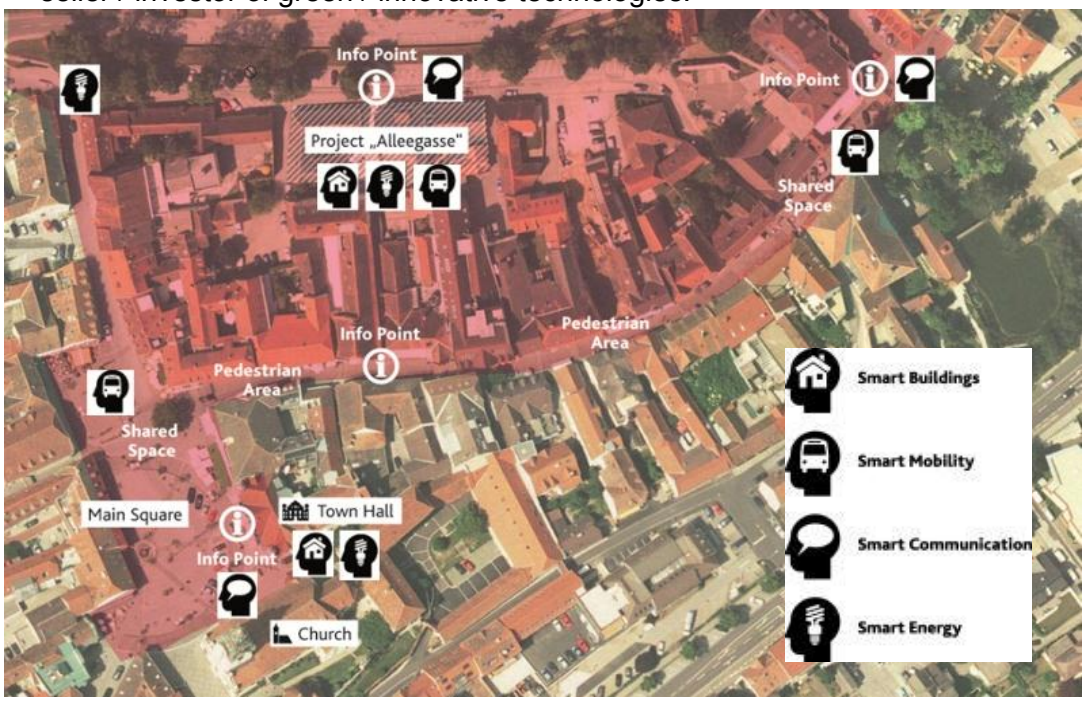

Fig. 3: Planned SMART CITY-demonstrations in downtown of Hartberg

Summing up a small town has many (other) degrees of freedom for sustainable urban policy. However, nodes must be found, which makes the complex Smart City-topic detectable for all. In Hartberg, this was done on the building sector, with an optimal interleaving of all other Smart City-topics.

4.4 Buildings as central “Smart City”-hub

In the building sector Smart City Hartberg has an energy-related orientation: About highest energy efficiency, renewable distributed generation from photovoltaics and a building-wide energy management for electricity, heating and cooling (central management, building automation, storage technologies, load shifting etc.). However, the buildings are also hubs of the Smart City-philosophy by linking all topics to each other. Thus demonstrations are integrative and visible:

- Implementation of an electric vehicle infrastructure in selected buildings;
- Implementation of a smart city-interactive information system (e.g. at the entrance to authorities, shops, offices or houses);
- Real-time information on energy consumption, CO_2-emissions, awareness raising, public transport (e.g. via the City Bus), car sharing points, e-vehicles-rental stations etc. in selected objects;
- Integration of a user feedback over the building infrastructure;
- Implementation of a flagship building, that is optimally integrated into the historic city area (on a PPP model);
- Demonstration of an intelligent and efficient landmarked building (City Hall);
- Implementation of business models in real estate (such as a sale of an apartment together with a car-sharing-utilisation).

With the term "Smart City" Hartberg therefore understands the coordinated linking of sustainable mobility technologies and flexible forms of suitable business models, which will lead over the nodal points of the building to a high quality of life.

5. Conclusions

Small towns have a great potential for implementing a climate protective and sustainable environment. However, this activation requires overcoming many challenges. The first results of the small smart city of Hartberg have shown, that it was worth to identify the city`s characteristics and to turn them into an advantage.

The earlier project development stage (establishment of the feasibility study) was much more time-consuming as proposed, because the comprehensive bottom-up approach involved more than 200 meetings. This has been resulting in a very high motivation of the stakeholders.

The close contact to the citizens and stakeholders in all project stages supports an ideal living lab approach (“user in the loop” & e-participation), whereas a balanced bundle of demonstrations could have been worked out for the demonstration stage.

The users and the quality of life have always been in the focus by a Living Lab approach. In this context an intensive preparation and coordination is necessary. The comprehensive bottom-up participatory process has been one of the key factors of success of this project phase.

Also a strong commitment of the city (government) is necessary, because the goal of a CO_2-neutral smart city must also be followed after the project period.

For the realization of sustainable urban development, it is advantageous if visible nodes are created via flagship projects. These has happened in the building sector, where all issues of sustainable urban development have been linked to each other (energy, buildings, mobility, economy, society, ...).

It has been advantageable for Smart City Hartberg not to pursue the development of new components and individual solutions. Thus Hartberg does not follow the implementation of single, but linked solutions. Hence compared to major cities several more topics and integrated demonstrations could have been addressed. But the project focuses on a smart and holistic

combination of almost mature technologies and systems. This approach is very complex / innovative and would otherwise be very risky.
For several investments the city of Hartberg acts as pre-commercial procurer. By these public pre-investments several private investors could have been encouraged to spend their money in smart city relevant projects. Thus a strong (financial) commitment of the city government enables leverage effects for private investments even in smaller cities (despite fewer economic growth potential than in bigger cities).
SMART CITY Hartberg enables smart demonstrations of sustainable urban development based on a Living Lab in a small urban area. It will create references for Austrian companies, provides experiences and recommendations for actions in the field of sustainable town development and provided extensive dissemination activities for multiplying the results.
Small cities show a significant potential for realizing a climate-protecting / sustainable environment. The activation needs to overcome several challenges that are different to major cities. „SMART CITY Hartberg“ has already overcome these challenges to establish a small city of the future.

Short Summary

For the upcoming transition of the energy system towards higher shares of renewable energies, the municipalities should be provided with a sound basis of information, scientifically supporting their decisions and aiming at overall optimal solutions. KomMod as a holistic high-resolution municipal energy system model offers such an analysis and the resulting strategic recommendations for a detailed and cost-effective future energy system of a municipality, thus helping to pave the way for future “Smart Cities”.

Keywords: Smart Energy Cities; KomMod; energy system model; municipality; mathematical optimisation

1. Introduction

Worldwide climate change mitigation is meanwhile seen as one of the most urgent and important challenges to humanity. This is most evident in cities in which as of approximately 2007 an ever increasing proportion of the world's population now resides and where correspondently most of the world's greenhouse gas emissions and energy consumption is concentrated. As this development is predicted to continue, the term “Smart City” has to have a special focus on energy if we want to tackle climate change [1].
Additionally, from a German perspective, cities also play a major role in the so-called Energiewende, or energy transition, that is, the transformation of the energy system from fossil and nuclear to renewable energy sources. While some of the required adaptions have to take place on a national level, many measures have to be implemented locally, for example, the energetic refurbishment of buildings, the installation of renewable energy based supply technologies as well as of new infrastructure for district heating and cooling.
Accordingly, many municipalities in Europe have recognised the resulting need for a significant reduction of their green house gas emissions as well as their energy consumption and have already taken on responsibility by setting themselves the relevant goals, for instance by joining initiatives like ICLEI or the Covenant of Mayors [2, 3]. These municipalities, willing to actively steer the transformation process of their energy systems, typically follow a pathway of three steps. First, an analysis of key indicators of their energy systems is carried out, and the municipalities commit themselves to climate goals. Secondly, the identification of possible measures for green house gas reduction and energy saving is done by studies on their building stock, on the reduction potentials of their energy consumption and the renewable energy potentials on their territory. And third, based on the first two steps, a refined specification of the municipal climate goals, together with a

roadmap of concrete measures to be taken to reach this target energy system, has to be developed. Besides social and political aspects which have to be taken into account, the roadmap is often developed under the premise of being cost-effective. The time horizon of such a roadmap involves decades and therefore has to be seen as an evolutionary process where the individual steps have to be evaluated and changed if and when necessary.
For the first two steps of the pathway shown, an annual analysis of energy flows, regarding demand and supply, local renewable energy potentials and so on, is usually sufficient. This means that the relevant studies are mostly based on annual cumulated amounts of energy instead of time series of demand and supply. Interdependencies between technologies as well as between the different energy sectors, electricity, heat/cold, gas, and transport, therefore are not yet taken into consideration. In contrast, at the latest for the third step, an in-depth analysis of the municipal energy system is needed, regarding time series and taking these interdependencies into account.
The energy system model, KomMod, described in the following and currently developed at the Fraunhofer ISE, delivers such an analysis and the resulting strategic recommendation for a detailed and cost-effective future energy system of a municipality, thus helping to pave the way for future “Smart Cities”.

2. Methodological Approach – The municipal energy system model KomMod

The development of KomMod is structured into three main tasks: analysis of the requirements of a municipal energy system model, comparison of the requirements with existing models, and creation of an energy system model, either based on an existing solution or by starting from scratch, that fulfils all needs.

2.1 Identified requirements

The future development of a municipal energy system is influenced by many parties forming a municipal community, among them, the municipal governance, (local) utilities, local industry, trade and commerce, citizens and other stakeholders.
The energy system model, KomMod, in the first place aims to address the needs of and find optimal solutions for this community as a whole and therefore takes a macroeconomic perspective. Accordingly the resulting solutions and recommendations are expected to differ from optimal solutions found for individual companies or groups of interest. The key questions from this perspective are what the future energy system should look like in detail and which measures ought to be taken to support the municipal goals best. To answer these questions, several fundamental aspects have to be taken into account.

As it is well-recognised that future energy systems will contain a high share of fluctuating renewable energies, an in depth-analysis has to be done in a high temporal resolution to make sure the energy supply is guaranteed at all times. A simplified calculation based on annual cumulated amounts of energy could, in contrast, lead to undetected temporal surpluses and shortfalls.
The same applies to spatial resolution. An aggregation of all data to a single spot would miscalculate the real conditions in certain situations. A solar thermal system on a building, for example, may provide excess heat during summer. Neglecting a spatial resolution, this heat could cover the neighbour's need for hot water too, even if there isn't any physical connection (piping) between the two buildings.

Another major aspect to be considered are interdependencies. This relates to cross-sectoral interdependencies between all four demand sectors, namely electricity, heat/cold, natural gas, and (local) transport, as well as to different technologies within a sector. Examples for cross-sectoral dependencies are combined heat and power plants (CHP), heat pumps (driven by gas or electrically), electric cars, and rooftop areas used for either photovoltaics or solar thermal installations. Intra-sectoral dependencies occur when for instance the specific CO2 emissions of a building could be reduced by insulation, by connection to a district heating network or by use of solar thermal energy.

Other kinds of dependencies, which also have to be considered, occur between structure (design) and operation of the components of an energy system. Below is a simple example of this.
Within a system consisting of a small thermal power plant run on biomass, a wind turbine and an electrical storage, times of little wind could be covered either by extended operation of the thermal power plant, an enlarged storage or additional wind turbine capacity. In each case, both structure and operation of the components would be affected by the decision, for example, that an enlarged storage may lead to a better utilisation of the wind conditions and therefore reduce the full load hours of the thermal power plant. For this reason it is necessary or at least useful to optimise structure (design) and operation simultaneously when dealing with strategic decisions.
Even in the above-mentioned very simple example, several solutions exist which might be equivalent or similar regarding technical criteria. It is very likely though, that they differ in cost as wind turbines and storages have higher specific investment costs than a thermal power plant, while the latter is much more costly during operation. Thus it is obvious that interdependencies between technical and economical aspects should be integrated into the calculations.

Against this background and regarding the complexity of the overall municipal energy system, a holistic energy system tool is needed which enables municipalities and other stakeholders to make decisions on a sound basis of information. The resulting future energy system and the roadmap to get there have to be specific to the municipality, offering an effective solution to reach their climate goals in a cost-effective way and taking the specific local circumstances into account, like building stock or local renewable energy potential.
An overview of a possible future municipal energy system including all of the above-mentioned demand sectors, interdependencies and a fundamental spatial structure is given by figure Fig. 1. As shown in the scheme, it can be useful to extend the system borders to the surroundings of a municipality to integrate agricultural areas as well as sites for wind turbines or large photovoltaic systems.

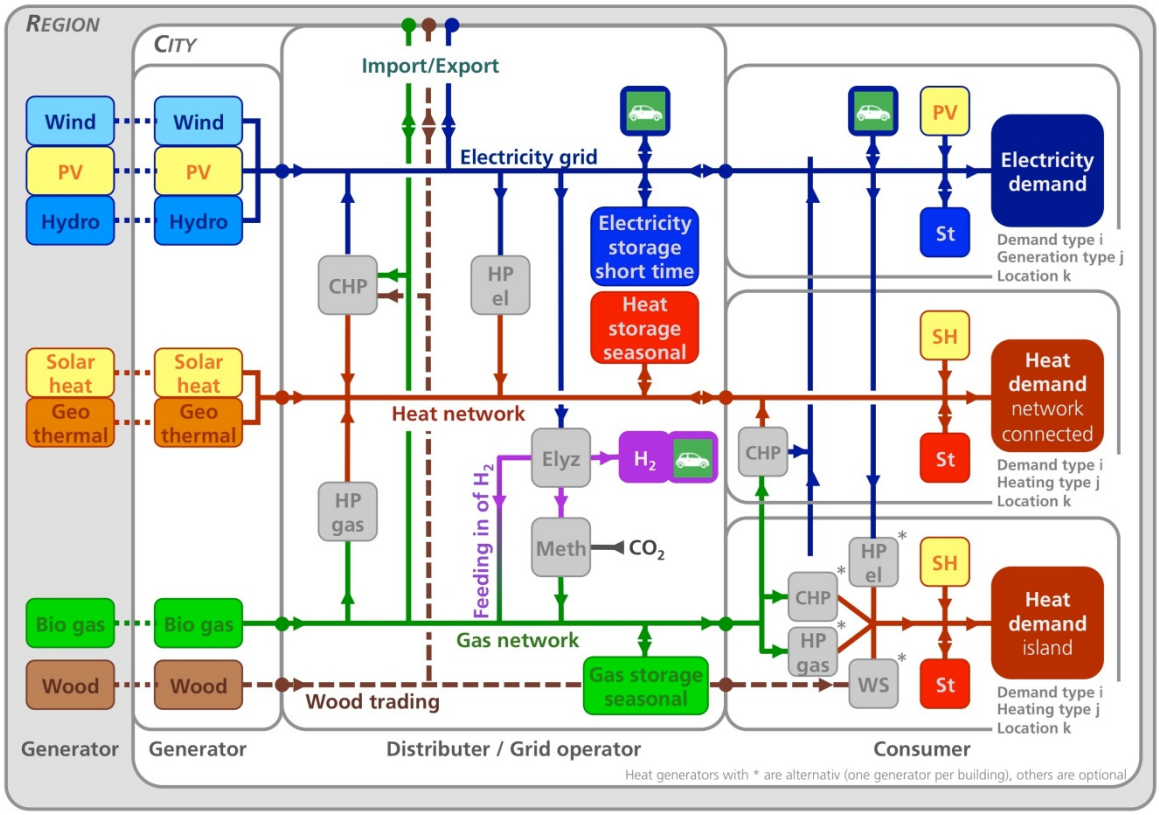

Fig. 1: Scheme of a municipal energy system based on renewable energies HP el/Gas = Heat pump electric / Gas driven, CHP = Combined Heat and Power, WS = Wood Stove, St = Storage, SH = Solar Heat, Elyz = Elektrolyzer, Meth = Methanation [4]

2.2 Analysis of existing energy system models

Over time many different energy system models have already been developed [5, 6, 7, 8]. Hence, it seemed reasonable to first take a look at existing models before starting from scratch. Complementary to the requirements described above with regards to content, the model has to fulfil several criteria with respect to flexibility and access, convenience, and stability. Crucial to the Fraunhofer ISE as a scientific institute is the ability to have almost complete access to every detail of the model, for example, to be able to adapt the model to future developments. This refers to the structure, the components included in the libraries, temporal and spatial resolution, and more. For the sake of convenience, the existence of component libraries (buildings, power plants, heaters) and a graphical user interface are desirable. More important though, is the computational power and robustness of the included mathematical solvers. A high developmental stage and the widespread use of the software therefore are wishful. Last but not least, licensing terms, including the right to change and distribute the model, and fees are of particular importance.

A comparison of the design specifications with existing models showed that none of them covers all of the identified needs. There are three main reasons for this discrepancy. The first reason is a deviation in scope. Many models are designed to deal with national or even the European energy system, hence the technical, temporal, and spatial resolution is, due to computational limitations, cruder than needed for a municipal dimension. The second reason is a restriction to only one or two of the above-mentioned four demand sectors, again often due to computational limitations. The third reason involves licencing issues and the resulting lack of publicly available documentation of models. As a result, it is hard to evaluate if any existing model does indeed cover the needs of or could be adapted to specific municipal requirements, and it is precisely for this reason that the Fraunhofer ISE initiated the development of an energy system model tailored specifically for the needs of a municipality.

3. KomMod – Design specifications

3.1 Holistic approach

KomMod is designed as a holistic and comprehensive energy system model to specifically fulfil the needs of municipal energy system analysis and optimisation. It is meant to serve as a tool for structural analysis and optimisation enabling strategic decisions from a holistic municipal community perspective. Technical as well as economical constraints are taken into account, covering the demand sectors, electricity, gas, and heat and in the near future also transport. The goal is to integrate most interdependencies between these sectors as well as between system design and operation into the model. KomMod therefore is built with a homogeneous modelling approach, implementing all components with the same modelling environment and including the optimisation of system design and operation into one simultaneously solved equation system. As a modelling environment, AMPL is used in combination with the mathematical solvers Gurobi and Conopt [9, 10].
Operation optimisation in this context relates to the derivation of general operation strategies for every component to best serve the needs of the whole system. The result for a certain component therefore may change if the rest of the system changes. This perspective is different from the optimisation that utilities do for their daily power plant operation, looking at only their own power plant portfolio. It also has to be distinguished from short term optimisation of forecasting and control where uncertainty, for example, of the prospected demand, weather conditions or market behaviour, plays a major role.

3.2 Perfect foresight and dynamic optimisation

Due to the strategic objective, the model is provided with perfect foresight over the whole time horizon of the optimisation. All input data therefore has to be available to the model at the beginning of an optimisation run, enabling the model to dynamically optimise over the whole time horizon simultaneously. Dynamic here refers to the fact that the requirements of future time steps are already taken into account for decisions regarding the current time step. This method is also commonly used for optimisation in real life environments, but with a much shorter time horizon due

to uncertainty. Dynamic in this context is different from the meaning within control theory – a field which KomMod doesn't aim for.
As the short term dynamics of the system components are not in the scope of KomMod either, every time step is seen as a point of steady-state operation. Limitations on a macroscopic scale, resulting from system dynamics, have to be taken into account, of course. Accordingly the component models include part-load efficiencies, load acceptance rates, minimal charging levels (reducing the net capacity of a storage) and self-discharge of storages for example. Some important properties, like minimal downtime, minimal run-time, and ramp-up time are still to be included in the model. Technologies are grouped into components of similar physical behaviour which can be described with identical equations. The equations within the component for combined heat and power (CHP) plants, for example, describe a CHP plant on a household level as well as a 800 MW hard coal power plant. The differences between the elements of a technology are expressed by a change in the parameter sets. As KomMod is built modular, any component model could be easily replaced by a more precise one if a specific technology should be examined in the system context in more detail later on.

3.3 Temporal and spatial resolution

The temporal resolution is set to an averaging period of one hour, intended to be reduced to 15 minutes. The range of 60 to 15 minute time steps provides a reasonable balance between the availability of data and the computational performance on the one hand, and the ability to cover times of shading due to passing cloud fields or times of wind calm on the other. Gusts of wind and single clouds won't be captured on a 15 minutes time interval though. While these have a huge impact on mechanical and electrical loads respectively, as well as on control engineering, their influence is negligible from an energetic point of view. The time interval chosen enables KomMod to provide answers to questions with respect to the amount and operation of short term storage.

Spatially the model is divided into zones, sub-zones, and building types. The size and the shape of the zones and sub-zones are adjustable to the specific needs of every municipality. A building type represents the smallest energy subsystem within the model. It is derived by grouping several different buildings with similar properties, such as the type of building (single family house, high-rise building), its age and heating demand, to one category thus allowing for a balance between detail and the amount of data [11]. With this concept of different levels of spatial aggregation it is possible to define interfaces at several levels which are of practical importance, as explained below.

On every level, from zones to building types, the energy balance for all three sectors (electricity, heat, and gas) currently included, has to be fulfilled for each time step. Except for the heating demand of buildings, KomMod expects the demand side to be given as input data, which therefore is fixed. The energy balance on every level has to be fulfilled accordingly on the supply side by either internal production or by import and export. KomMod allows import and export between the different spatial levels as well as an exchange within a level. To keep transfer routes short the direct exchange within a level is preferred.
The boundary of a building type is also interesting from a legal aspect as it is the interface between the house owner and the utility company. As KomMod calculates the time series at this boundary for every sector, it can provide utilities or grid operators with information about structural changes in the demand patterns if, for example, the share of photovoltaics or micro-CHP plants would increase in the future.
Sub-zones can be used to distinguish an area that differs in at least one property from the rest of the zone but still for some reason belongs to that zone. This could be the case when the sub-zone is a potential extension area for a district heating network which already exists in the rest of the zone. Here again, KomMod calculates load patterns and annual energy demand, also at the interface between the existing network and the potential extension, thus delivering key indicators for a utility provider or grid operator to decide pro or contra the extension.

3.4 Dealing with stochastic effects and uncertainty

KomMod is designed as a deterministic mathematical model. The underlying equations, transferring input into output data, don't contain any stochastic elements, and identical input parameters therefore will lead to the same results (there might be a deviation if several equal optima exist or if equations become non-linear and the model gets stuck in different local optima). The known and fixed relations between input and output facilitates troubleshooting of the model if necessary. It offers the possibility to reproduce calculations and, compared to a model containing stochastic elements, makes it easier to understand the overall relations between input parameters and the resulting output. In an optimal case this would lead to a better general understanding of the whole system as underlying general principles could be recognised.
KomMod aims at real world problems and even if it is a deterministic model, it cannot be ignored that uncertainty occurs in real life all the time and in different ways, and this must therefore be incorporated into the model where possible. Examples are stochastic effects like prediction uncertainties in terms of both demand and supply, in user behaviour, wind speed, and solar irradiance. Other sources of uncertainty derive from measurement errors, such as a lack of knowledge, insufficient or missing diagnostic options, and social aspects. While some measures dealing with uncertainty can be integrated within the pre-processing of KomMod or handled by scenario calculations and parameter variation, others are out of scope. According to the strategic focus of KomMod it is provided with real data but not online data.

3.5 Input data

Several input data for both the demand and supply side of each sector is required to enable the model to start with calculations. Above all, the technologies and resources which are available at a specific location have to be defined. Thus far, solar thermal systems and photovoltaics, wind turbines, combined heat and power plants run on fossil and renewable fuels, electrical and thermal storages, and different boilers are implemented in the model. Heat pumps and water power, inter alia, will follow.
For every supply technology to be included in the calculations limitations on fuel resources, for renewable energies mainly due to limited available surface areas, have to be given. Often this is coupled with administrative decisions regarding land use planning and other regulations. This applies to rural areas and agricultural ground as well as to development areas where it could be determined that for new buildings a certain amount of solar thermal systems or photovoltaics installed on the roof is mandatory. Information about the existing infrastructure, like power plants, district heating networks and the building stock, also has to be entered into the model.
Furthermore time series for weather data, solar irradiation, wind speed, and ambient temperature has to be known on the supply side. On the demand side the current demand for electricity and process heat has to be given, while the heating demand of every building type is calculated based on the ambient temperature and the irradiation at every time step.
In addition to the technical and energy-related limitations described above, economical values also have to be set. This includes interest rates, an average inflation rate, several specific costs for all technology included, existing and possible extensions of district heating networks, power plants and other infrastructures, as well as the refurbishment of every building type.

3.6 Output data

As KomMod optimises design and operation of every technology included simultaneously, it delivers recommendations for the capacity and number of facilities to be installed, as well as the relevant time series for these operations. Each facility is displayed with its location, its land requirements, its investment and operation costs. For all building types the best supply option for heat and the optimal refurbishment rate is calculated, leading to conclusions about extensions of district heating networks, if available. In combination with the expertise of the user, strategic recommendations for municipal stakeholders are a major outcome.

4. KomMod – First results, discussion and conclusions

Within this section first results will be presented serving as examples to show the practical relevance of the criteria catalogue and the soundness of the course of development described above. The underlying data is drawn from real measurements and technical specifications, but it is not consistent and doesn't belong to one single real site. Accordingly the results shall only be used to check the relevance of the formulated requirements and the compliance of these requirements with the model, but not to draw additional conclusions especially with regard to decisions in a real life environment. For this reason only a graphical analysis without underlying data will be presented. It should be emphasised that different and consistent data might lead to severe changes, for example, concerning the relevance of different technologies or their operation.

4.1 Temporal and spatial resolution

The figures Fig. 2 to Fig. 5 with an hourly resolution show clearly the well known diurnal variations particularly of electric demand and insolation. Besides the huge difference in the absolute values of the heating demand between winter and spring, these curves clearly show at a glance that temporal resolutions of one year and even down to a daily basis are too rough to analyse demand, fluctuating energies, and storages in depth, leading to a severe underestimation of the needed installed capacity and the negligence of interdependencies.

While it might be sufficient to represent the electric grid with a single node in many cases it is obvious that the results fail for the heat sector as figure Fig. 3 demonstrates. The different heating technologies and fuels are used in the order of their specific cost. Under the given circumstances this means that the CHP plant and the gas boilers are run constantly at full load and the solar thermal installations provide as much heat as possible. Only the load of the oil boilers is actively varied to cover the residual load. As already explained earlier this would only be possible if all suppliers and consumers were connected to a single district heating network. Hence the next step in model development is the integration of spatial disaggregation together with building types and district heating networks.

4.2 Interdependencies

Comparing the figures for electricity and heat in spring (Fig. 4, Fig. 5), the necessity to integrate inter-sectoral interdependencies becomes obvious. For the CHP plant it shows that the shape of electricity and heat supply curves is identical, implying that a certain amount of the one comes with a fixed amount of the other simultaneously. While for larger plants this ratio can be influenced and production can be shifted towards one side or the other within certain limits, the operating hours are strictly coupled. This can be seen around the 3120th and 3240th hour, when the CHP plant is switched off despite a need for heat supply which then is covered by the gas boiler. Looking only at the heat figure this doesn't seem plausible as, in the model, heat from the gas boiler is more expensive than that from the CHP plant. In combination with the electricity figure it can be seen that the model chose to operate the CHP plant electricity-led during that particular period and hence it can be concluded that electricity taken from the storage must be cheaper than that from the CHP plant and that the overall savings in cost on the electric side outweigh the additional expenses on the heat side. Accordingly, the operation of the different technologies changes if the fuel costs of the CHP plant are set to lower values. In this case, which is not shown in the figures, the CHP plant would be preferable also at the electric side at least at times around the 3120th hour and the operation of the CHP plant would swap from electricity-led to heat-led. It should be underlined that it is not predetermined in the model whether the operation of the CHP plant is electricity-led or heat-led, it could even change from time step to time step within one optimisation run. These reflections also show that technical and economical aspects have to be examined concurrently.
Similar changes in operation, as when changing the specific costs, also occur when changing the restrictions on the resource potentials. This means that changing the restrictions doesn't only affect the installed capacity of the technologies as is obvious when reaching the limits but also might change their operation widely at the same time. For this reason it is important to simultaneously optimise both aspects, structure and control.

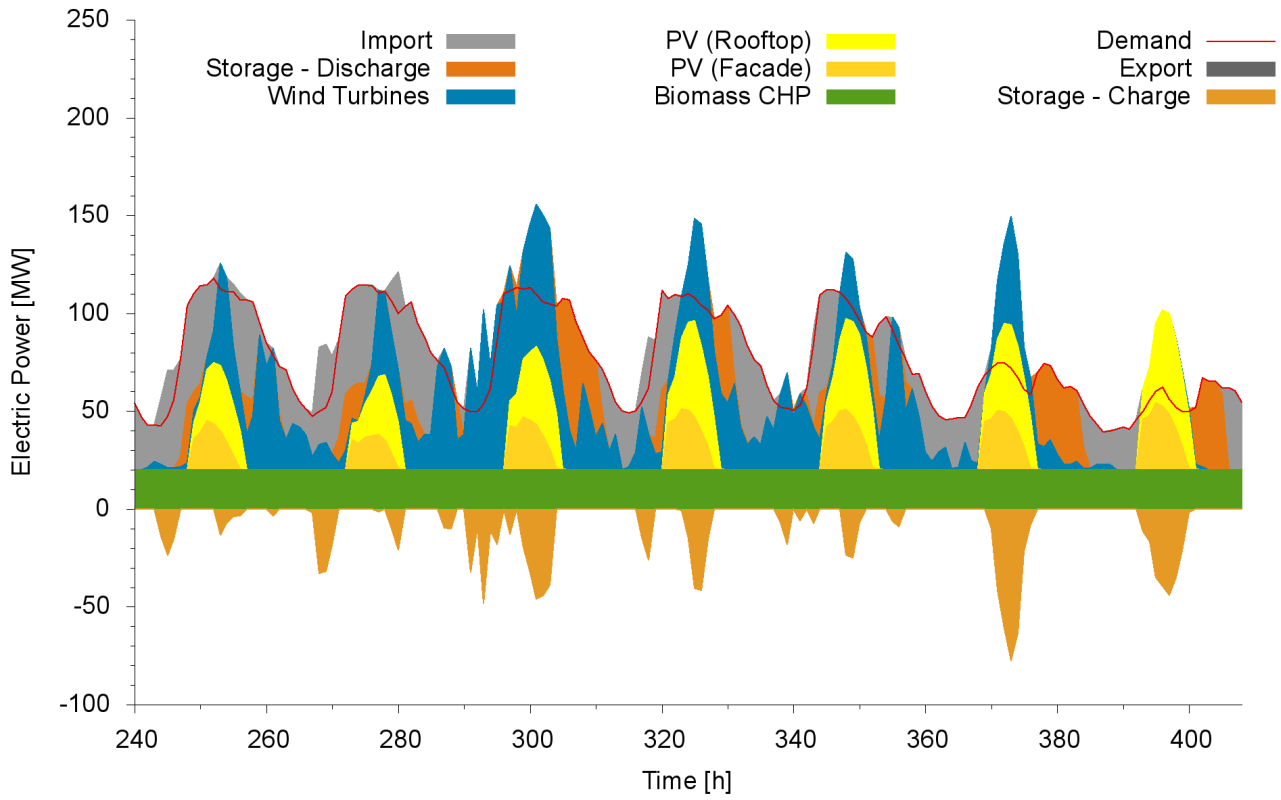

Fig. 2: Electricity demand and supply for one week in winter

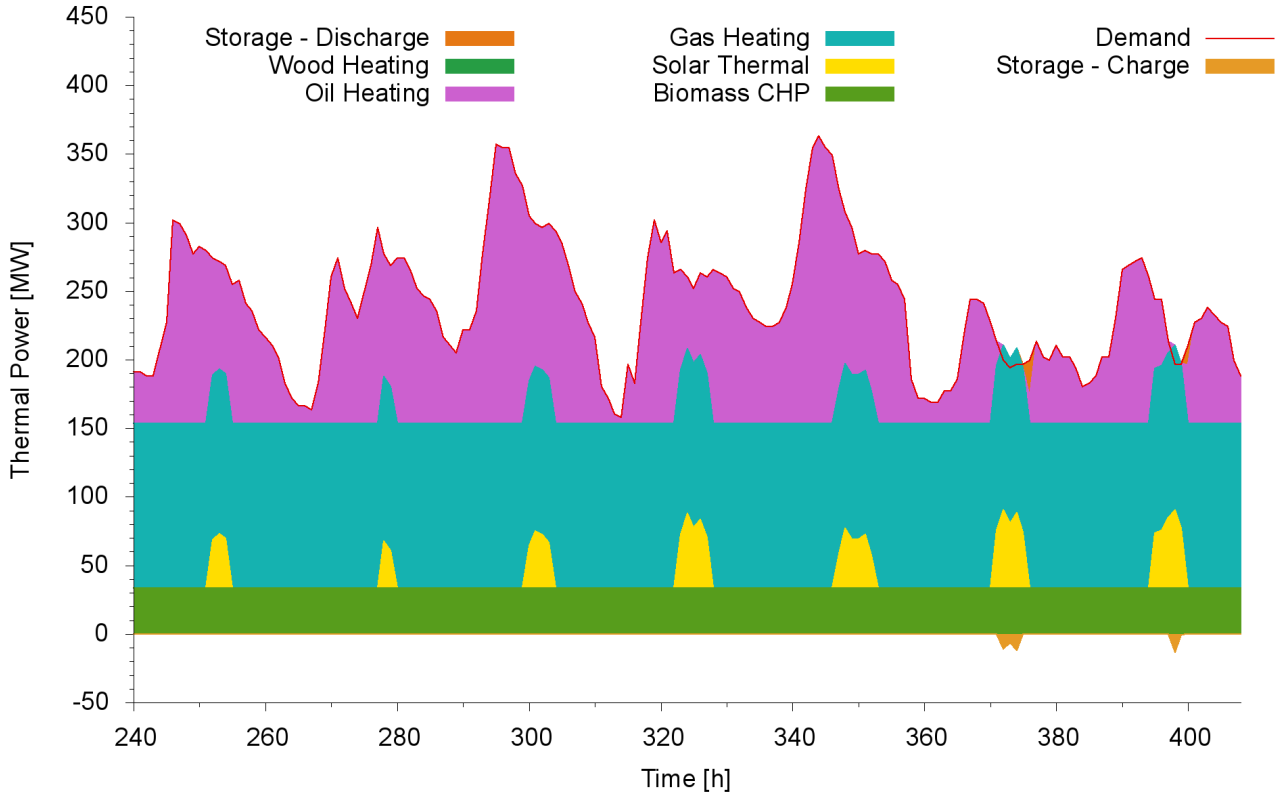

Fig. 3: Heat demand and supply for one week in winter

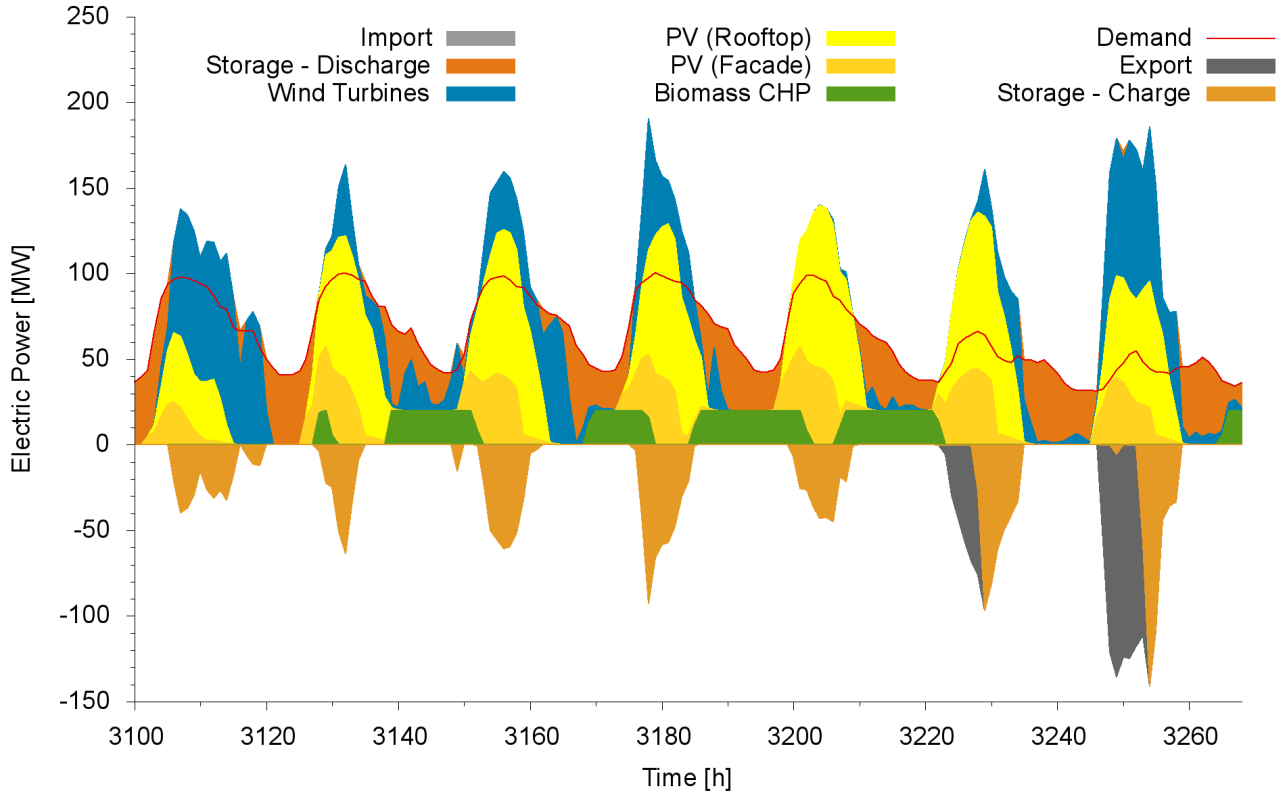

Fig. 4: Electricity demand and supply for one week in spring

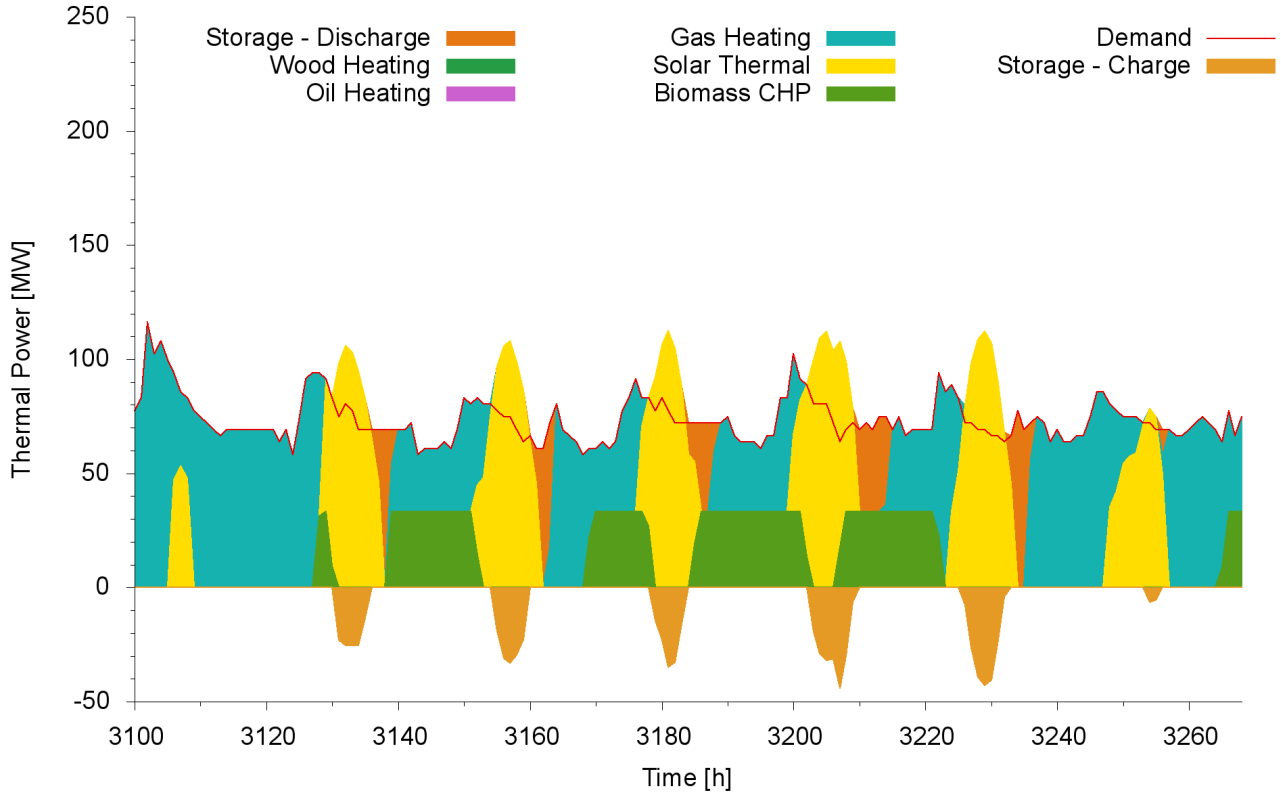

Fig. 5: Heat demand and supply for one week in spring

Together with the fact that especially the resource potentials and the demand patterns depend strongly on the local conditions, it can be concluded that the model has to be adapted to these specific conditions and that in general it won't be possible to transfer solutions directly from one municipality to another.

Looking at the figures, the necessity of modelling technologies with a high technical resolution can also be verified. As a first example, rooftop and façade photovoltaics will be compared on the basis of their supply curves (Fig. 6, Fig. 7), extracted from the complete figures above. In the model the two technologies differ in their installed capacity, efficiency, angle to the horizontal (rooftop 30 degrees and façade 90 degrees), and orientation (rooftop direction south and façade direction south-east). Three main differences can be observed. The curve of the façade installation reaches its maximum before the one of the rooftop system due to the orientation. The difference in angle results in a lower seasonal influence on the production of the façade system as well as in a squatter and rather levelled shape of the curve. Additionally it leads to lower peak loads and a lower energy production of the façade system per area or installed capacity, respectively, which cannot be drawn from the figures as the installed capacities and efficiencies differ from the rooftop installations. It is clear that the mentioned effects have an impact on the availability of electricity gained from photovoltaics and hence on the supply security and grid loads.

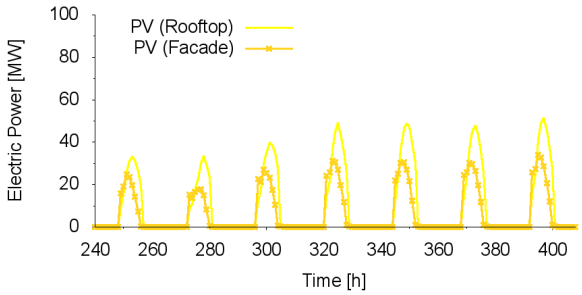

Fig. 6: Comparison of rooftop and façade PV in winter

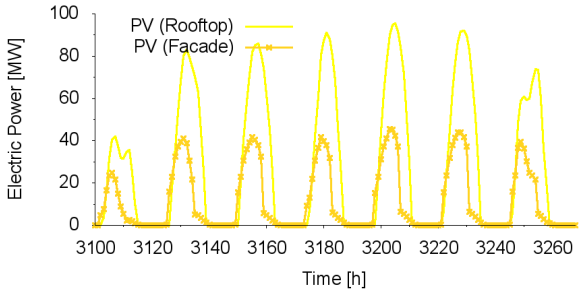

Fig. 7: Comparison of rooftop and façade PV in spring

A second example for the relevance of a high technical definition shall be given with respect to energy efficiency curves compared to annual average values, here exemplified with rooftop photovoltaics and solar thermal installations. While the energetic efficiency of photovoltaics rises with falling temperatures, solar thermal installations decline in efficiency at lower temperatures due to increasing thermal losses to the environment. The latter is especially important as it is directly opposed to the heat demand. A thermal efficiency averaged over time therefore would lead to a shortfall when the heat is needed the most. These effects can also partly be observed in the figures when looking at the switching times of solar thermal installations compared to rooftop photovoltaics (Fig. 8, Fig. 9). In spring the switching times of both systems are pretty much the same but in winter the solar thermal applications start notably later to produce energy and stop much earlier than the photovoltaics. The reason is that during winter when ambient temperatures are low, with solar thermal applications a fair amount of the insolation is needed to cover heat loss to the environment, thus lowering the net output. In times when the

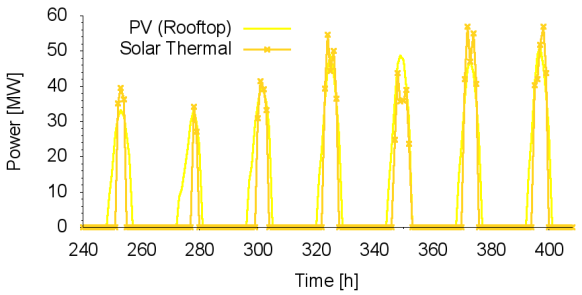

Fig. 8: Comparison of rooftop PV and solar thermal installations in winter

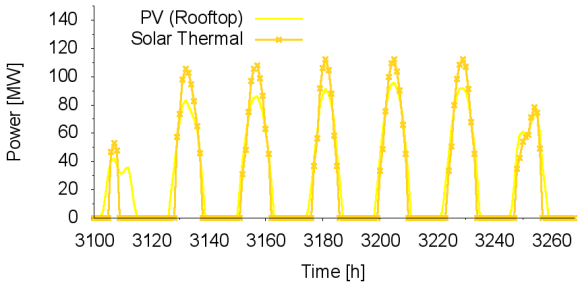

Fig. 9: Comparison of rooftop PV and solar thermal installations in spring

insolation is too weak to provide a net surplus the system is shut down. In this example both systems were orientated southwards but differed in angle (rooftop 30 degrees and solar thermal collectors 45 degrees to the horizontal) which in winter even improves the conditions in favour of the solar thermal system.

4.3 Perfect foresight and dynamic optimisation

The impact of dynamic optimisation and perfect foresight can be seen from the curves of the electrical and thermal storages (Fig. 2 to Fig. 5). It stands out that both storages are charged and discharged consecutively, thus being mainly used as short term storages for anything between a few hours and two days. This doesn't originate from the capacity limits set within the model as these were not reached. Under the premise of perfect foresight it is useful to charge the storage as late as possible to minimise the losses occurring until discharge. Around the 3240th hour (Fig. 4) this results in exporting electricity before filling the storage. This behaviour is not very realistic concerning risk management, of course. It therefore has to be seen as a theoretical optimum providing a lower bound which could be used to evaluate real-life solutions. The most apt solution to integrate risk awareness in this special case would be to swap charging the storage and export as the resulting additional losses could be probably ignored under real life conditions.
The dynamic behaviour of the model becomes apparent several times in winter (245th, 268th, 280th, and 318th hour with electricity, 373th and 398th hour with heat) (Fig. 2, Fig. 3). Taking a look at the electricity figure it can be observed that electricity is imported to fill up the storage only to be immediately discharged again while the import of electricity continues. The reason for this behaviour is that electricity imports are limited arbitrarily to 50 MW, so supply can only be guaranteed either by increasing the installed capacities of the supply technologies or by buffering demand peaks via storage.
With the heat sector the situation is different. Here the storage is not used due to capacity restrictions but to reduce costs as cheaper heat derived from the gas boilers replaces more expensive oil.

4.4 Conclusions and outlook

As a main outcome, the assumption could be validated that for a sound target energy system, and even more for the roadmap to get there, municipalities are in need of a detailed and high-resolution energy system model, tailored to their specific needs.
Even with the partly inconsistent data used for the first evaluations, it became obvious that only highly resolved temporal calculations are able to include effects resulting from fluctuating energy sources, the use of energy storage, and different kinds of interdependencies (cross-sectoral, intra-sectoral, structure and operation, technology and economy). This means also that models which are based on annual calculations and which are currently widely used for the first two steps on the pathway to becoming a smart (energy) city are inadequate for the third step.
To cover all sorts of interdependencies, additionally to the high temporal resolution, a high technical resolution and at least a basic spatial resolution are necessary – this could also be proved with the results gained with KomMod.
The full potential of a high temporal resolution can only be tapped when the level of technical detail is also appropriate. Examples which have an important influence on the whole energy system are the integration of load ramps or the deviation in operation of solar applications due to differences in orientation - features which can’t be properly integrated in annual calculations. A fine technical resolution also has to be integrated due to the fact that with higher shares of inflexible renewable energies, together with the limitation of the use of flexible (fossil) fuels like gas and oil or their use in combined processes, the energy system will become inelastic and less robust than today. Accordingly the interactions of the different technologies become more important and the technical detail in which they are modelled has to be increased to be able to provide solutions applicable to real life environments. The results show this fact in the operation scheme of the CHP plant, as well as in the different operation patterns of the solar technologies, leading to different residual loads.
The necessity for a spatial resolution could be shown in the heat sector but would also occur wherever the topology plays a significant role like it does with networks. Additionally with spatially resolved systems it is possible to split up costs and energy flows for different groups of interest, allowing to take the particular view of private house owners or utility providers.

Furthermore it could be shown that the identified requirements have a notable impact on the optimisation results and that the course chosen to develop KomMod is plausible and in line with these requirements. The next steps will be to implement a spatial resolution, building types and district heating networks, followed by the integration of the transport sector and, of course, to validate KomMod and the first findings also with consistent real data. Later on methods to integrate uncertainty should be evaluated and new methods which allow for the identification of robust paths have to be developed.

5. Acknowledgements

Jan-Bleicke Eggers would like to kindly thank Prof. Dr.-Ing. Prof. e.h. Dr. h.c. G. Tsatsaronis, Technische Universität Berlin, for supervising his dissertation on KomMod.

Project –“Morgenstadt: City Insights” - Analysis of Interactions Between Key Factors

Elvira Ockel

Scientific Researcher
Fraunhofer Institute
for Building Physics
IBP, Germany
Elvira.Ockel@ibp.fra
unhofer.de

Katrin Lenz, Fraunhofer Institute for Building Physics, Germany, Katrin.Lenz@ibp.fraunhofer.de

Short Summary

The project „Morgenstadt: City Insights“ is dealing with the complex interactions of city developments. Its research activities on the most important sectors for the cities of the future – mobility, energy, communications, security, buildings, resources and governance – will lay the foundation for creating smart and sustainable system interconnection for urban structures. Different competences of the Fraunhofer Gesellschaft will join forces and combine technology management for essential technology- and organization-based urban systems with practical knowhow of industrial, political and cities partners. A transdisciplinary approach will help identify systems and success factors of cities on their way to future sustainability. As a result of the long-term process best practices towards sustainable and smart urban ecosystems will be identified and complemented by a systemic analysis of innovative processes in cutting edge cities especially with regard to transferability.

Keywords:

Morgenstadt; CityInsights; sustainability; interactions; systemic interconnection; energy; buildings; government.

1. Introduction

The future living space of our growing population will focus on large cities that offer rich social connection, interconnected work and home space as well as all necessary services concerning healthy, comfortable living. As expectations and standards rise, the challenges within city development gain complexity and new approaches to overcome them are required. [1] Even today climate change, infrastructure, economic development and life-quality induced by scarce resources and the mere number of people are ever-present questions for larger cities. Ecological sustainability as well as pursuit of economic prosperity are the two key issues for cities in the future. Both goals can be achieved by recognizing cities as future markets for sustainable concepts of mobility, building, communication, energy generation, production and consumption. But these concepts will inevitably link different technology sectors and products with each other in a much stronger way than today. Solutions will increasingly have to overleap sectorial boundaries and combine multiple technologies, as well as interconnect different sectors. [2]

As Europe’s largest application-oriented research organization the Fraunhofer Gesellschaft has long expertise in city development. 12 Fraunhofer Institutes have introduced various innovative approaches in their research field. Now their expertise will be combined and focused in the collaborative, transdisciplinary research team “Morgenstadt: City Insights”. Partners from the industry,

from interested cities and international value partners further enhance this team. The concept of this network creates a strong background in precise research, innovative applications and integrated urban solutions. Together they will use their knowledge in key factors such as mobility, energy, communications, security, buildings, resources and governance, to create a foundation for smart and sustainable urban solutions of tomorrow. By creating such variable insights, problems like natural catastrophes that concern almost all research fields can be addressed in one multidimensional approach.

Hereby the goal of the project is to synchronize emerging urban demands and global best-practice approaches in a strategic research project and to thereby develop the basis for innovation of new strategies, products and urban solutions.

2. Research subject – Morgenstadt: City Insights

The research focus of the “Morgenstadt: City Insights” is to create a knowledge foundation about the urban environment and the interconnection of its key factors. Cities nowadays face various challenges that cannot be solved from only one key factor or separately in each key factor. Therefore, interactions between the key elements have to be analysed. By integrating the identified solutions of key factors into one systemic and cross-sectoral approach, the cities of the future will be put in a position that allows them to combine unique solutions and to provide basis for entering new markets for sustainable urban systems.

The key factors that are represented in the Morgenstadt: City Insight research mobility, energy, communications, security, buildings, resources and governance have been chosen because of their large impact on city developments and their high interaction forming the basis of current challenges. One of those challenges is for instance transportation of masses of people in very short time and during rush hours. What are the future ways of guaranteeing this kind of mobility or a better one? How can we avoid traffic jams and trains running late? Which vehicles and technologies will help lowering energy demand on transportation? Already at this stage we can see a connection between two key factors: talking about future *transportation* is impossible without regarding future *energy* sources, ways of energy transmission and technology for storing produced energy. One innovative solution to create energy for transportation is the concept of “plus-energy houses”, which may use surplus energy for supplying electric cars.

That fact brings us to the third key factor: *buildings*. Growing cities need to provide standards for new buildings, concepts for retrofitting, strategies for the arrangement of and especially approaches for energy efficiency of future cities. Another important aspect in growing cities is density, asking for well-balanced concepts which take into account surface areas, height and distance of and between buildings as well as for transportation systems and their roots.

In addition to the impact of buildings on energy challenges, recent years also introduced many challenges for the security of buildings, such as being resistant to floods, earthquakes or fire as well as to terror attacks. Through the example of Hurricane Sandy in New York City, which is one of the represented Cities in Morgenstadt: City Insights, it is demonstrated, that the before mentioned key factors interact with the key factor *security* for urban environments. Security, as in article 3 “Systemic view on cities – New York City after Hurricane Sandy” mentioned, is a cross-sectorial component influencing every other field, especially in those cities at risk (i.e. in New York City with natural disasters). Here, security in traffic and transportation, security of buildings, security of energy resources, such as nuclear power plants and very recently the security of personal data is an ever-growing issue. How can we create easy access and interaction with information all around the city without risking data leakage or attacks in the network? Communication is gaining more and more importance in our everyday life and now we have the chance to use it to create better systems for our city of the future.

The last important key factor also connects to most of the above mentioned: *resources*. Every new building, car or security system will someday fail or need to be replaced. We have to start thinking about the whole cycle our resources complete before implementing them. Waste, recycling and reuse of material will gain more weight as *resources* get scarce and space for collecting waste

material becomes rare.

Insight into all those key factors and their interaction will be created by analysis of six global cities with good reputations about their development and their ideas for the city of the future. New York, Berlin, Freiburg, Singapore, Tokyo and Copenhagen are the chosen cities. All of them are already working at developing their cities and preparing them for future challenges. For each city a defined number of known best practices will be investigated. Used legislative standards and technical concepts, financial programs and roadmaps, political incentives and laws will be examined to get an objective overview of state of the art and ambitious solutions.

For analysis of each city, the project is divided into three working steps. First, analyse urban best practice worldwide. This step covers the capture of today´s challenges and concepts on the partner level. The methodology will be based on expert interviews and meta-studies of existing knowledge and approaches. The second step explores leading cities in on-site field research. Researchers will spend several months for on-site and in-depth analysis in represented cities. For each study a detailed report will be compiled. The third research module deals with identifying of requirements for innovative concepts. The result will be a summary of the preceding research covering a wide range of global best practice. After concluding a catalogue if synchronized requirements and a broad insight into global best practice will be used as the sound foundation of the consecutive Morgenstadt research stage (2013-2015).

3. Systemic view on cities – New York City after hurricane Sandy

To show the systemic interaction of different key factors, we will introduce the “New York Cities actions” [Q] after hurricane Sandy. In the following we will review the reaction of the New York government and the changes causes on one of our urban research objectives by a natural catastrophe.

3.1 New York City

With 8.24 million inhabitants New York City (NYC) exceeds all other cities of the USA. By 2030 it will be furthermore home to over nine million people. Growing into one of the largest metropolitan areas worldwide, it has to face immense challenges to adapt to the current situation. Most of New Yorks infrastructure and buildings satisfy only last century’s standards and therefor have to undertake great changes in order to master climate change, changes in society and security of both natural and human attacks. Since 2007, Mayor Bloomberg is facing these changes with an unprecedented city wide effort. He created the PlaNYC 2030 [Q] in order to prepare his city for population growth, climate changes and economic risks as well as to offer a rich quality life for all future inhabitants. In order to pursue these goals, a network of 25 city agencies has been created and significant progress has been made on the defined milestones and long-term goals.

In 2007, NYC set a goal to reduce GHG emissions by more than 30% by 2030 compared to 2005 levels. The PlaNYC describes a series of actions that have yielded significant progress toward this goal. Many initiatives have been already started to reach that goal. For example the “Greater greener buildings plan (GreenNYC)” that was introduced to create awareness of energy efficiency, especially in larger building complexes, and to enforce new building standards by 4 local laws and some further tax incentives. On the other hand, GreeNYC tries to accomplish an open mind-set in New Yorks inhabitants and offers counselling on any questions about energy saving, waste reduction, and rational usage of resources. The PlaNYC also approaches other sectors. Traffic should be improved, affordable housing should be created, waste management and recycling should be further advanced.

3.2 Consequences of hurricane Sandy

2012 at the end of October hurricane Sandy hit the coast of New York. Although this coast has always been vulnerable to flooding and storms, Sandy brought great damage to many people and

buildings. 43 people had to give their lives in consequence of the events. 200 homes were destroyed completely and another 500 homes have major structural damage. The reconstruction process will take a lot of time and require financial investments around 71.4 billion dollars. Many weeks passed with lack of resources like petrol, electricity or food. Now half a year after Sandy, you can still see the consequences for those regions. Some buildings are being repaired; some rebuild and others are totally lost. This example shows us to some extend how climate change can create new challenges for cities and it also shows us the importance of climate resilience to prevent damages in such dimensions. The natural catastrophe also shows how many different key factors need to be combined to create innovative solutions against this problem. To use only governmental means, would cause the endangered regions to be evacuated and resettled. On the other hand, security measures like protections walls and water drainage systems cannot be standalone solutions, if the buildings are made of light material or on a bad foundation. Even the buildings cannot themselves prevent any damage such an event would cause on a region because it cannot influence the impact on streets, wires or vehicles. To create an overall approach you have to consider the interconnections and synergies between all factors involved. Therefor we can evaluate the best-practice reaction of New York government to those events in order to give some insight into urban systems.

3.3 Governmental reaction

The PlaNYC [3] is a constantly reviewed and changing plan. It adapts to unknown situations to redefined awareness and to current research progress. One key element of the PlaNYC has been to create a resistant building structure in coastal areas with high risks for flooding and storms. Therefor City's Comprehensive Waterfront Plan tries to identify the outreach of natural catastrophes at the coast of NY. Now after Sandy a living example of the importance of this element, efforts were increased and solutions are sought. Even one week before Sandy hit, the Office of Long Term Planning, initiated an Army Corps study [4] about steps to reduce the impact of coastal storms. Usually those studies take years to be completed, but after Sandy the problem became much more immediate. So these are the steps that will be undertaken to create a more climate resilient New York City.

3.3.1 Future Flood Zone changing

Since Sandy in many cases exceeded the given Flood Insurance Rate Maps (FIRMs), that were indicating risky zones based on previous flooding. Considering this the Federal Emergency Management Agency (FEMA) will update those maps and include recently damaged zones. It should also remove additional impediments to flood-resistant construction, and modify regulations to mitigate potential negative effects of flood-resistant construction on the streetscape and public realm.

Those maps will also be used for future building codes, since they should apply for all houses inside the endangered zone. Until the final adoption of those maps in 2015 the department will address those zones on basis of the non-binding maps. In 2015, the building codes will be advanced on the new map base and regulations will also address those regions.

Fig. 1: Areas within which text Amendment would apply, [4]

3.3.2 Flood Resilience Zoning Text Amendment [4]

To give the people rebuilding their houses best insight in their opportunities, the DCP has proposed a Flood Resilience Zoning Text Amendment. This includes several steps. First it should enable all people at risk of storm surges or coastal flooding to create a more climate resilient home for themselves. Therefor, the current data of Sandy was integrated into a map of New York City, by the Federal Emergency Management (FEMA). This map contains information about the zones in New York being at risk of natural catastrophes, and also creates the basic zoning step for some climate resilience guidelines. These guidelines mainly consist of new building codes required for all endangered zones.

3.3.3 Rezoning

On January 31 2013 the Mayor´s Office created the Executive Order No. 230 to enable owners of buildings inside the new Federal Emergency Management (FEMA) flood risk zone to build climate resilient. Previously some height limitations of building codes were in conflict with latest flood-resilient standards. Therefor these limitations will be suspended to guaranty the additional flexibility required for further steps. Now people can rebuild to a higher elevation and thus follow the new building codes for flooding areas. To prevent misuse of these changes, the executive order will expire and be replaced by a full zoning text amendment.

3.3.4 Building Codes

The proposed text amendment is created to enable those buildings destroyed or damaged by Sandy as well as those buildings being build new in such a region to be designed and constructed based on most current research results on flood standards. Building codes [5] apply to all buildings being new and all improvements that exceed 50% of the market value of those buildings. They are regulated by the Federal Emergency Management (FEMA) Flood Insurance Rate Maps (FIRMs) that defines a 100-year flood zone as well as different flood proof heights (Base Flood Elevation (BFE)) for each part of that zone. The buildings are divided into 2 different zones and apply 3 different flood-proofing methods.

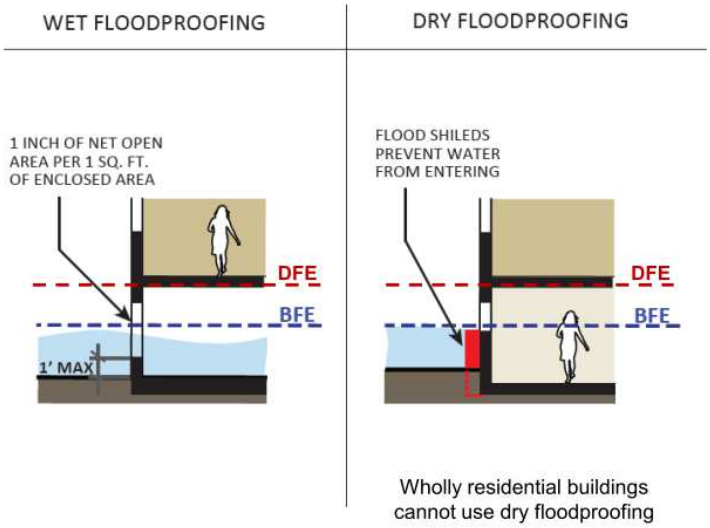

Fig.:2 Wet and dry floodproofing, [5]

In order to be protected buildings at risk have to be elevated above the BFE. The building part below the BFE can be either wet-flood proofed or dry-flood proofed. Wet floodproofing allows flood waters to enter the enclosed areas of a house. In contrast, dry floodproofing prevents the entry of flood waters.

The wet flood proofing method can be applied to all building types, but it is not practical for areas that are to be used as living space. It requires 1 inch of net open area per 1 square feet of enclosed area. Thus a flood should be directed to bypass under the building and create less damage since its impact is redirected. The dry flood proofing can only be applied to buildings that are not exclusively residential buildings [5]. In order to prevent damage it applies flood shields at the elevated level and thus protects the house by sheltering from the impact.

The A zone that was now extended to further coastal regions is required to elevate the lowest level of their buildings above the Base Flood Elevation (BFE). The building must be wet food proofed and the enclosed space under the BEF level can only be used for parking, storage or building access. Commercial or buildings with different usages can also be protected by dry flood proof spaces below the BFE that are not residential.

The V zone is endangered by high-velocity wave action. Therefore the building needs to be elevated on piles or columns and can only use breakaway walls to enclose the level below BEF. By creating such a large space, it offers less resistance to waves and thus receives less damage.
Those new buildings codes should not only prevent damage in times of crisis, but also protect against higher flood insurance premiums. In spite of the changes many conflicts between several building codes make it difficult for owners to rebuild or retrofit, and further regulations will be necessary to easy the application.

3.3.5 Further steps of Text Amendment:

In addition to the above mentioned building codes the text amendment [Q] addresses the potential effects to flood resistant construction in the streetscape and also regards protection of non-building related infrastructure. To achieve this not only the buildings height will be measured in respect to the BFE, as shown before, but also mechanical systems, off-street parking and building access have to be provided above the grade. Additionally the streetscape has to be adapted to these flood proof requirements.

3.4 Systemic interconnections

At reviewing this event and its consequences for the whole city of New York, one may see how much of the key factors interact and how their connections have to be integrated into solutions in order to overcome the challenges of security in NYC in the future. We will present a partial systemic view on solutions and the events caused by Sandy.

3.4.1 Mobility

The entire damaged infrastructure has to be rebuilt or repaired after hurricane Sandy. Although rebuilding infrastructure seems not to be an interconnected step, when you look at the connections to other fields you can see how important mobility becomes in this context. Regarding the interaction between mobility and security, you realize that an effective infrastructure is necessary to enable fast evacuation on short notice, especially in endangered areas.. Streets have to be built in a way that allows bypassing even while the flooding starts making mobility difficult. Also right after the catastrophe, mobility of rescue teams and first aid has to be possible. Sometime after the immediate danger the mobility will be necessary to transfer resources for reconstruction as well as to transfer waster from broken buildings. Later on mobility becomes necessary to transfer food and medicine to inhabitants. Particularly the elderly are suffering the effects of the climate disaster, because they are often isolated and have no contact with outside. Viewing these connections the infrastructure of risk areas becomes more focused.

3.4.2 Communication

In the first waves of a natural catastrophe communication is the essential part to protect people from damage. How to communicate a disaster fast to a large area? Here the interconnections to governance on one side and buildings on the other side create a direct information pipeline. Important data about danger, evacuation plans and further proceedings has to be made available by the government. Thus there can be no restrictions on such datasets and no long hierarchical confirmation lines that would prevent information to be communicated. On the other hand people have to receive that kind of communication. At the same time many options are connected to buildings that are the primary living space of the population. Buildings could include danger alarms, automatic protection systems being controlled by central institutions, or even alarm buttons to warn nearby people of perceived dangers. For improving communication in between inhabitants, Saviour, fire service, automatic protection systems or central institutions you cannot ignore those connections and still have a successful concept. Only combined they build a reaction channel for better handling catastrophes.

3.4.3 Governance

In a first approach you could say that the governance has no influence on natural disasters. They cannot prevent them from happening and they cannot influence the damage they leave. But again, if you look at the other influences the government has, you can see easily, as in the reactions on Sandy, how much they can achieve. In this example the governance interacts with the buildings by giving guidelines and instruction to provide resilient building structures. They also provide codes for the placement of wires and thus affect the energy delivery in the aftermath. Furthermore the government can develop a concept to purchase storm-damaged properties, as happened in New York. New York governor has announced a $400 million plan to purchase homes which were destroyed by Hurricane Sandy and preserve the land permanently as undeveloped coastline. [6]
Thus they enable a quicker start for reconstruction and a much better base for the first aid and rescue troops. With their interaction to those two key factors, buildings and energy they have a large influence on danger prevention and on fast recovery after disasters.

3.4.4 Buildings

Buildings have already been mentioned in most other comparisons. They do have a strong connection to the resources they are built of, to the energy they use, to the guidelines by governments they are built after, as well as to security and communicational availability inside them. Along with affecting the wellbeing of their occupants, buildings affect the nearby as well as the

global environment. As the main living and working space in cities buildings interconnect all key factors into applicable measures and methods.

3.4.5 Resources: energy and water

Resources as well as buildings play a large role in between many other key factors. Resources are scarce and have to be used wisely. They are the key to new and innovative technologies, unknown improvements and financial incentives.

There is a number of households, that is still without power or water after Superstorm Sandy. Energy as well as water has direct connection to the consequences of or reactions to Sandy. And if you look closely, Sandy exceeded all previous catastrophes in this area. This is in part due to climate change and therefor strongly dependent on the interconnections between resources (energy and water) and governance as well as resources (energy and water) and buildings. Large parts of energy usage and carbon footprint are located in buildings. In this context resilience become very important for urban cities of the future. We need robust and climate adapted buildings as well as infrastructure and innovative decentralised systems in order to accept the challenge of further effects of climate change. In order to build energy efficient buildings we need strong governmental guidance and incentives, as well as functional resources that do not damage the environment and still offer the same comfortable living space.

3.4.6 Security

Especially in the example of Sandy security shows its cross-sectorial character. The uppermost objective of the governance is the security of their people from any damage on their lives, their finances of their comfort. Therefor buildings, infrastructure, energy and water supply, communication privacy and limited resources are all used in respect to the wellbeing and safety of the people using them.

4. Conclusion and Outlook

The Climate change, resource depletion, population growth, increasing consumption, individual mobility and climate resilience are dangers and questions that are all directing our attention to the development of our cities. They will be the anchor of our future living quality, economical markets and network structures. Considering such a large impact, the conception redefinition of urban environments has to be a key research field.

The enormous challenges that our future cities have to face can only be solved by creating an intuitive but deep insight into the systemic interaction of key factors inside a city. As shown in the example of New York City no solution can focus on only one key element if it is to be successful. New York City´s “superstorm” Sandy and its consequences show how climate change face cities with new challenges. The natural catastrophe also shows how many different key factors need to be combined to create innovative solutions against this problem. To use only governmental opportunity, would cause the endangered regions to be evacuated and resettled. On the other hand, you cannot handle without government, often as a key driver. Security measures like protections walls and water drainage systems cannot be standalone solutions, if the buildings are made of light material, false construction or on a bad foundation. To create an overall approach you have to consider the interconnections and synergies between all factors involved. Now NYC is developing a long-term plan to cope with extreme weather events that will get the lights back on quickly, keep the gas stations open, ensure the hospitals maintain power, and guarantee a working transportation system. Furthermore the first Executive Order allowed home and property owners who are rebuilding after Hurricane Sandy to meet new flood standards without violating zoning codes. It will become apparent in the future, if those measures had a holistic approach.

To consider such dynamic and interconnected research fields, a new way of multidisciplinary and interactive research groups have to be formed as well as new structures for perceiving, processing and evaluating urban research data. Also solutions have to increasingly overleap sectorial boundaries and combine multiple innovative technologies from different expertise fields into one

greater step of development.

Many urban environments have already developed various solutions to increase energy efficiency, reduce carbon emissions, create strong governmental participation and at the same time provide rich and healthy living for their population. Those concepts are important, but require the next step into necessary changes of urban systems. New relations between information, people, products and resources form the centre of an innovative loop over the next few decades and into sustainable urban cities. This will only happen if representatives from different business sectors, research institutes and governance officials join together for recreating urban systems.

The “Morgenstadt: City Insights” takes this first step into exploration and refinement of our future.

Towards Sustainable Knowledge Ecosystem with Open Data, Co-creation and User Empowerment

Urban ecosystem, as called by Alberti [1] urban ecological space, encompasses the total natural capital and flows on which a city depends to meet the long-term needs of its inhabitant. In order to involve inhabitants to co-creation of sustainable ecosystem on can facilitate the development of the knowledge ecosystem, which by definition of Nonaka et al [2] is organic configuration of dynamic virtual and physical places where one shares a context with others to create meanings. The explicit information is transformed to internalised knowledge in knowledge creation processes. The purpose of this paper is to understand how the creation of meanings and knowledge can be supported and what kind of services city can develop for the users to support their environmental friendly decision making processes and behaviour.

More precisely this paper focuses on the services, which emphasizes the role of information and knowledge as a method for user empowerment in urban ecosystems guaranteeing user involvement. The goal of this paper is to present and analyse two potential service solutions for improving the user empowerment in the knowledge creation processes towards sustainable ecosystem.

Two practical case studies are described by using document analysis, observations and focus group interviews. They demonstrate how public sector can through open collaboration provide the knowledge and power needed for sustainable user decisions. One case study is representing the virtual interface for sustainable local energy system design, where traditionally separated information is gathered to one database. The system aims to help users to have comprehensive facts in order to make their decisions concerning energy solutions. The other one is a physical place, Urban Mill, for knowledge creation, which aims to provide a common platform for different stakeholders of local ecosystem. The co-working place offers a platform for city officials and researchers to co-create sustainable innovations.

Based on user experiences the success of platform services provided by city cannot be fully assessed. However the results can be reflected back to the literature. When considering the service portfolio, city should strive to support the development of sustainable knowledge ecosystems. It is not only operational service provision but a strategic choice to effect to the societal challenges. The city as service provider needs to redefine its role. The sustainable and environmental friendly behavior can be strengthening within platforms, which provide positive user-experience, open data and social collaboration.

The results indicate that in order to support sustainable behavior the user centric approach is not only about designing sustainable solution. The more significant factor is to provide processes, which empower the users to make their own decisions. The comprehensive and shared knowledge is one of the most important elements of these processes. The empowering processes are the small initiatives towards sustainability strategies as the two case platforms indicated. One could have more research of identifying different ways for sustainable behavior among users.

Keywords
Urban ecosystems; open information, knowledge; user involvement; co-creation.

1. Introduction

Commonly the concept of the ecosystem reflects a national society aspect, including the network of all important economic, social, political, organizational, institutional and other factors that influence the development, diffusion and use of innovations [3], [4], [5]. An ecosystem is the totality of organisms and environments that interact interdependently [6]. If ecosystem is considered to be sustainable, it is a biological environment and series of habitats that is able to thrive and support itself without outside influence or assistance. In ideal sustainable ecosystems, everything is already provided within the ecosystem for life to survive. Additionally urban ecosystem, as called by Alberti [1] is urban ecological space, encompasses the total natural capital and flows on which a city depends to meet the long-term needs of its inhabitant.

Ecosystem management is a process that aims to conserve major ecological services and restore natural resources while meeting the socioeconomic, political and cultural needs of current and future generations [7],[8]. Ecosystem management acknowledges that the interrelation of socio- cultural, economic and ecological systems is paramount to understanding the circumstances that affect environmental goals and outcomes. These definitions connected to ecosystems are capturing societal wide phenomena including both natural and human environments. The processes are in regime level and are managed e.g. by different policies and regulations.

In order to involve inhabitants to co-creation of sustainable ecosystem one can facilitate the development of the knowledge ecosystem, which by definition of Nonaka et al. [2] is organic configuration of dynamic virtual and physical places where one shares a context with others to create meanings. The explicit information is transformed to internalized knowledge in knowledge creation processes. Drucker [9] argues that knowledge is the only meaningful resource today. Nonaka [2] continues that knowledge is one of the most important assets to create values and hence, sustainable competitive advantage. Knowledge is individual and shared resource, which according to Bronfenbrenner [10] develops e.g. to sustainable behaviour in micro-, meso-, exo-, and macro- subsystems, which constitute the settings and life space within which an individual develops. In this model, each of the subsystems influences the individual and the other subsystems. This paper argues that in order to achieve the sustainable ecosystem from individual perspective, city can effect both to the individual subsystems and social knowledge ecosystem by providing the virtual and physical platforms as a service supporting sustainable knowledge ecosystems.

2. Platforms

2.1 Open data

More precisely this paper focuses on the virtual and physical platforms as services. They emphasise the role of information and knowledge as a method for user empowerment in urban ecosystems. Open data refers to the idea that data produced by the public sector should be freely available for everyone to use and republish without any restrictions from copyright, patents or other mechanisms of control. Advocates of open data claim that there are many kinds of benefits with the approach. Having access to relevant information offers a possibility for citizens to contribute in decision-making. This is considered important in moving towards participatory democracy in which users are engaged in a more direct dialogue with the city in contrast to representative democracy.

In order for data to be considered open it will need to meet certain criteria. These criteria have been adopted from Open knowledge Foundation [11]. Open data is material, which is not classified in order to protect identities or avoid security problems. The data must be possible to find and available as a whole in a convenient and modifiable form. The data must be provided under terms that permit reuse and redistribution including intermixing with other datasets. There should be no discrimination against fields of endeavor or against persons or groups. For example, non-commercial restrictions that would prevent commercial use, or restrictions of use for certain purposes e.g. only in education, should not be implemented. The data must be available in an open data format, whose specification is publicly and freely available and places no technical or monetary restrictions for the use [12], [13], [14] and [15]. Open data can be available both in virtual and physical platforms.

2.2 Knowledge co-creation process

Knowledge management theories [24] focus on the social nature of knowledge creation. Nonaka and Takeuchi [24] have a comprehensive, even critical view on knowledge creation, which includes a broad set of processes that underpin a double spiral movement between (a) tacit and explicit knowledge and (b) individual-group- -wide co-creation levels. Tacit knowledge was first coined by Polanyi [26] and it is that which is in the mind of the individual. It is intangible and difficult to describe. By contrast explicit knowledge is tangible. Explicit knowledge is everything that is written down or otherwise encoded within an documents, systems and processes. [27], [24] and [28]. Open data is explicit by its nature.

Nonaka and Konno [25] have used the knowledge cycle to illustrate the interaction between tacit and explicit knowledge in the process of knowledge creation, knowledge sharing and learning. The knowledge learning cycle can also be called a SECI- process (Socialisation, Externalisation, Combination and Internalisation). Socialisation (from individual tacit knowledge to group tacit knowledge) is a process of creating common tacit knowledge through shared experiences. A "field" of interaction, where individuals share experiences and space at the same time can be built for socialisation, thereby creating common unarticulated beliefs or embodied skills. Externalisation (from tacit knowledge to explicit knowledge) is a process of articulating tacit knowledge into such explicit knowledge as concepts and/or diagrams, often using metaphors, analogies and/or sketches. A dialogue intended to create concepts from tacit knowledge triggers this mode. Combination (from separate explicit knowledge to systemic explicit knowledge) is a process of assembling new and existing explicit knowledge into systemic knowledge. Often, a newly created concept should be combined with existing knowledge to transform it into something tangible. Open data has its role in this phase of knowledge creation process. It serves as a raw material for combination. In the phase of internalisation (from explicit knowledge to tacit knowledge) a process of embodying explicit knowledge into tacit, operational knowledge such as know-how. These four modes of knowledge take place in a continuous knowledge learning cycle [24], [25] [29]. The next question is what are the requirements of the physical and virtual platforms where knowledge co-creation takes place.

2.3 Virtual and physical platforms for user involvement

The interest in this paper is in virtual and physical platforms Nonaka et al. [37] have described in the qualitative manner the characteristics of the physical, mental and virtual platforms for sharing the knowledge – they are also defined by Japanese word “ba”. Knowledge co-creation needs many ba, which exist on multiple levels and are connected to each other organically to form a greater ba. It is possible to connect different ba to an evolving, larger whole. The structure reminds network with hubs, knots and links in between. The experience of becoming part of a whole larger than oneself is worth thinking about. Good ba is like an instrument. The music doesn’t come from the instrument. The music comes through the instrument when someone plays it skillfully.

High quality ba have their own field and atmosphere, that help people and groups to focus on what is most important, and that provide access to their deeper sources of creativity. These platforms need an open boundary that on the one hand provides a cocoon in which to do creative work, and that on the other hand provides openness and a flow of new perspectives, people and ideas that come with it.

Good ba happens not outside but in the midst of activities. Building ba in the sense of task accomplishment, it is important that everyone has equal access to the centre, with every participant in a good platform at the same distance from the centre. However, the centre is not a fixed point. In ba, anyone has the potential to be a centre, and the centre can change as the context evolves. Ba is a sphere that is constantly moving along an evolving trajectory. There is also need to understand imaginative seeing: Innovation and inspiration start with seeing differently. The capacity to see differently and deeply is crucial and yet difficult to develop. It involves suspending one’s judgment and allowing reality to emerge.

Good ba embodies the diversity of experience and talent. A good platform enables essential dialogues, which allow participants to share their views and experiences and to see themselves through one another. The quality of people’s conversations is one of the most important measures of the quality of platform and the vitality and health of a system.

Good ba needs creative chaos, care, and love in order to tap into people's highest level of energy and commitment. The energy of ba is provided by its self-organising nature. To make ba a self-organising platform, it is important to create conditions that allow for autonomy, chaos, redundancy, and variety, and that foster the development of love, care, trust, and commitment. In order to assess the services supporting sustainable knowledge ecosystems it is essential to focus on their ability to foster love, care trust and commitment which best can be achieved through positive user experience. In the studies of user experiences of physical and virtual places Nenonen & Kojo [23] modified trough abductive reasoning Diller's et al [24] classification of experience for assessment. The developed model has six dimensions: the atmosphere, the frequency, the functionality, the familiarity, the narrative and the importance.

3. Method and sample

3.1 Method

The research is based on data was gathered through two case studies using document analysis, observations. Additionally data was gathered by interviewing both the people involved in the development of the knowledge co-creation platforms as well as the users of the platforms. The goal of this data gathering was to get user experiences connected to both platforms.

They demonstrate how public sector through open service platforms can support the knowledge co-creation. One case study is representing the virtual platform for sustainable local energy system design, where traditionally separated information is integrated with new energy data. The other case study is a physical platform for knowledge co-creation.

The gathered data was analysed by using a six-dimensional model that has been developed by Nenonen and Kojo [23] to capture the intangible elements of the experience of place. The framework can be used in analysing, developing and designing user centric platforms. The six-dimensional (the atmosphere, the frequency, the functionality, the familiarity, the narrative and the importance) framework of the experience of place is applicable for a variety of space segments including also virtual and physical platforms for experiences.

The atmosphere is related to indoor environment and the solutions - how they fit and affect human senses. According to Nenonen & Kojo [23] the dimension of the atmosphere includes the elements that are affecting the holistic sense-experience: smell, taste, sight, feel, and hearing. Also different cognitive symbols (such as signs) relates to this dimension.

The frequency experience refers to activities happening in the certain rhythm and tempo. Dimension of the frequency is connected with the use of time, sense of time and rhythm of time. The dimension includes e.g. the sense of history or the sense of short or long period of use.

The dimension of the functionality indicates how supports the activities and the performance that is done there. It also includes the easiness to switch between different purposes. The dimension of familiarity of the place refers to easiness of the use and e.g. effortless adoption to the use.

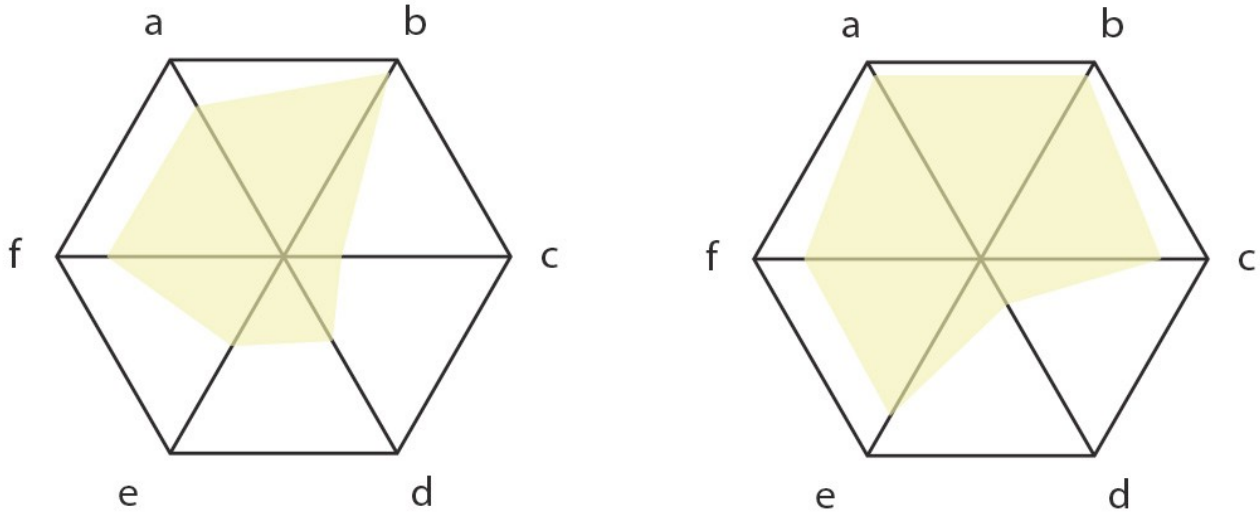
The dimension of narrative means the constancy and coherency of the story. Features such as identity, brand, and purpose relate to this dimension. The dimension of the importance expresses the significance and meaning for the users. It relates to tangible and intangible values as part of the experience. The meaning is related e.g. to the concepts of appropriation, belonging, ownership, control and privacy.

3.2 Case 1 Virtual Platform: Energy data interface

The first case study is a virtual platform for sustainable open and dynamic energy system design, where traditionally separated information is gathered to one database as part of the strategic climate and energy actions of the Finnish City of Espoo. The purpose of opening energy related data is to promote user involvement in innovation regarding sustainable energy system development. The interface aims to help users to have comprehensive and explicit facts in order to make their decisions concerning energy solutions. The integration of the geothermal map, the solar energy map and the weather data provides unique material, which is both inspiring and useful. This interface is combining this data with other existing geo-referenced information. The virtual interface also contains a tool for estimating the hourly energy consumption of building stock. One intention is to demystify the planning of renewable energy by visualizing timing mismatch of energy production

and consumption. The platform makes it possible to openly compare different solutions and to choose optimal solutions for energy production and consumption balancing.

3.3 Case 2 Physical Platform: Urban Mill



The other case study is a physical platform for open data and knowledge creation. Urban Mill aims to provide a common co-creation place for different stakeholders of the local ecosystem. The co-working place is open for city officials, researchers and businesses to co-create new sustainable innovations. Urban Mill is a demonstration of an emerging thematic boundary zone for urban innovations. Urban Mill has 1300 sqm of working and co-creation place and foremost brings together the research and innovation actors of Built environment development, Ubiquitous and Responsive City ICT, Urban services and Urban life transformation. Urban Mill's start-up phase was launched in January 2013 as a joint effort of the City of Espoo, Aalto University, Aalto University Properties Ltd.

Urban Mill is a platform for open collaboration. There is no absolute control of the collaboration and no hierarchal leadership. This platform provides a concrete place, space and identity for the joint actions and brings together specialized research teams under one roof, still without being exclusive in any way. The space is flexible and can be transformed for different purposes. It defines itself more as a service than as a concrete facility.

3.4 Case analysis

By filtering the gathered data by using the six-dimensional model one were able to identify the common themes in content but also to illustrate the weight of the comments by visualising the analysis in Figure 1. The gathered data was analysed as single data and as combined data clusters of the user experiences. An interval scale was used to rate each of the six dimensions.

Dimension	Scale and Qualities
a) atmosphere	1 weak – 6 strong
b) density and frequency of time	1 stable – 6 changing
c) functionality	1 single use – 6 multi-use
d) familiarity	1 difficult – 6 easy
e) narrativeness	1 weak – 6 strong
f) importance	1 non-memorable – 6 memorable

Case 1 Case 2

Figure 1. The user experiences of the platform

4. Results

The analysis of data indicates that there are differences and similarities of the virtual and physical platforms. Both of the platforms had a significance and importance for users: they were experienced as memorable. Additionally they had strong atmosphere: in virtual platform this was based on cognitive triggers and in physical platform more to holistic sense-environment of partly rough space. The third common factor in experience was the experience connected to time: both platforms were changing.

The clearest difference of the platforms can be seen in the functionality dimension. The virtual platform has a clearly defined use: energy system design. Physical platform on the other hand is only offering a multiuse platform. Especially the virtual platform is lacking possibility to interaction. Another difference in the case platforms concerns the narrative of the cases. Physical platform, Urban Mill was an empty test laboratory, which means that the building has already its history. By branding the place step by step and filling the place with different activities e.g. by evolving student project growing in the psychical environment. The recycled furniture and dynamic atmosphere provides inspire both for an individual and collective memory. Story has been formed little by little. This aspect is mostly lacking in the virtual platform, however the application prototype remembers the cached information so it forms a personal user continuum.

Dimension of familiarity is low in both cases. The interview results indicated that the platforms were not easy to use. The familiarity can be developed by increasing the guidance and signs and care in both virtual and physical interfaces of co-creation platforms.

To conclude the analysis the considerations concerning success of provided services are following:
- Importance reflects to proposition that the platforms are memorable – this strengthens the relationship between the platform and the user. It can be seen as a seed for the commitment and trust.
- Atmosphere is strong in both cases: one can consider if it has consequences for different types of users – the strong atmosphere is not self evidently positive or negative, but can exclude some user segments.
- The changing nature of the platform was one of the third common dimensional factors. The dynamics might has some effects to the willingness to commit to the platform – the changing nature can also be connected to the phase of platforms: they change due to the fact that the concepts are on their embryonic phase.

5. Conclusions

Based on user experiences the success of platform services provided by city cannot be fully assessed. However the results can be reflected back to the literature. When considering the service port folio, city should strive to support the development of sustainable knowledge ecosystems. It is not only operational service provision but a strategic choice to effect to the societal challenges. City as service provider need to redefine its role. The sustainable and environmental friendly behavior can be strengthening with platforms, which provide positive user-experience, open data and social collaboration.

The results indicate that in order to support sustainable behavior the user centric approach is not only about designing sustainable solution. The more significant factor is to provide processes, which empower the users to make their own decisions. The comprehensive and shared knowledge is one of the most important elements of these processes. The empowering processes are the small initiatives towards sustainability strategies as the two case platforms indicated. One could have more research of identifying different ways for sustainable behavior among users.

The limitation of the research is the analysis of user experience based on qualitative data only. However user empowerment and end-user co-creation can be studied by using data from case histories and a large amount of very varying user scenarios. Further studies could focus on key performance indicators and analysis of effectiveness of described solutions. However the achievement of quality “ba” is a matter of qualitative and activity based solutions more than a measurable and financial topic. The idea still is to enhance co-creation by supporting love, care and trust within different platforms – virtual and physical.

Summary

The main purpose of this ongoing research is to assess the cooling effects of vegetation in urban microclimate. Considering the influence of Leaf Area Index – LAI, this study will quantify the intensity and spatial distribution of the microclimate effects in border regions for urban parks, such as Trianon Park, located at Paulista Avenue in downtown São Paulo/ Brazil. Considering Trianon park as a large mass of vegetation with few sparse areas, an average leaf area index for the entire park was estimated based on two indirect gap-fraction method, the LAI-2000 plant canopy analyser (LI-COR) and a camera system with eyefish lens (Nikon Coolpix 4500). The hemispheric photographs were analysed using can-eye software. Microclimatic meteorological data was obtained in two areas of the park during four consecutive days of measurements, beginning on 28th October 2012. This database was important to adjust the ENVI-met model to local conditions before starting the parametric studies. Parametric simulations on ENVI-met were developed to investigate the effect of the park on its surroundings, indicating the influence of LAI measured previously. Results indicated that, concerning the intensity of the effect, the average difference between air temperatures inside the green areas (LAI=2.5) and the surrounding streets is about 2ºC at 2 p.m. and the extension of the effect can reach 10 m from the park.

Keywords: urban vegetation, urban microclimate, leaf area index, ENVI-met.

1. Introduction

Vegetation plays an important role in moderation of urban climate. It varies according to the mesoscale circumstances, but in any case vegetation can give a significant contribution to the climatic conditions [1]. Areas covered by plants have some common properties by which they differ from build-up and hard surface unplanted areas. Leaves of plants absorb most of solar radiation which impinges upon them. A small part of of the radiant energy is transformed by photosynthesis into chemical energy and in this way reduce the rate of heating of the urban space [2].

Previous studies have shown the vegetation benefits in urban environment, which include: microclimate modifications [3,4,5], removal of air pollutants [6,7], tree shading as passive cooling for buildings façades [8,9], influence in human health and aesthetic value of green areas [10,11,12].

Considering the microclimate, vegetation is important due to its properties on energy balance. According to Penman-Monteith method [13], the equation for evapotranspiration rate by plants is direct related to the quantity of stomata in the surface of leaves. In this sense, the density of leaves,

which can be represented by the leaf area index – LAI, is an indicator of gas exchange (oxygen and carbon dioxide) as well as the water vapor loss in transpiration.

LAI is a dimensionless variable and is defined as one-half the total green leaf area per unit of ground surface area [14] drives the within and the below canopy microclimate, determines canopy water interception, radiation extinction, and water and carbon gas exchange. LAI is a key parameter in models describing the exchange of fluxes of energy, mass (e.g. water and CO_2), and momentum between the surface and the planetary boundary layer [15].

This study is part of an ongoing research about the impact of vegetation on urban microclimates, using predective models such as ENVI-met. This computational model considers the density of leaves to simulate the micro scale interations of surface-vegetation- atmosphere.

2. Methodology

2.1 Area of Study

São Paulo is located in the Southeast region of Brazil. It is a sprawling megacity which metropolitan area houses almost 19 million inhabitants, distributed in an area of 8051km^2. Nowadays, São Paulo is characterised by a heterogeneous urban structure, which has been caused by the rapid growth of the city during the last century. One of the effects of this growth is the social conflict of high-rise office towers close to poor informal settlements.

For decades, downtown has suffered a continuous degradation process and has gradually been abandoned by its residents. The city's plan distribution is very uneven, the metropolitan area of São Paulo experiences simultaneously massive urban sprawl in its peripheries and population decrease in its central parts Now the average density in the city centre is approximately only 64 inhab/ha [16] in spite of a high built density.

Today, 48% of the territory of São Paulo is significantly lacking in plant cover of any type. Although the Environmental Atlas of São Paulo [17] indicates adequate arborization with more than 7m^2 of green area per habitant, some other neighbourhood in downtown area has almost zero (Sé, Republica). The highest temperatures were found in the central area without green areas and the lowest in urban parks.

The municipal district of São Paulo has 35 urban parks distributed throughout the city, with a total area of 1,579 hectares, corresponding to 1.12% of the total area of the municipal district. In the downtown area, there are seven urban parks and this study focuses on Tenente Siqueira Campos Park (or Trianon Park), situated on Paulista Avenue.

2.2 Field Measurement at Trianon Park

2.2.1 LAI Measurements

There are two main forms to obtain the LAI values: the direct and the indirect methods. The first one can be accessed directly by using harvesting methods such as destructive sampling or by non-harvesting litter traps during autumn leaf fall period in deciduous forests [18].

The indirect methods consist in measurements of light transmission through the tree canopy. It can be calculated by Beer-Lambert law, which defines the empiric relation between radiation intercepted by the canopy and the total incident solar radiation. For this study, two methods were applied based on gap fraction distribution: using the instrument LAI-2000 Plant Canopy Analyzer (LI-COR) and the technique via hemispherical canopy photography [19], between August and September of 2012.
Although the park is crossed by Alameda Santos Street, it has a pedestrian bridge to connect the two separated parts. During planning process, a grid of 20x20m was created over the site plan of

the park to define points for measurements (figure 1). The Area 1 was located close to the main entrance of the park from Paulista Avenue, which has low-density trees with 6 points for LAI measurements. The Area 2 is in the middle of the second block of the park and it has a very dense group of trees (points 10-22).

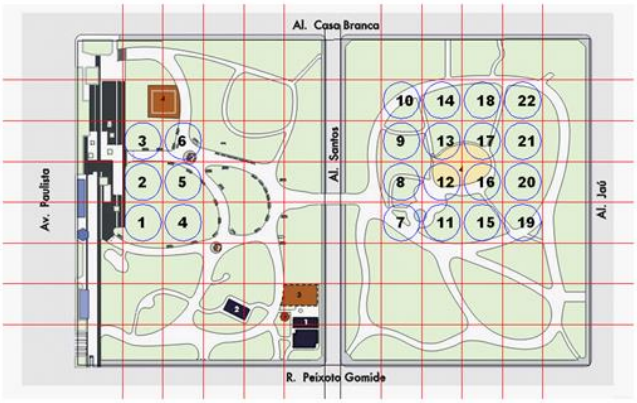

Fig. 1: Location of 22 points for LAI measurents at Trianon Park

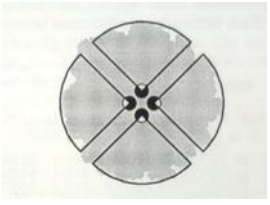
Fig. 2: LAI-2000 Plant Canopy Analyser
Source: LI-COR

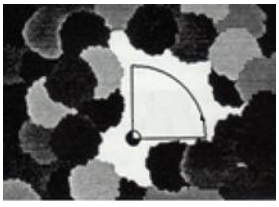
The LAI 2000 (figure 2) is a portable instrument that calculates Leaf Area Index (LAI) and other canopy attributes from light measurements made with a “fish-eye” optical sensor (148° field-of-view). Measurements made above and below the canopy are used to calculate canopy light interception at five zenith angles (7 º, 23 º, 38 º, 53 º, 68 º), from which LAI is computed using a model of radiative transfer in vegetative canopies Moreover there is an in-built optical filter that rejects incoming radiation with wavelengths below 490nm in order to minimize the radiation scattered by the canopy [20].

To reduce the margin of error in the results, there is an option to use 5 different view restricting caps, which serves to limit the azimuthal field of view of the optical sensor in circumstances that it is necessary or desirable to block part of the view. For the conditions of Trianon Park view restricting caps were used to remove the operator from the sensor’s view and to reduce the required clearing size for above-canopy readings in this dense urban park.

Pre-sensitivity tests of the equipment LAI-2000 were conducted in the surrounding of the Faculty of Architecture and Urbanism of the University of Sao Paulo/ USP. The estimate value for LAI with the LAI-2000 was made using the single sensor method to collect readings outside and below the canopy. These tests were made in two days on July/ 2012 with different sky conditions and using 90 º and 180 º view caps.

According to the best results obtained during pre-tests at USP, the same conditions were considered at Trianon Park. The single sensor method was used for measurements with 90° view cap and under a very uniform overcast sky conditions. This helped to avoid sun glare or sun flecks during field measurements. To obtain the LAI values for each point in the park, 4 measurements were performed below the canopy (figure 3a) and 1 external to the canopy (figure 3b).





(a)

(b)

Fig. 3: Internal points with the cover of 90° (a) and external point with the cover of 90° (b).

The results of LAI values in all points varied from 1.46 to 3.86, and are shown in Figure 4. The average value of LAI in the 22 measured points was 2.52.

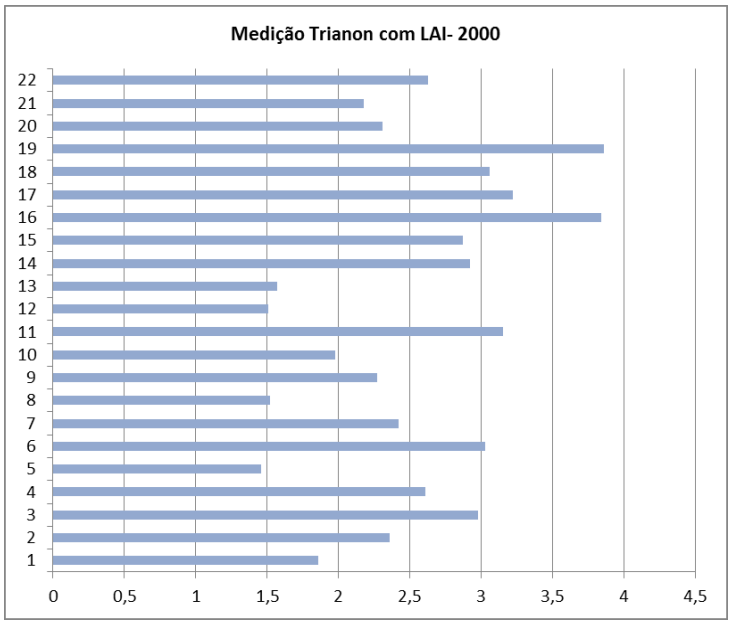


Fig. 4: LAI values measured at Trianon Park (22 points).

Hemispherical canopy photography is a technique for studying plant canopies using photographs acquired through a hemispherical (fisheye) lens from beneath the canopy (oriented towards zenith) or placed above the canopy for downward looking. Furthermore, the use of fish-eye lens allows the gap fraction to be evaluated in all viewing directions, which increases the accuracy of the derived biophysical variables (LAI) and there is a potential to characterize the azimuthal distribution of the foliage and the departure to non-random leaf arrangement. In addition, it is also possible to derive estimates of the leaf area index for canopies growing on sloppy terrains [21].

For Trianon Park, a coupled system based on a fish-eye lens (Nikon FC-E8) and a digital camera (Nikon FC-E8) were used under overcast sky conditions. The hemispherical photographs were taken on August 15 of 2012, from12h to 15h. The analysis of all photographs were done using Can-Eye model.

Firstly, the camera and lens were calibrated to define optical center and projection function. Then, each image was pre-processed in the model. The pixel brightness values for the blue band are extracted from each RGB image to achieve maximum contrast between leaf and sky, because absorption of leafy materials is maximal and sky scattering tends to be highest in that band [22, 23]. Thresholding procedures were applied in order to identify the optimal brightness threshold and distinguish vegetation from sky.

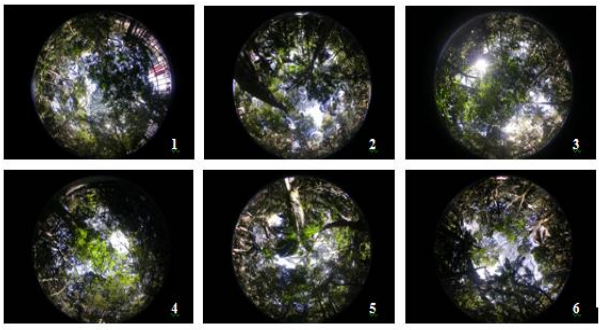

Fig. 5: Results of hemisferical photographs (1-6) taken at Trianon Park

Fig. 6: Color classification and image pre-processing using Can-Eye model

Comparing the final results from both LAI measuring systems, it can be seen that the average LAI values had few differences, varying between 2.14 (hemispheric photographs) and 2.52 (LAI-2000), calculate from 22 defined points at Trianon Park.

Each system has its specific measuring details and the choice has to consider the local conditions for the studies. In this sense, the Trianon Park has a dense arrangement of trees distribution with few spots among them. For these characteristics, the technique using hemispherical images had a better application comparing with LAI-2000 instrument as it evaluate an average LAI for a determined area, but not for a single tree. Overestimated values can be found using LAI-2000 as it considers not only leaves but other elements such as branches and trunk.

3. Preliminary ENVI-met Simulations

3.1 ENVI-met Model

The micro scale model ENVI-met [24] was chosen for this study due to its advanced approach on plant-atmosphere interactions in cities. The numerical model simulates aerodynamics, thermodynamics and the radiation balance in complex urban structures with resolutions between 0.5m and 10m according to the position of the sun, urban geometry, vegetation, soil and various construction materials by solving thermodynamic and plant physiological equations.

The model calculates the energy balance for long and short waves, considering total radiation, air fluxes, air temperature, humidity, local turbulence, reflection from buildings and vegetation. Based on the studies of Deardorff [25] and Jacobs [26], it also implemented a numerical model to calculate the main variables related to plant physiological behaviour: transpiration, evaporation, latent heat flux, water exchange, stomata resistance, leaf temperature and energy balance for soil-vegetation system [27].

To adjust the model, previous climate monitoring was carried out from September 28th to October 1st of 2012 at the park. With this database as a starting point, preliminary studies were done for the initial simulations in ENVI-met. These parametric studies were important to adjust the model main variables and to verify the influence for each parameter in the input data. Before inserting the green areas, it was fundamental to adjust the output values to the measured climatic conditions of the city of Sao Paulo.

3.2 ENVI-met Parametric Simulations

ENVI-met model, instead of using LAI, considers the parameter Leaf Area Density – LAD to calculate plants physiology. According to the ENVI-met plant database, there are 11 types of vegetation, which have specific characteristics according to the following aspects: CO_2 fixation (C_3 or C_4 plants), minimum stomata resistance, short-wave albedo, height of the plant, total depth of the root, Root Area Density - RAD and Leaf Area Density – LAD.

LAD is a parameter defined as the total one-sided leaf area (m^2) per unit layer volume (m^3) in each horizontal layer of the tree crown. The LAD profile was calculated by integrating LAI values [28]. For this study, a vegetation data basis was created based on the previous data survey mentioned before that pointed out the main tree species used in the city of Sao Paulo and their canopy characteristics quantified by Leaf Area Density – LAD.

Based on LAI measurements results, the ENVI-met simulations consider a medium canopy with LAI value of 2,5. The tree is 20m high and its leaf density started 4m above the ground to avoid obstruction for wind flux at the pedestrians' level. The parametric tree model had ellipsoid leaf area distributions with maximum LAD located in the middle height of the crown (Figure 7).

The input data for the simulations are presented in Table 1, based on previous parametric studies carried out to adjust the model. The input area domain was created with information from the park and its surroundings. Two receptors were considered for simulations: one in the middle of the park and another one in the sidewalk without vegetation to give specific information for each point.

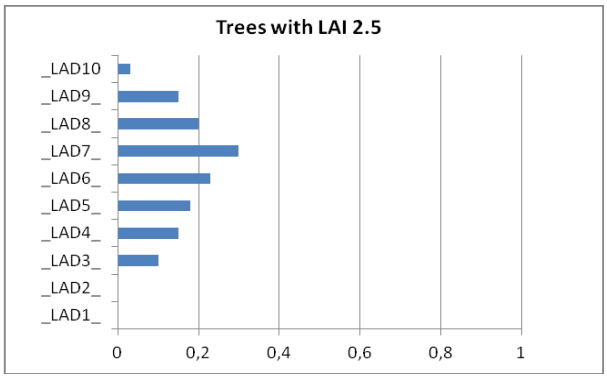

Fig. 7: LAD (Leaf Area density) (m2/m3) in 10 layers of the tree model (LAI=2.5)

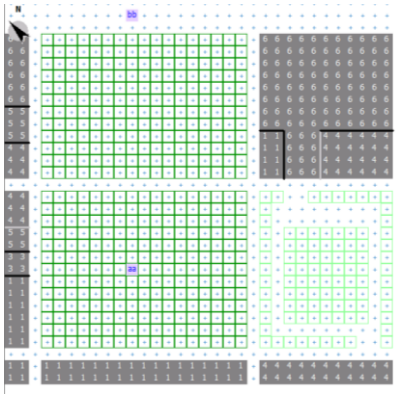

Fig. 8: The input area domain for ENVI-met simulations

Table 1: Input configuration data applied in the ENVI-met simulations.

Start Simulation at day	**28.09.2012**
Wind Speed in 10m ab. Ground [m/s]	**0.1**
Wind Direction (0:N/ 90:E/ 180:S/ 270:W)	**200**
Initial Temperature Atmosphere [K]	**283**
Specific Humidity in 2500m [g Water/ kg air]	**9.5**
Relative Humidity in 2m [%]	**79**
Initial Temperature Upper Layer (0-20cm) [K]	**287.6**

4. Analysis of Results

From the results of simulations, the receptor located in green areas of the park showed a reduction up to 2.0ºC compared to air temperature in the sidewalk. Over paved areas the simulations showed an average air temperature of 26.5ºC at 14h, while 24ºC under the canopies.

The results for superficial temperature indicated that trees have a significant impact by lowering the surface temperature by up to 29ºC. The tree canopy blocks part of the direct solar radiation and avoid the rapidly surface warming up. In the street, the superficial temperature varies from 41ºC to 45ºC, while in the green areas, it goes between 26ºC and 27.5ºC.

Concerning the intensity of the effect, the average difference among air temperatures inside the green areas and the surrounding streets is about 2.0ºC. For surface temperatures, the dense tree shading (LAI=2.5) has shown average differences of 17ºC under the canopy. In that sense, green areas can be an important strategy to mitigate the warming up effect in cities due to the shading and evapotranspiration process.

Regarding the spacial distribution of vegetation, results show that the effect is very local, and the influence of green areas doesn't go very far from the green borders at pedestrian level. Measurements at Trianon Park showed that the effect for air temperature can be felt under the canopy and approximately 10m away from the canopy. As an indicator to urban planning, green areas should be better distributed in small groups of trees than a large park.

The effect of tree canopy shadow has also a great potential to ameliorate the microclimate and mitigate heat stress in a hot humid climate. On the other hand the shade efficiency of trees will depend on the type of plants and the amount of leaf density. Because of this parameters such as Leaf Area Index and Leaf Area Density are fundamental to improve the positive impact of vegetation, considering the plant local influence.

5. Acknowledgments

This research was supported by Fundação de Amparo à Pesquisa do Estado de São Paulo – FAPESP and Conselho Nacional de Desenvolvimento Científico e Tecnológico - CNPq. The authors are grateful to Labaut staff for their assistance in the field measurements .

1. Short Summary

The City of Graz is currently the fastest growing capital city in Austria. The demand for living space has grown rapidly in recent years and, according to forecasts, will continue to grow in the coming decades. In this context, the upcoming major construction volumes require sophisticated growth which meets requirements of sustainability. This was the motivation behind the development of the research project “ECR Energy City Reininghaus”. “Reininghaus” is a former brewery site and the biggest underdeveloped urban area in the City of Graz. The research project ECR aims to develop urban strategies for the new conception, the construction, the operation and the restructuring of the city district Graz Reininghaus. In order to cope with this complex task, a large transdisciplinary team, including five institutes of the Graz University of Technology, worked together on this research project. Furthermore, the development of several demonstration projects is planned for this area. The most advanced of these demonstration projects, called “Plus-Energy Network Reininghaus South” [6], will be presented in this paper.

Keywords: CO_2 neutral city district / plus energy buildings and networks / framework plan energy

2. The City District Graz Reininghaus

The overall aim of the research project *Energy City Graz-Reininghaus* (ECR) [1] is to support the developing activities of the municipality of Graz to establish a new city quarter in the area called “Reininghaus”. The area Reininghaus is an underdeveloped plot of land (a former brewery area) near to the city center of Graz (about 1800 m distance to the main square) with about 110 hectare space and a possible full capacity for about 12000 future inhabitants on a maximum net floor area of about 560000 m² (*Fig. 1* and *Fig. 2*).

3. The Research Approach

In the scientific community there is a long tradition of working on the energy efficiency and/or sustainability of one building. Typical research teams in this field consist of an architect, an energy planner and an expert in the field of building physics. Usually, the review systems in these cases are relatively limited and the task is clearly defined and manageable. The extension of the review system to a group of buildings or even to a whole city district increases the complexity of the task in three different ways:

The number of system components increases

On the one hand, working on the “district scale” means dealing with at least hundreds of dif-

ferent buildings and on the other hand, the number of the involved stakeholders (individuals and institutions) increases.

The interaction between the system components increases
One important interaction lies in the architectural design of the space between the individual buildings to create streets and squares. Another important interaction between the individual buildings lies in the technical infrastructure, which creates different kinds of networks (district heating, electricity supply, water supply, wastewater sewer)

The review time increases
In contrast to when working on the realization of one building, which, may be completed within a few years, the development of a whole district means planning in decades.

The following findings have to be taken into account: According to the above-mentioned increase of the complexity of the project itself, the complexity of the project management increases, which leads to a dramatic increase of time consumption in that field. The limitation of the research projects to a duration of three years means that they are limited in their scope of action to a small time slot of the whole development. Because the parameters of the development cannot be predicted for such a long working period, the development scenarios are a fundamental aspect of the project work. Another consequence of the long period of development lies in changing the level of abstraction, which increases and leads straight to thinking on the level of typologies.

4. The Research Team

One fundamental component in the research setup is the formation of the research team and the communication structure between all relevant stakeholders. Consequently, the City Planning Department (Stadtbaudirektion) of the City of Graz, the Graz University of Technology and the County of Styria (Department 17A energy economics and general technical affairs), have worked together to process the submitted lead-project. The Environmental Department of the city of Graz and the Graz Energy “Energie Graz” provide additional professional input for the project. The research team of the Graz University of Technology, represented by the Institute of Urbanism, is composed of the Institute of Thermal Engineering, the Institute of Technology and Testing of Building Materials and the Institute of Process and Particle Engineering. The Department of Geography and Regional Science of the University of Graz supports the project as regards climatological assessment. Several companies and external experts are involved with the project team, this currently being ECO-World Styria,.

5. Framework Plan Energy

The research project [3,4] is based on the idea of designing an energy self-sufficient and CO_2- neutral city district. For this reason an “energy framework plan” covering the whole district has been developed [5]. The framework energy plan concerns various fields of investigation. Electric energy, thermal energy and embodied energy has to be taken into account as well as the methods of urban design and the rules and mechanisms of the local authorities. The work plan is structured as follows:

- Survey study of supply and demand, locally available energy potential versus demand
- Development and simulation of different scenarios for the overall energy concept
- Development of default values for further development

5.1 Survey study of supply and demand

In order to provide a comprehensive analysis of the future supply and demand in the area,

the waste heat opportunities of the companies in the neighbourhood have been investigated as well as the possibility of using geothermal potential. On the demand side, different scenarios for the further development of the city quarter have been created. Different levels of heat protection of the buildings as well as different scenarios for building density have been taken into account. As a result of these investigations, demand and supply scenarios for heating and electricity have been developed. Figure 4 shows an example of the preliminary results of the energy potential analysis, which are part of the final report of the potential assessment for reference framework energy [1]. The color of the Quarter provides information about the coverage regarding heating demand. The electricity is indicated with “+” in areas where it is easy to meet the demands and “–“ in ones requiring energy, because the self-generation is not sufficient.

As a result of the potential analysis, the heat demand may be covered with endogenous resources (regional by solar and geothermal use). Furthermore, it will be possible to use the waste heat from the surrounding industrial plants, which is sufficient for the supply of the city district. However, the electrical demand cannot be satisfied using only photovoltaic systems.

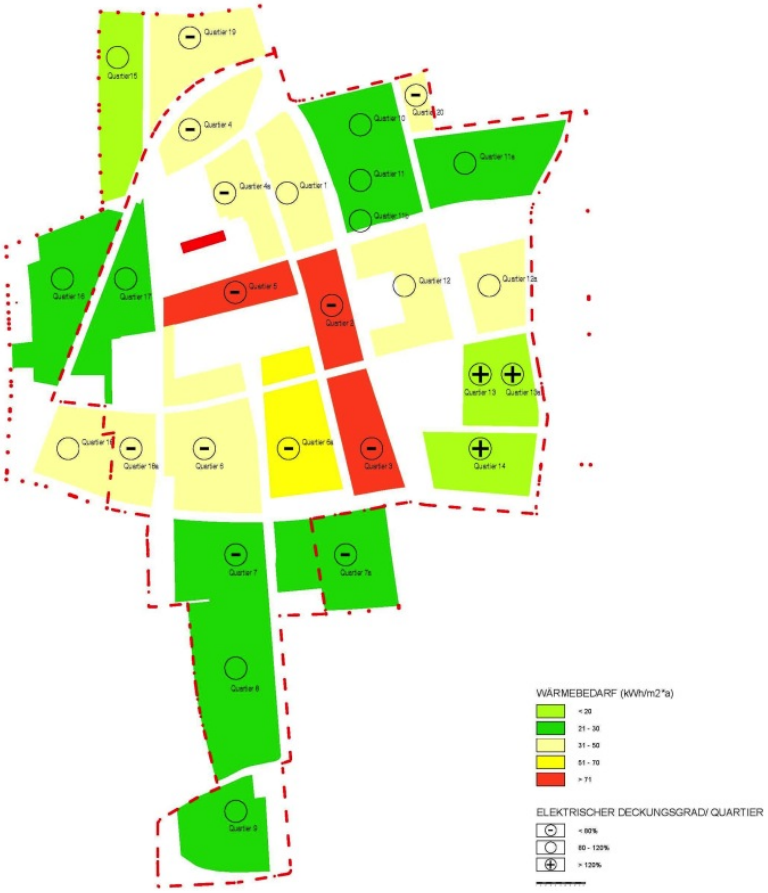

Fig. 3: possible heating demand coverage by using local heat resources and possible electricity demand coverage with photovoltaic on the quarter level. Source: ECR Coreteam & City of Graz, Executive Office for Urban Planning, Development and Construction [3]

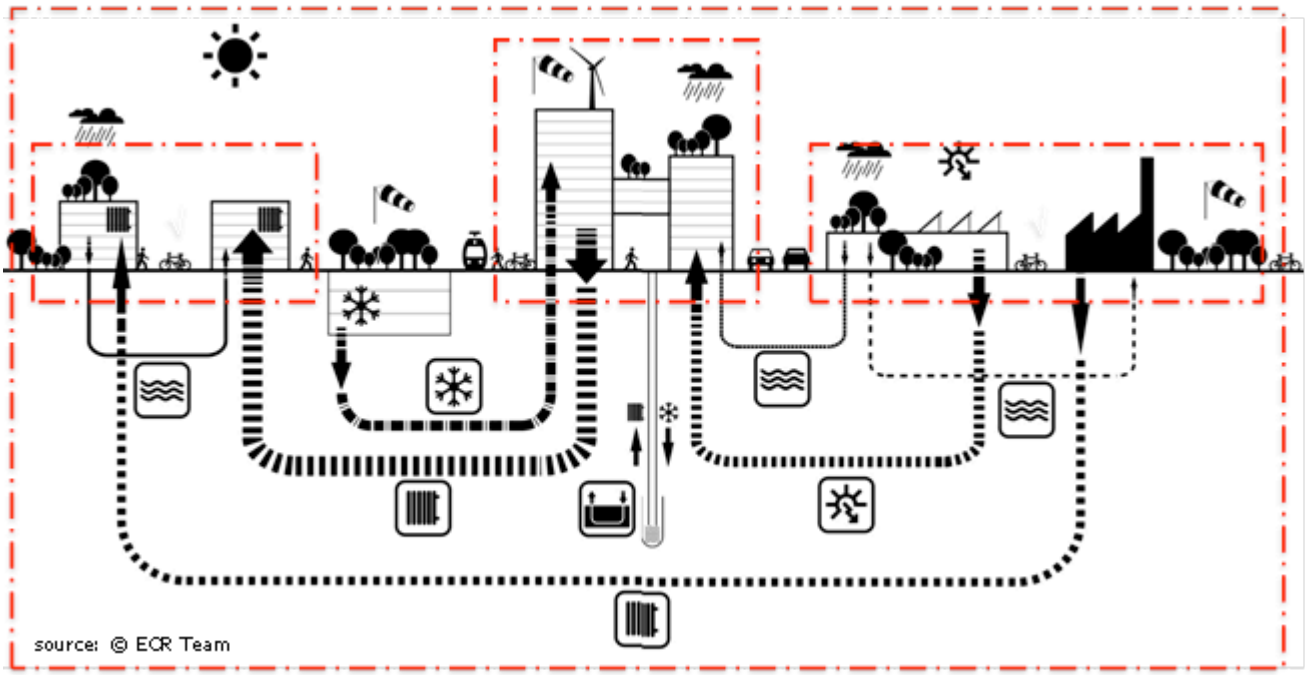
In addition, the project team searched for and investigated similar research and development projects on a national level as well as on a European level. The contact with several project teams was initiated in order to compare experiences. One of the most promising projects in this context is “NACHASPERN” – the sustainable city district "Aspern" and the city district Freiburg-Vauban [LIT]

5.2 Development of different scenarios for the overall energy concept

The initial working hypothesis describes the conception of an energy self-sufficient city district. This should be seen as a visionary approach to force the project team to examine local energy potentials as far as possible and to anticipate upcoming future developments.

The main focus of the examination is the aim of the inter-linkage of buildings and industrial energy resources as more or less sustainable energy producers. Central supply solutions will be confronted with semi-centralized and decentralized possibilities of inter-linkage. For example, taking advantage of the cooling energy potential of the existing brewery cellars or the waste heat of industrial processes already located in the city district (Fig. 4).



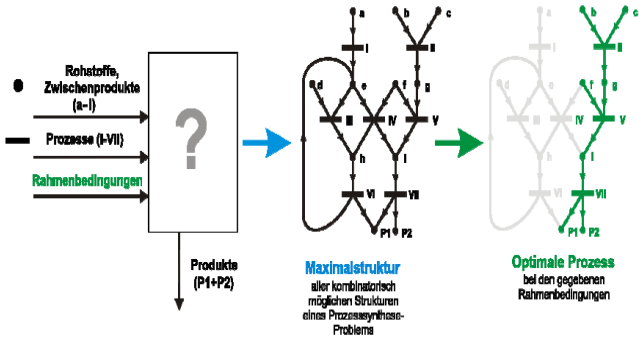


Fig. 4: schematic sketch to illustrate the changing of single system borders to a holistic approach

One possible approach is the investigation of technical building equipment (energy saving heating and ventilation systems, avoidance of air conditioning). In addition, urbanistic attempts (activation of possible energy potentials, natural heat of the earth, building density, best possible climate-oriented positioning of buildings, solar activation of roofs and facades, use of process heat, block-type thermal power station, feeding of the energy surplus to communal networks) have to be taken into account.

The simulation and optimization of the whole energetic system is a very complex problem. Several sources of energy can be processed to a variety of energy sources within a large set of technologies and nets. The question arises how to investigate such a complex system. The project team decided to follow two different, parallel approaches.

The “design-based” approach is open to a large variety of optional components which can be interlinked to an energy system. It can be done by Process-Network-Synthesis (PNS) on the basis of energetic and economic parameters for the technologies considered [10]. The Process-Network-Synthesis is able to combine these parameters with sufficient energy systems and optimizes a setting of a maximum structure to enable an optimization of a chosen objective simulation function like costs or greenhouse gas emissions (e.g. CO_2).
The method is the outcome of an ongoing development within the framework of process

technology. The structural heart of the method is a bipartid graph method (P-graph-method) which models all respective process networks that can be applied in advance and provides combinatorial rules to find the most feasible network solutions of the generated process network (maximum structure). Relevant technologies and the related flows of materials and energy (in this project especially electricity and heat) enter the maximum structure. This maximum structure is the initial point for a precise evaluation of all feasible process networks. Over a branch-and-bound optimization routine, all raw materials, energy flows and intermediates are linked to the desired products at the end of production/demand chains and can be computed with the help of software built around the p-graph method.

Maximum Structure **Optimum Structure**

Source: p-graph, basic software employing this method is freely accessible from www.p-graph.com/pnsstudio.

The final result of such an optimization process greatly depends on the system environment (costs of resources, technologies, transport, restrictions, spatial planning, …). According to the specific cost of building applicable facility networks, the most feasible structure (optimum structure) is generated.
Energy optimizations of smart energy systems for urban areas have been recently described in different projects [11, 12]. Fig. 5 shows an overview of the chosen approach describing the special framework conditions of this project.

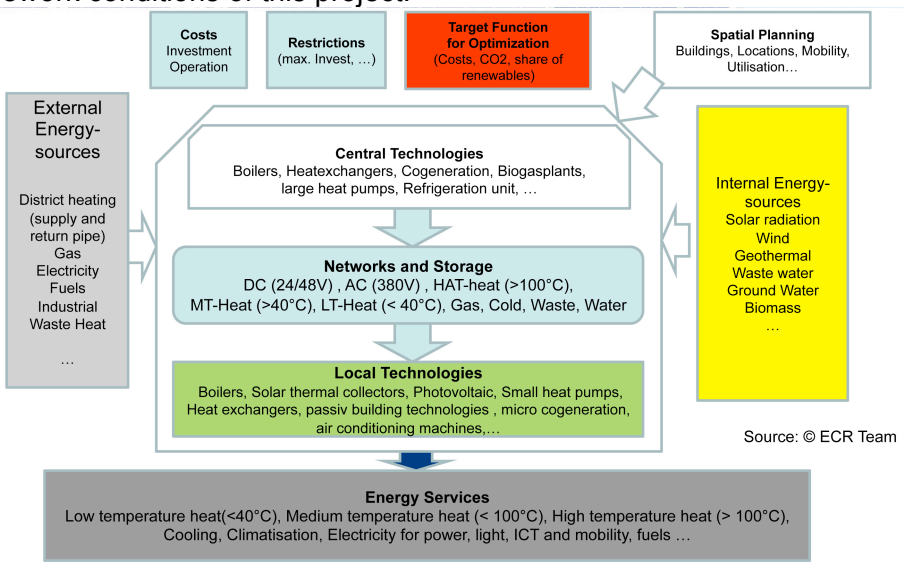

Fig. 5: Systematic approach of the process-network-synthesis, source: Hans Schnitzer, TU Graz

The most resource efficient and economically feasible process networks of the generated maximum structure can be calculated with PNS. Setting the economic value added as target value provides an efficient way to optimize energy networks. It is also possible to optimize an ecological target value (e.g. finding the process networks with the lowest CO_2 emissions) but this is not considered in the project. However, an ecological assessment (e.g. ecological

footprint evaluation) could be added additionally after the project, simply by taking the final result of the PNS-optimization into account.

In contrast to the previously mentioned “design-based” approach, the “assessment approach” focuses on a small variety of optional energy system components. The design of the energy system is mainly created on the basis of proposals made by the planners and developers responsible. Thermal simulations have to clarify the determination of relevant system parameters. In the case of the presented project, the use of thermal energy from waste water resulting from an industrial process is explored. The temperature of the waste heat is increased by a heat pump process and distributed to a district heating system which provides energy for heating and domestic hot water. The inquiry will be carried out with a simulation tool called TRNSYS [LIT]

5.3 Development of default values for further development

The research project ECR focuses on two different levels. On the one hand, it deals with the development of the city district Reininghaus itself. The key objective is the development of a comprehensive energy concept regarding urban, thermal and building engineering for an entire city district. An overall energy master plan will be an integral part of the “Charta Reininghaus” (agreement on the development of buildings) and will set preliminary standards for future investors. On the other hand, the project has to work out generally valid results that can be helpful in similar development projects. In this regard, the followings aspects have to be worked out.

- The initiation and supervision of the development process for the energy-optimized and sustainable city district Graz-Reininghaus.
- Development of energetically specific values for the anchorage in private-legal contracts between the City of Graz and future investors.
- Concepts for the suitable integration of the energetically specific values in local plans/ regulations (City Development Concept STEK Graz, City-District-Development)
- Concept Graz-Reininghaus and Development Plans for the 20 city-quarters.
- Drawing-up of recommendations and founding of a knowledge base for future energy-optimized city developments in Graz and the County of Styria

6. Plus-Energy Network Reininghaus South

The multifunctional neighborhood *Plus Energy Network Reininghaus South* (+ERS) is realized within the urban planning area of Graz-Reininghaus. The project aims at optimizing the energy concept of the single buildings as well as of the building cluster in order to achieve a plus-energy standard within the residential neighborhood. The research project partners are the Aktiv Klimahaus Ltd (Investor) and AEE INTEC - Institute for Sustainable Technologies, Nussmüller Architects ZT Ltd and Graz University of Technology.

With the realization of Plus Energy Network Reininghaus South (+ESR), a flagship building will be put into practice, which sets economically, technically and organizationally innovative solutions for the construction of Plus-energy linked building concepts of the future. The Plus-Energy attempt will not be limited to the building-level, but will operate on the level of a multi-functional building-linking concept. In the first step, the single building will be optimized and changed from an energy consumer to an energy producer. In the second step, synergies within the building-linking concept lead to a further optimization of the system.

The new, multi-functional neighborhood is split into two parts, the first being the front building complex (*Fig. 5* on the left marked with a blue line). It will consist of offices and commercial premises with a supermarket and apartments for elderly people (assisted living) on the first floor. This complex (net floor area of about 23 000 m²) developed by “WEGRAZ Gesellschaft für Stadterneuerung und Assanierung m.b.H.” will form a block along Peter-Rossegger-Straße and provides shelter for the twelve residential multi-family houses behind. The second part (*Fig. 5* on the left marked with a red line), was designed for residential use (net floor area of about 10 000 m²) and consists of 12 „Point houses“ with 143 flats.

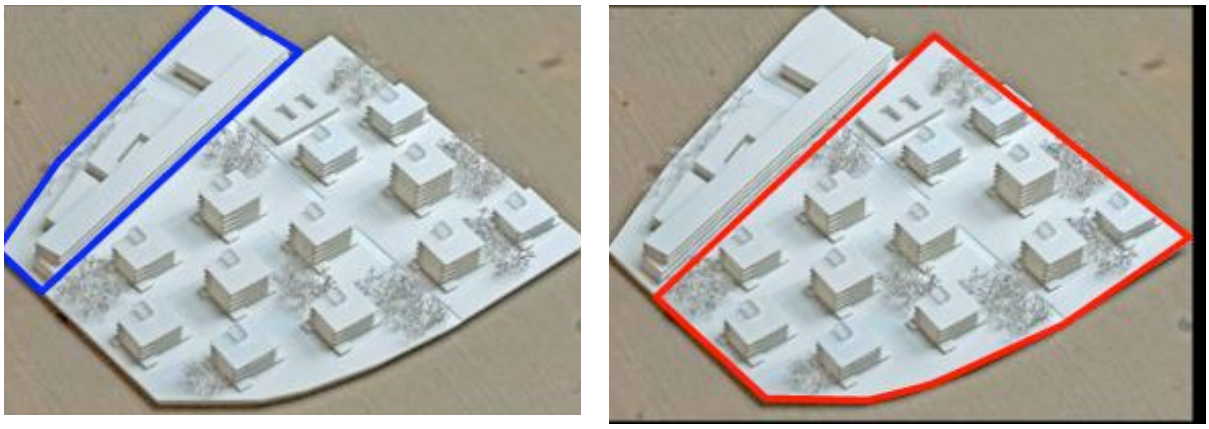

Fig. 6: Reininghaus area on the left picture (Source: ECR Coreteam & City of Graz, Executive Office for Urban Planning, Development and Construction and a model of the planed buildings on the right side of the picture, Source: AEE INTEC & Nussmüller Architects ZT Ltd

The starting point of the project development is the optimization of the energy concept of each single residential building: both the optimization of the energy supply by so-called “energy piles” and photovoltaic modules and also efficiency measures and the reduction of energy use on the part of the residents.. The next step is to optimize the heating network that connects the twelve residential buildings. Finally, the biggest impact will be the establishment of the heat network with the front building complex. The expected consumption pattern of the office and commercial premises diverges from the one of the residential buildings. Therefore a high potential for lowering peak loads is evident. To guarantee the overall goals aiming towards sustainability, the research project will be assessed using the TQB building certification system both in the planning stage and during the in use stage with the use of a monitoring project [7,8,9]. Fig. 8 shows the first building realization of the Plus Energy housing flagship building in Graz-Reininghaus.

Fig. 7: Building site Plus Energy Building in Graz-Reininghaus

Fig. 8: Completion of the first Plus energy Building in Graz-Reininghaus

7. Sustainable urban development

In order to ensure the high sustainability of the future urban neighbourhood, ECR sustainability aspects were already being considered in the early planning stage. Furthermore, the sustainability evaluation has been carried out based on different system boundaries described in the following.

7.1 Sustainability management in ECR-project

The upcoming CEN/TC 350 standards provide different approaches for facilitating the sustainability of buildings. Thereby, social, economic and environmental aspects as well as technical and functional performance should be included and fulfilled simultaneously.

To show the pros and cons concerning sustainability performance of urban development, different development scenarios based were evaluated. During the last decades, various building certification systems has been placed on the market. In our case we decided to apply the DGNB assessment method for urban neighbourhood development. The results indicate that parameters such as building density and system boundary are important aspects in the context of Life Cycle assessment aiming at improving sustainability performance in urban neighbourhoods.

7.2 Sustainability assessment of Plus-Energy network Reininghaus South

The evaluation of the sustainability assessment [8] is based on the ÖGNB building certification system. The assessment is divided in the five main areas: Location and Equipment, Economy and Technical Quality, Energy and Supply, Health and Comfort and Building materials and Construction.

A maximum of 1000 points can be reached, 200 in each assessment area. The assessment includes qualitative as well as quantitative criteria. The present building reached 880 points with a heating energy demand of 7,22 kwh/m2*a. The final assessment result is shown in Figure 9.

Fig. 9: Completion of the first Plus energy Building in Graz-Reininghaus

8. Conclusion and Outlook

A broad and comprehensive discussion with different project partners is necessary to cover all fields of district/ urban development and to consider all the different demands and needs. This does, however, take a lot of time and requires a great deal of effort on the part of the project partners.
What remains open are political questions e.g. how to deal with the waste heat from industry and what may be stipulated for private companies and investors?
Dealing with energy supply on urban scale also raises questions on how to guarantee the energy supply without the need for building a backup system (local waste heat vs. district heat).

Looking at the process, it is obvious that urban development requires the involvement of many stakeholders and many (different) interests as well as the solving of complex issues, which will require time. Technical questions can be solved far more easily than other questions.

The expected result for the *Plus Energy Network Reininghaus South* is that the successful implementation of the project will create an exemplary role model and demonstrate the economic feasibility of plus energy networks for housing. It will both contribute to a CO_2-neutral building portfolio and enable a self-sufficient and sustainable operation of buildings while improving the user comfort

A major innovation within the subproject *Plus Energy Network Reininghaus South* will be that, in contrast to already existing case studies, the successful integration of the project in the energy network will demonstrate the use of energy monitoring over a certain period (proof of concept of the network idea).

9. Acknowledgements

The research project *ECR Energy City Graz Reininghaus* [1] and the *Plus Energy Network Reininghaus South* [2] is funded by the City of Graz, The Federal State of Styria and the Programme “Building of Tomorrow” of the Austrian Federal Ministry of Transport Innovation and Technology (BMVIT) via the Austrian Research Promotion Agency (FFG).

Summary

Social sustainability aspects of construction and construction works are discussed in various contexts and thus address a vast amount of topics, aims and objectives. This paper describes the concept that has been developed for the assessment of buildings by the European Committee for Standardization (CEN).

It was still in the beginning of this century that sustainability had a high focus on environmental aspects only. But, when defining in 2003 the working program for developing standardised methodologies in the standards of CEN TC350, all stakeholders committed to all three dimensions of sustainability: developing assessment standards for the environmental, economic and social performance of buildings. Over the years Europe-wide consensus was sought and found on how to measure social performance aspects that define and influence the building user's health and comfort, safety, accessibility, etc.

Following the standard's methodology, by means of 22 main social performance aspects it allows now to characterise a building's social performance. The new draft standard (prEN 16309) has been finalized recently with the methodologies for this assessment. It represents a comprehensive view on all 22 aspects that determines the social performance of the building-use as part of the building's life cycle. The assessment of the 22 aspects is carried out and presented in 7 information modules, each representing major activities in the building use: e.g. using the building, maintaining it, repairing, refurbishing, etc. All the processes of these activities may define how the building is performing for the user in terms of comfort, safety, etc. The methodology successfully follows the same structure and philosophy as applied in the CEN TC350 standards for environmental and economic performance assessment.

Furthermore there is a close relation of the CEN TC350's building assessment framework to the European regulatory framework, in specific to the CPR (Construction Product Regulation) which is outlined and discussed.

Keywords: social sustainability, social performance of buildings, CEN TC350 standards, EN16309, methodology, social indicators, CPR

1. Sustainability assessment in different views

There are many angles for making an assessment of the performance in sustainability: from evaluating the sustainability of a small and single object or product to assessing the worldwide consequences of policy choices. Sustainability is a "container" word that on itself

does not set limits to the objects of assessment, to the boundaries of the assessment nor to the type of indicators of assessment.

Ness et al. [1] have given a categorization of sustainability assessment methods by differentiating their temporal focus. Methods or tools can either be retrospective (indicators and indices) or prospective (integrated assessment) or both (product-related assessment). Indicators and indices may cover single aspects e.g. I/O energy flows or several aspects; the latter being non-integrated like the UNCSD indicators or integrated like the ecological footprint. Integrated assessment methods also have a spatial focus and serve as policy instruments (Environmental impact assessment, strategic environmental assessment, risk analysis, vulnerability analysis, system dynamics, etc.). Among the product-related methods are life cycle assessment and life cycle costing which can be either attributional ("retrospective") or consequential ("prospective").

Finkbeiner et al. [2] have introduced a "Maslow pyramid" for sustainability assessment approaches: At the bottom of Maslow's pyramid of human needs are basic needs like breathing and food, followed by needs for safety and love in the middle part and on the top reside esteem and self-actualization. Finkbeiner et al. have situated Life cycle thinking as a qualitative and broad concept at the bottom. Then quantitative but single aspects like carbon footprinting are next, followed by life cycle assessment covering all environmental impacts quantitatively. Above are resource efficiency and eco-efficiency assessments that combine environmental and economic indicators. On top of the pyramid is the full life cycle based sustainability assessment with the social dimension added.

Halog/Manik [3] have set up an integrated framework for assessing a system's sustainability. In the core is the assessment of the three dimensions (ecological, economic and social dimension) according to the methods that have been established (life cycle assessment, materials flow analysis, etc.) or that are currently developed (social life cycle assessment). This is supplemented by methods for integrating stakeholder interests via AHP and by system modelling methods.

Within the complex landscape of numerous sustainability assessment methods being more analytical or more policy related, more programme- or tool-oriented, covering various issues quantitatively or qualitatively, etc. the presented CEN TC350- assessment methods need to be positioned firmly. Standardisation anyway is a matter of conventions, of good communications and of positioning an assessment in order to avoid Babylonic confusions. The following sub-chapters address some of the controversial issues concerning social building performance assessment and shall thus serve to describe the focus and to set the limits of the CEN TC 350- assessment method.

The series of standards of CEN TC350 follows a mandate of the European Commission providing harmonised methodologies for the sustainability assessment of construction products and works. The standards enable comparability of the results of sustainability assessments of buildings. A system (principles, data requirements and methodologies) for the assessment is provided and the impacts and aspects are defined that can be expressed with quantitative or quantifiable indicators, which are measured or calculated. It applies to all CEN-CENELEC standards that EN-standards reflect a common view and that existing and applied methodologies are within the scope of the respective standards. The standards of CEN TC350 do not intend to constrict or predetermine scientific LCA of buildings that is driven by research interests and will often focus on specific questions. But for rules and regulations, for building certification and for assessment schemes it is important that common and transparent rules are developed to ensure that results are comparable.

The CEN TC350 standards are developed as a basis for tools for the assessment and design of more sustainable buildings. The methodologies defined in the CEN TC350 standards are not intended for product comparisons and are not meant for selecting products by consumers or buyers. The standards allow product manufacturers and product developers to evaluate the contribution of a product to the sustainability performance of a building.

1.1. Social versus Societal

Contrarily to the environmental or economic assessment the meaning of the social assessment is not so clear-cut. In Tritthart/Rohracher [4] a matrix was developed to provide a structure in which the elements of social sustainability of buildings are integrated. The columns held the aspects as they occur during the building's life cycle stages, i.e. from social impacts of the production of building materials and components, during the design stage, during the construction process, during the use and finally at the end-of-life stage. In the rows social issues according to the 'system-level' of its impact were situated, i.e. from social aspects of using the building itself to social impacts on the neighbourhood / local environment and then to the broader impacts on society at large.

Although it is the dedicated aim of the CEN TC350-work to take into account the whole life cycle it became apparent that, at this point of time, it was only the impact of the building on the user that could be covered in a European standard. Several issues beyond this narrow focus were discussed, e.g. stakeholder involvement, responsible sourcing, architectural quality, etc. but were lacking a generally accepted calculation method. The impacts on the neighbourhood were limited to loads caused by the building in use (e.g. noise, glare, etc.) not comprising any possible benefits or issues like increased traffic, etc.

The societal evaluation would describe the impact of the building and the use of the building in a wider context. Possible questions of this wider context are: What effect has this building (e.g. a big office building) on the movement of people (transportation) in a public infrastructure, what is its effect on the supply of public space, what need for facilitating services and utilities in the direct neighbourhood (e.g. a data server-centre on the supply of electricity, gas, water, data grid, etc.) will arouse? Are regional employment possibilities generated? Is the cultural heritage of the community affected by the building?, etc. The choices to make depend on the point of view: is it the building that is assessed or is the scope to assess the impact that the specific building has on societal systems?

The above mentioned issues are part of urban planning considerations that among others deal with interaction between buildings, between buildings and infrastructure, e.g. buildings and energy supply systems, and between buildings and (local) society, etc. These "higher level" design issues need different, e.g. consequential assessments.

CEN TC350 assessment methodology is limited to the social performance of the building in its use, that means where there is a "user". The user is every person that is regularly entering into the building, employees, residents, janitors, service personnel, etc.

1.2. Process-assessments and Social life-cycle-assessment

The stages of the life cycle of the building comprise several typical processes, to name the most important ones: design process, production processes, construction process, operating process, demolition process, recycling processes. The processes have a direct impact on all persons that are involved in these processes, in specific on workers that are hired to run them. There are many instruments and tools that deal with environmentally sound process management, e.g. the EMAS as defined most recently in the EU-Regulation 1221/2009.

Social implications of the processes are covered also by a variety of legal and of voluntary instruments. Some of those building related matters are: occupational health issues, safety of workers in specific on a construction site, corporate social responsibility (CSR) commitments of the companies that are involved. Some are to be assessed in accordance with methodologies and criteria defined in Regulations or Directives while others follow a standardised methodology. For instance the assessment of processes and applied policies in a company is covered by the ISO standard ISO 26000.

Social life cycle assessment (SLCA) evaluates the social impacts that occur during the life cycle of a product. In the current early stage of the development of SLCA, the methodology draws on elements that are set by human rights, life cycle thinking (e.g. for procurement

decisions of authorities), and corporate social responsibility. Instruments and methods of related fields are often further elaborated and provide inputs for SLCA, e.g. the working environmental LCA (WE-LCA) and social impact assessment. Of specific interest is the identification of 'hot spots' of social relevance, like child labour or illegally employed construction workers.

An important constituent of SLCA is the stakeholder concept. A stakeholder is defined according to ISO 26000 as individual or group that has an interest in any decision or activity of an organization. Stakeholder engagement is an activity undertaken to create opportunities for dialogue between an organization and one or more of its stakeholders, with the aim of providing an informed basis for the organization's decisions. In SLCA, categories (impacts, like working conditions and rights, health, security, etc.) are in a first step assigned to stakeholder groups – typical stakeholder categories are "worker", "consumer", "local community" and "society [5]. If it is a building that is assessed the primary/main stakeholder to take into account is the building user.

A precondition of the CEN TC350 standards was to restrict on the building performance and not to deal with process management decisions. However, the consequences from processes on the user of the building are assessed. Building management decisions are e.g. decisions on maintenance (e.g. cleaning intervals), on repair and refurbishment of the building. In some buildings even the operation of HVAC systems is centrally influenced, e.g. hot water temperature or heating system set points. These issues evidently determine the social performance of the building and have to be included in the assessment. Examples for management decisions that do not have an effect on the performance but are albeit crucial for the satisfaction of the users are the provision of a help-line or of documentation.

1.3. Integrated building assessment

Since the 1990's several building assessment systems have been developed in many countries in the world. The starting point was without doubt environmental concerns but human needs like good indoor climate and questions that touch both social and environmental aspects like public transport connections and proximity to services have often been integrated, too. Nevertheless these issues were stringed together rather arbitrarily and not systematically. For a discussion of the most well-known assessment systems and their strategies to integrate social aspects and impacts refer to Tritthart/Rohracher [4].

In the last years some research projects have been conducted to advance towards integrated building assessment. Within the LEnSE project for the first time a differentiation into the three dimensions of sustainability was introduced: the ecological, the economical and the social one. A comprehensive list of criteria was compiled by reviewing existing systems and literature. Some criteria were elaborated and a generic method to arrive at an aggregated result was proposed [6].

SuperBuildings was a research project funded by the European Commission under the FP7 Cooperation Programme project (http://cic.vtt.fi/superbuildings/). Its aim was to go one step beyond standardization by considering the output of the standardisation processes and focus on the validity of sustainable building indicators, on comparability of assessment results, benchmarking criteria and the usability of indicators in building processes. Sustainability assessment requires a substantially more complex approach compared to those for environmental and health aspects only. Consequently the project dealt with the question, how an assessment system needs to be structured and what it needs to contain in order to deal with the full complexity of sustainability assessments. In specific it was found that indicators of most assessment schemes do not cover the full range of sustainability issues.

The SuperBuildings-experts recommended that the subjects of concern should follow the three "dimensions" of sustainability: the environmental, economic and social dimension. In each dimension the subjects of concern (which are also referred to by the term "areas of protection", "safeguard subjects" or "areas of concern") are split into values specific to this dimension (like e.g. biodiversity, human health, etc.) and into stability aspects (like social

equity or economic prosperity). Specific goals could be consequently defined and indicators that could show the performance of the object of assessment. Different stakeholders need appropriate aggregation of indicators and emphasis on their area of interest e.g. depending in which stage of the building's life cycle they are engaged.

In addition to the common categories such as land use, resources, energy (which can be classified as resource inputs) and resulting impacts (e.g. on health and on local and global environment and on financial matters) further categories relating to the outputs in terms of benefits resulting from the use of the building will need to be included into consequential sustainability assessments. Sustainability requires a long term perspective. Consequently topics such as durability, resistance (resilience) and adaptability as design parameters come to the forefront [7]

In the concept of CEN TC350, technical and functional aspects play an important role as requirements that are set up by regulations, by clients, by architectural design and by the choice of materials and construction techniques. But the building's performance according to these aspects is not assessed. The functional design, followed by the technical design of a building (or part of a building) is excluded from an assessment according CEN TC350. However all what is resulting from this design (or from the existence of a building) is scope of the CEN TC350 assessment. The projected or realised functionalities and technical performance are handled as basic background or as the "fundament" of the assessment and consequences or impacts that are caused by them are assessed. The figure 1 shows the relevance of the technical and functional aspects within the building assessment and other assessment methods.

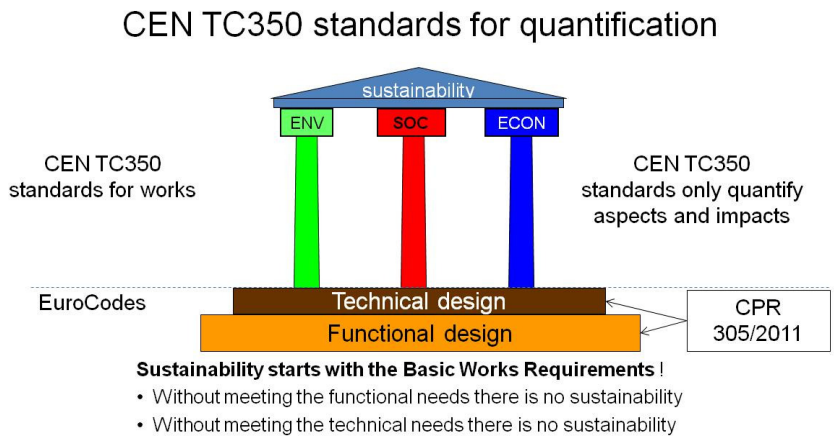

Fig 1: Greek temple graphic

2. Mandate to a common language

For a declaration of sustainability and in general for reliable information on sustainability a common language is prerequisite [8]. It took almost ten years from the first initiatives to have a whole set of standards available for sustainability assessment of buildings and of construction products. The construction sector agreed with the European Commission to develop a common language for communicating environmental performance of products and to develop a set of European standards for this purpose. The aim of the mandate M/350 "Sustainability of construction works" was to develop voluntary horizontal standardised methods for the assessment of the sustainability of construction works and core rules for the product category of all construction products. The standards in the suite of CEN TC350 describe the harmonized methodologies for assessment of environmental, social and economic performance of buildings and building products over their life cycle. In particular, the environmental performance of products is described in the Environmental Product Declarations called EPD (according ISO 14025).

Most of the sustainability standards - all environmental assessment standards - are finalised and available now. The package of standards will be completed with the standard on social performance methodology (EN16309, in 2013) and with the standard on life cycle costing methodology (EN16627, in 2014). The standards provide the indicators, the methodologies for measuring and quantification of the indicators, and provide the communication format. The parameters for measuring sustainability are selected and agreed indicators as used and widely accepted across Europe. We have 22 environmental parameters (indicators), 6 aspect categories for describing social performance and 3 indicators for quantifying the economic performance of a building. Of course the environmental performance parameters, the social parameters and the economic parameters are interlinked and inter-depending.

There is a vast literature on sustainability indicators and indicator systems, and requirements on both. In accordance with the CEN procedures at the start of the standardisation process the existing French and Dutch national standards were taken into account including the aspects, impacts and their indicators. In the CEN TC the National Standardisation Bodies and other expert-stakeholders representing European industry associations, architects and contractors associations, consumer organisations and program owners are represented. This community evaluates and selects proven and widely applied indicators for describing and quantifying accepted aspects and/or impacts of sustainability.

3. Sustainability information down the construction chain

The standards then deliver a whole ‘basket’ of sustainability indicators, they do not qualify buildings or construction products, therefore are applicable across Europe. A program, e.g. BREEAM, DGNB, etc. or national/regional rules or regulations, or even a building owner, or private consumer, may set minimum or maximum values to the building performance. Programs are helping to process all the parameters into qualifications; they use (or have announced to use) the CEN TC350 standards for collecting the data on product performance (EN15804 based EPD's) and apply them in the environmental, social or economic assessment of the building; amongst others the environmental assessment according EN15978. After quantification of the building's impact over its lifecycle these programs have their own methodology for qualifying on the basis of grouped parameters, giving different weight to different parameters. Unfortunately this is not always very transparent and well communicated. It is good and acceptable that programs compete but the rules for qualifying sustainability performances need a standardised and all transparent methodology yet.

A sustainability assessment is much more than collecting data in a spreadsheet. It requires competence of the assessor on the use of the building, the construction process, the end-of-life processes, but also on adapting scenarios and corresponding product data given in the EPD. But on his turn the manufacturer - the sole owner of the EPD and liable for his declaration - cannot limit his assessment to his production process only: all upstream information must be included in the assessment. This is followed by scenario based downstream aspects and impacts of the product. This makes product life cycle assessment complex and costly. "The level playing field, fairness and transparency has a price". The functional and the technical performance of a construction product is depending on the building system and it requires scenarios in order to make a useful declaration on a quantified contribution of the product to the sustainability. Comparing products and selecting products based on environmental performance stated in an EPD is only possible under strict conditions. In practice a direct comparison by means of EPDs is impossible: the scenarios in the life cycle should be identical. EPDs are the input for a holistic building assessment taking into account the functional and technical performances in a building context. For a producer this also means that his contribution to an higher sustainability (environmentally, socially and economically) of course should be done by big and small improvements on every step in the building chain.

4. Methodology

CEN TC 350/ WG 5 has been working on standards for social assessment of buildings. A framework standard has been published (EN 15643-3:2011) introducing the basic concepts and containing the categories that constitute the social assessment according to CEN TC 350. The new draft standard prEN 16309:2013 was finalized recently and will be sent to formal vote in summer 2013. It lists the indicators that are used to determine the performance of a building for the framework-categories. For all indicators the calculation method is given. In addition it contains detailed guidance on some essential notions, e.g. on specifying the rules describing the scenarios.

This methodology standard prEN16309 tracks the relevant aspects for the building's use ranging from "normal use" for the building user, as well the impact on the use of the building during maintenance operations, during repair and during refurbishment. Similar to the assessment of the environmental and the economic section, assessment is done in modules. The social assessment is based on 22 aspects (each using a number of appropriate indicators) which systematically are applied on the whole use stage (and consequently communicated in 7 information modules). The methodology corresponds to the same modular structure and philosophy as applied in the CEN TC350 standards for environmental and economic performance assessment. However this generation of the standard prEN16309 is limiting the social performance assessment to the use stage of a building.

Building life cycle – Use Stage	
Building-related characteristics	**Control and user interactions related characteristics**
Accessibility 1) Accessibility for people with additional needs 2) Access to building services Adaptability 3) ease of potential for adapting to other use Health and comfort 4) Thermal characteristics 5) Characteristics of indoor air quality 6) Acoustic characteristics 7) Characteristics of visual comfort 8) Spatial characteristics Impacts on neighbourhood 9) Noise 10) Emissions 11) Glare/ overshadowing 12) Shocks/vibrations Maintenance and Maintainability 13) Maintenance Operations Safety and security 14) Resistance to climate change 15) Accidental actions (earthquake, explosions, fire and traffic impacts) 16) Personal safety and security against intruders and vandalism 17) Security against interruptions of utility supply	Health and comfort 18) Thermal comfort 19) Indoor air quality 20) Visual comfort pacts on neighbourhood 21) Emissions Safety and security 22) Security against intruders and vandalism

Fig. 2: Table of social aspects for assessment (corresponds to table 1 in prEN16309)

4.1. Boundaries of the assessment

The object of assessment is the building, its foundations and external works within the area of the building's site and any temporal works associated with the building's use (including refurbishment). It is possible to restrict the assessment to a part of a building but this has to be reported explicitly. Next to the social aspects measured for the user of the building, social aspects caused by the building or the building use that effect the direct neighbourhood of the

building are pursued: noise, emissions like odours, glare and overshadowing and shocks/vibrations. The guiding principle for this choice was to encompass the neighbours' health and comfort-related issues that can be attributed directly to the building. Thus the assessment reaches as far into the neighbourhood as direct effects that are caused by the building.

The social performance of the building is on the one hand based on functionalities of the building that facilitate specific use, comfort of use, health and well-being etc. This also includes users with specific needs and even options and potentials for future users or changed use (e.g. adaptability, flexibility). On the other hand it has been proven in studies and by experience that users prefer to have the possibility to control their environment and in specific the comfort conditions (room temperature, level of luminance, ventilation, etc.). So in prEN 16309 the aspects of the categories are distinguished into building fabric related and control related aspects (see fig.2).

For the assessment detailed information on the physical characteristics of the building has to be compiled. This is the building model. It describes the shape and size of the building, the technical systems, the arrangement, type and size of building elements (e.g. windows, staircases, etc.), comfort levels, etc.

4.2. Life cycle stages and information modules

The life cycle stages are in general distinguished into before-use-stages (production of building materials and components, construction), the use stage and after-use-stage. All 3 dimensions of a sustainability assessment (environmental, social and economic) are based on these life cycle stages and results of assessments are presented per life cycle stage. As specified before, the standard prEN16309 limits the assessment to the use stage.

In parallel to the environmental and economic assessment the methodology is structured in information modules. Each lifecycle stage is represented by several information modules. The use stage is split up in 7 information modules: the use (information module B1), maintenance (information module B2), repair (information module B3), replacement (information module B4), refurbishment (information module B5), operative energy use (information module B6) and operative water use (information module B7). The information modules B2 to B7 enable and support the functional and technical performance of the building over its life time (the time of use of the building). This modular approach requires to specify scenarios for each of the information modules but then allows to assess how activities, circumstances and conditions impact the user in using the building. In applying the defined aspects of assessment over the 7 information modules a simple but very comprehensive matrix approach defines the assessment methodology.

4.3. Scenarios: first and most important performance indicator

Needless to say that the future of a certain building is never predictable. Assumptions have to be made for the use of the building in terms of the service life, the type and pattern of use, the change of use over time, but also on the type and frequency of maintenance, repair, replacements and even refurbishments to maintain the technical and functional performance of the building. This also includes social performance related scenarios to energy-use and water-use that facilitate the use of the building. The more detailed the scenarios for all the information modules are specified, the more detailed information on the social performance can be evaluated and can distinguish performances of different building designs.

The assessment for each information module starts with defining and specifying the scenario.

Scenarios shall be realistic and representative (ref. to EN15643-1). They are based on the technical and functional specifications for every building and thus are building design specific and depending on the use of the building. So the building and use specific descriptions of scenarios will be key information to be linked to the assessment outcome. Rather vague and

less detailed scenarios will result in outcomes open for many disputes. The objective and use of the (social performance) assessment as well as the timing of the project (conception phase, planning phase, construction phase) will allow to specify the scenarios in different levels of details. Describing scenarios certainly will show to be a crucial task of the assessor before starting with the checklist of indicators per aspect category. The level of details and the importance of the influence on the aspects should be well balanced: on one hand the assessor should consider all efforts of a very comprehensive assessment task and on the other hand he should avoid a very complex assessment that is not justified by the objective and use of the assessment. For an eventual verification of the assessment by an independent verifier the descriptions of scenarios and their level of details, probably will be the most important information part to confirm. The checklist results per information module and per social aspect indicator are rather objective performance statements then.

4.4. Principle steps of the assessment in EN16309

The course of the assessment has been anticipated to proceed along the following steps:

It will start with identifying the goal of the assessment and the intended use of the object of assessment.

This is followed by the specification and description of the functional equivalent, the specification of the reference study period, the system boundaries and the building model. The functional equivalent is the summary of the functional and technical requirements for the building as specified in principle by the owner/user of the building and predefined by rules and regulations to be applied for functions and technical solutions. Main inputs for this first assessment step are the client's requirements and legal requirements. The functional equivalent serves as the basis for comparisons of assessment results for various designs for a building.

The architect's design of functions and technical solutions to the demands from client and regulations then is to be described in referring at least to these demands. It may be obvious that a very detailed functional equivalent will limit the freedom of design whereas a functional equivalent specified in very general demands on functionalities of the building may invite for very creative and different solutions for a building.

In a third step the scenarios are developed for all information modules of the use stage. This of course needs to be guided by all-time related information: the reference study period (service life of the building equal to the length of the use time) and the frequencies of maintenance, repairs and replacements, etc.

The checklist for the standardised aspects then is the fourth step in the assessment methodology. This is the main part of the assessment and is the evaluation of the aspects per indicators as determined in prEN16309. Several of the indicators are quantitative which means that they can be calculated following the specified method. Where possible the standard provides a mandatory minimum list of items. Otherwise only examples of social performance indicators are given in the checklist. This European standard had to take into account that Member States in Europe specify their regulatory demands for buildings (following the 7 Basic Requirements for Construction Works according the CPR 305/2011) in different ways: very specific solutions and rather general formulated functional performance demands. Assessment scheme owners may issue a specific checklist that is more appropriate for a building type and for the regional/national situation.

For the assessment a series of calculation sheets were developed and examples are given in the annex of the standard prEN16309 (only an excerpt of these sheets is given for illustration). It is envisaged to give the sheets to the full extent in a Technical Report.
The final steps in an assessment are the Reporting, Communication, and Verification. Verification shall be applied if there is an intention to make results of the assessment publicly available.

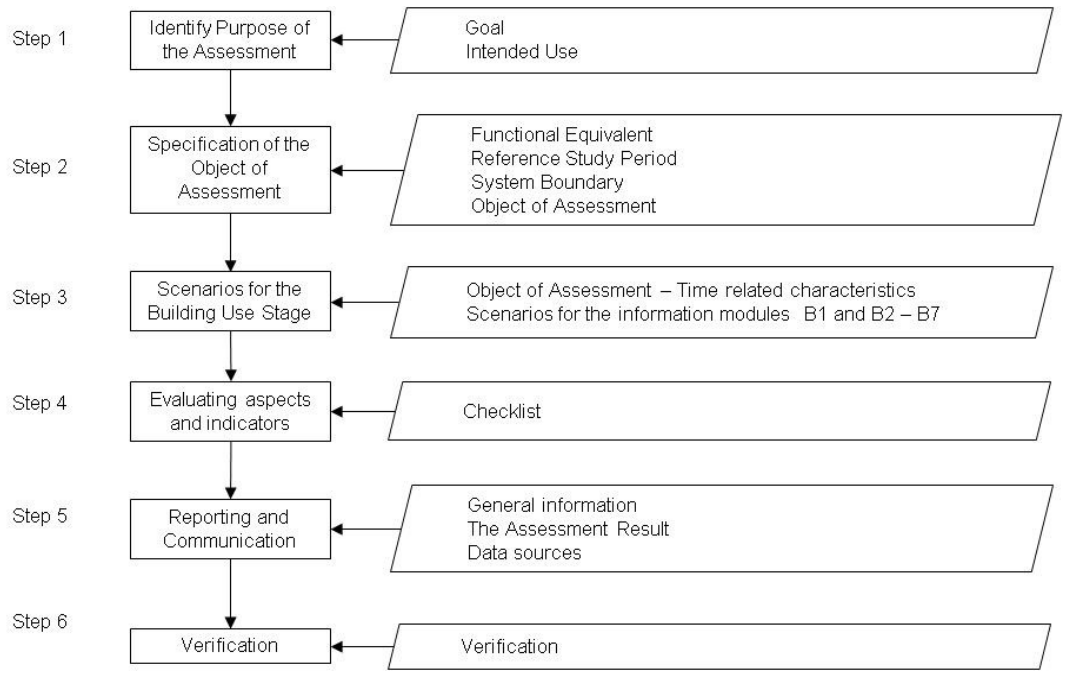

Fig. 3: Steps in the process of assessment in prEN16309

5. Relation to the Construction Products Regulation and its Basic Requirements (BRCW)

5.1. Sustainability in the Construction Product Regulation

The most important fact in terms of the assessment and communication of sustainability of construction products in Europe is represented today by the Construction Products Regulation adopted on 9 March 2011 (CPR). CPR aims to ensure reliable information on construction products in relation to their performances, including the environmental performances. This is achieved by providing a “common technical language", offering uniform assessment methods of the performance of construction products. These methods have been compiled in harmonised European product standards (hEN) and European Assessment Documents (EAD).

The CPR has already entered into force and will be fully applicable starting from 1 July 2013. What has changed from the previous Construction Product Directive EU N. 89/196/EEC is that the manufacturer of a product is kept liable for the declared product performance not only during the use stage of the product but also during the installation stage before use and after use in the end-of-life.

Within the CPR a new 7th Basic Requirement for Construction Works (BRCW) - "sustainable use of resources" - is added to the existing 6 BRCW´s. Regulators are struggling with this basic requirement to works. CEN TC350 standard experts are convinced that the standards provide all means to meet any need for quantifying and judging on the use of resources. However, this does not mean that sustainability is now specified in the CPR: There is no immediate and direct link between the CPR and a legal demand for a manufacturer to declare the sustainability for his product; not yet. Some Member States think that other rules and regulations do cover already the sustainable use of resources and no new and additional requirement for information is necessary. Other Member States feel the need to impose a demand to quantify this "sustainable use of resources" in the built environment. Whether this then will result in a demand for "essential product characteristics" is unsure for the moment.

5.2. Member State Notification, mandates to CEN product TC's

As noted above, this does not mean that sustainability is now specified in the CPR. It requires several procedural steps and a lot of administrative actions and adaptation of product standards. Foremost a national legal demand for this sustainability information on a product is required to start this procedure. In case it requires indeed new information from construction products, then Member States have to inform (notify) Europe, i.e. the European Commission, that all products that wish to be applied in their buildings shall provide that information: "essential product characteristic(s)". Then a procedure is started where the European Commission mandates the Technical Committees (TC) of CEN/CENELEC (the European Standardisation Body) to include these "essential characteristics" in the Annex ZA of the harmonised European product standards (hEN) for construction products. The European Commission should deal with sustainability product characteristics, like they have to do and did for the "usual" mechanical, thermal, acoustical, chemical product characteristics. By mid 2013 we have the situation that both the BRCW nr. 3 ("hygiene, health and the environment") and the BRCW nr. 7 ("sustainable use of resources") have led to a situation that more and more countries are putting up requirements to the environmental performance and sustainability performance of buildings. And, crucial, this then already has led to new requirements for declaring product characteristics. The Netherlands, France, Germany and Belgium have already submitted or are on the verge of submitting decrees and rules for demanding environmental product information on construction products.

In order to prevent that these new national (or even regional) requirements for product information are becoming a "barrier to trade", it requires a mandate from the European Commission that, certain and defined product characteristics related to sustainability, are from now on also "essential characteristics" and are to be included in the manufacturers declaration of performance (DoP) when the product is applied in one or more of the EU-countries. The declaration of performance will be mandatory for all construction products according to the Construction Products Regulation (CPR 305/2011) per 1-7-2013.

6. Conclusions

This paper describes the new standard prEN 16309 and shows that a building's social performance can be assessed now parallel to its environmental assessment. The methodology of assessment defined in prEN 16309 uses the same general topics and is structured in the same way as the environmental part of sustainability assessment: e.g. system boundaries, life cycle information modules, scenarios, etc.

Like the environmental and the economic performance assessment standards from CEN TC350 the new standard prEN16309 is assessing the performance of buildings and in particular the effect of the building on the user of the building. This standard has, apart from the effect on the direct neighbourhood, boundaries that exclude societal effects caused by the building and its use: spatial planning, zoning, infra-structure (traffic systems, utilities and utility supply), employment, etc., are subject of other assessment systems that apply a consequential analysis of sustainability performance. The sustainability assessment of buildings (and construction products) in the suit of standards of CEN TC350 quantify or describe the sustainability aspects of it attributionally.

Furthermore the scope of the social performance assessment according prEN16309 is limited to the lifecycle use stage. Some indicators are quantitative indicators, in specific the indicators for the indoor performance and comfort aspects. But there are also indicators for social aspects where a performance of the building cannot be measured and quantified within the possibilities of a standard. For these indicators a descriptive performance is attributed and assessed systematically in a checklist.

For the functional and technical related performance indicators of the building that have a social impact on the building user, the checklist methodology refers to the existence of applicable national or international requirements. Depending on the building type and on the

building use the client and / or the assessor decide whether the social indicator is relevant. Most of the specified social performance indicators and measures are mandatory in the checklist however some are given as examples.

The CEN TC350 standards provide methodologies for measuring and describing but do not qualify what is sustainable or not: this is left to national or private tools that use evaluation, benchmarking, weighting and rating systems, based on the results of the assessments by the before mentioned methodologies.

The social performance assessment specified in prEN 16309 is very comprehensive however the principle is based on a matrix assessment. The methodology is following the LCA system of the environmental and economic methodology standard. Scenario building per information module should serve at the same time all three dimensions of sustainability. There is a dynamic development in the last years to shift the LCA method towards a broader life cycle sustainability assessment, see for instance the call for paper in the International Journal of Life cycle Assessment [9]. The standard prEN 16309 takes an adequate step in this direction.

All CEN TC350 standards are or will be available soon, as first generation standards. Stakeholders in Europe now have to gain experiences in working with the standards and in using the assessment results. Until summer 2013 there has not been a case study according to the prEN 16309 though. Their feedback will be used to find further European agreement on how to revise and update these standards. For future revisions the limitation of prEN 16309 to the use stage and an extension to even more social aspects will probably be points of discussion.

Short Summary

The HarWin (Harvesting solar energy with multifunctional glass-polymer windows) FP7 project focuses on the development of innovative windows and their integration in buildings. These innovative windows aim at improving significantly the energy efficiency of windows and buildings and performing environmentally well on a life cycle base. The improvements are based on reduced material usage and weight, reduced thermal conductivity and energy consumption and hence, reduced environmental life cycle impacts. The innovation lays in the integration in the window of intelligent phase changing materials and novel glass-polymer composites with wavelength management capability. As windows are multi-component and multi-functional systems, an appropriate Life Cycle Environmental Assessment (LCEA) method is needed. Based on an evaluation of best available methods and tools for LCEA an adapted method for windows is proposed. This paper furthermore discusses how the method proposed can be used efficiently during the development process of the innovative window.

Keywords: Ecodesign, Energy related Product, Life Cycle Environmental Assessment, Multi-functional windows, Product Environmental Footprint, recyclability

1. Introduction

Windows are complex entities, not only as stand-alone objects (i.e. they are composed of several materials and they are designed to fulfil several functions) but also in their integration in the building (i.e. interaction with the interior and exterior environment). Although the primary function of a window is to allow daylight to enter a building and to provide visibility of the exterior environment, they fulfil many more functions. They provide protection against heat and cold (thermal insulation), prevent noise nuisance (i.e. acoustical protection) and create an attractive appearance of the building. They however might fulfil even more functions such as allowing for ventilating the building and protection against injuries and break-ins. Often, an overall acceptable solution needs to be found as an improvement of the performance of one of the functions may lead to the worsening of another one (e.g. improvement of the heat resistance often results in a reduction of the visible transmission factor). This overall optimum is moreover highly determined by the context. Both the desired and achieved window performances are amongst others determined by the function of the

building, the climatic context, local conditions and the user behaviour.

To fulfil the multitude of functions, windows are composed of several components. They typically consist of a glazing, a frame, sometimes with the integration of a ventilation grid, a gas filler and auxiliary materials. Currently, several technologies exist for each of these components and have evolved rapidly during the past centuries to improve the window performance for one or several of its functions. The glazing has evolved from single glazing to multi-layer glazing filled with air, a noble gas, or a vacuum space. Low-emissivity coatings were added to further improve the thermal insulation of the glazing. Similarly, the window frames have improved in terms of heat resistance; and air and water tightness. As the windows are often one of the weakest points in the building envelope regarding its heat resistance (with an insulation value of approximately three times worse than the rest), improvement is still needed. Innovative concepts are furthermore required to tackle the drawbacks of the new technologies to date such as high weight and material usage of multi-pane glazing. Searching for innovative windows with the above goals is the aim of the FP7 HarWin project [1]. The innovation lies in the integration in the window of intelligent phase changing materials and novel glass-polymer composites with wavelength management capability.

The aim of the HarWin project is furthermore to ensure that the newly developed innovative windows will not only have additional technical, functional and energetic functionalities, but that these will also present an overall improved environmental performance over their life cycle. For this purpose, a life cycle environmental assessment (LCEA) method is required which could be used during the development phase of the innovative multi-purpose window.

Several studies were performed in the past to calculate the environmental impact of windows as a set of components, as a stand-alone product or as integrated in a building ([2], [3], [4], [5], [6], [7], [8], [9], [10]). These studies confirm that windows are complex entities and their integration in the overall building design should be taken into account [3], [4]. The studies furthermore confirm that their performance and related required characteristics do not only depend on the climatic context, but also on specific (local) conditions (e.g. shadowing, orientation), function and user behaviour. LCEA studies of windows highlighted the importance of the use stage and recommend considering carefully this life cycle stage [3], [4], [5]. The life span of the window and its components were furthermore identified as important characteristics, which is determined by the durability of the components, the window design and its integration in the building (e.g. level of disassemblability) [2], [4], [9]. It is therefore important that the $LCEA_{HarWin}$ method explicitly takes into account durability, recyclability, reusability and recoverability of windows.

An overview of existing LCEA methods is given in section 2 of this paper. The proposed $LCEA_{HarWin}$ method and its integration during the design process of the innovative windows (i.e. ecodesign) are discussed in section 3. The final section describes the conclusions and steps forward.

2. Existing Life Cycle Environmental Assessment Methods: overview

Several potential methods are available which could be used within the context of HarWin. Four methods were analysed: EN 15804:2012 [11], Product Environmental Footprint (PEF) [12], Methodology for Ecodesign of Energy-related Products (MEErP) [13] and Resource Efficiency Assessment of Products (REAPro) [14]. The ISO 14040:2006 and ISO 14044:2006 standards on Life Cycle Assessment (LCA) were moreover considered as general framework [15], [16]. The results of the analysis are briefly summarised in the subsequent subsections.

The four methods were analysed in terms of:

- Life cycle approach in order to avoid burden shifting across product life cycle stages;
- Multi-criteria approach in order to avoid burden shifting across environmental impact categories;
- Alignment with the International Life Cycle Data System (ILCD) recommendations because the ILCD impact categories and models are widely supported by LCA experts in the scientific community [17];
- Allowing for consistent design decisions;
- Transparency;

- Data quality requirements (as a prerequisite for good quality results);
- Covering durability, recyclability, reusability, recoverability issues (as identified in previous research as important issues).

2.1 EN 15804:2012

The European Standard EN 15804:2012 provides core product category rules for all construction products and services [11]. The standard "*provides a structure to ensure that all Environmental Product Declarations (EPD) of construction products, construction services and construction processes are derived, verified and presented in a harmonised way*" [11]. Although in principle, the standard recommends to include all life cycle stages, only the production stage (raw material acquisition, transport to manufacturer and manufacturing) is strictly required. If all life cycle stages are covered, the information should be subdivided in several predefined modules. Reuse, recovery and recycling potentials at the End-of-Life (EoL) stage of the product are not included in the system boundary and, if included, should be communicated in a separate information module.

The EN 15804 requires a multi-criteria environmental assessment considering 7 default impact assessment categories: global warming [kg CO_2 eq.], ozone depletion [kg CFC11 eq.], acidification for soil and water [kg SO_2 eq.], eutrophication [kg $(PO_4)^{3-}$ eq.], photochemical ozone creation [kg ethene eq.], and depletion of abiotic resources elements [kg Sb eq.] and fossil fuels [MJ net caloric value]. Although the EN 15804:2012 requires to use the characterisation factors according to the ILCD recommendations for all categories except for abiotic depletion potential, the required units do not all coincide with these of the ILCD recommendations. Extra environmental information is furthermore required regarding resource use and output flows.

From the analysis, it was concluded that the EN 15804 has a different goal than what is aimed at in HarWin and therefore does not seem to be fully appropriate for HarWin. The main reasons are the following: recycling is not taken into account, there is no comprehensive list of impact categories and the impact assessment models are not completely in line with the ILCD recommendations. Some aspects can however be taken from the standard when developing the $LCEA_{HarWin}$ method, such as the time and technology related specific requirements for data quality.

2.2 Product Environmental Footprint (PEF)

The PEF method is a multi-criteria measure of the environmental performance of any type of product throughout its life cycle [12]. It has been developed by the Joint Research Centre of the European Commission and published as an annex of the recommendation linked to the Communication "*Building the Single Market for Green Products - Facilitating better information on the environmental performance of products and organisations*" [18]. PEF information is produced for the overarching purpose of seeking to reduce the environmental impacts of products taking into account supply chain activities (from extraction of raw materials, through production and use, to final waste management).

The PEF method considers 14 default impact assessment categories: climate change [kg CO_2 eq.], ozone depletion [kg CFC-11 eq.], eco-toxicity – freshwater [CTUe], human toxicity – cancer effects [CTUh], human toxicity – non-cancer effects [CTUh], particulate matter/respiratory inorganics [kg PM2.5 eq.], ionising radiation – human health effects [kg U^{235} eq.], photochemical ozone formation [kg NMVOC eq.], acidification [mol H+ eq.], eutrophication – terrestrial [mol N eq.], eutrophication – aquatic [kg P eq. (fresh water) and kg N eq. (marine)], resource depletion – water [m^3 water use related to local scarcity of water], resource depletion – fossil [kg antimony (Sb) eq.], and land use [Kg (deficit)].

From the analysis it was concluded that the PEF method seems appropriate for the LCEA of windows within the HarWin project because of several reasons. The environmental impact categories are comprehensive and the related indicators, models and characterisation factors are in line with the ILCD recommendations. The PEF method follows a two-step procedure (i.e. screening and final PEF) which seems most appropriate for HarWin (see section 2.3). The prescriptive guidelines furthermore ensure consistent and comparable results. The data quality

requirements guarantee that results are based on good quality data which is an important characteristic of this method. Recycling, reuse and energy recovery are all included, both at the start and end of the product's life cycle. However, no specific indices are calculated which emphasise the durability, recyclability, reusability or recoverability as such.

2.3 Methodology for Ecodesign of Energy-related Products (MEErP)

The MEErP methodology provides guidance to analysts and stakeholders involved in the preparatory studies for implementing measures under the recast of the Ecodesign Directive [19]. A structured approach is proposed to analyse environmental, economic and technical performances of product alternatives and comprises seven tasks: scope definition, market analysis, analysis of consumer behaviour during use and EoL, description of technologies, environmental and economic assessment, consideration of design options and setting up a stock model. The analysis comprises a base-case (i.e. the average product representing the EU market in terms of resources efficiency, emissions and functional performance), a Best Available Technique (BAT) case representing the best commercially available product with the lowest resources use and/or emissions and Best Non Available Technique (BNAT) case which refers to an experimentally proven technology that is not yet brought to market.

The environmental method gathered in the EcoReport tool recommended by MEErP proposes 9 environmental impact categories: Greenhouse Gases [kg CO_2 eq.], acidification [g SO_2 eq.], Non Methane Volatile Organic Compounds [g], Persistent Organic Pollutants [ng Teq. of TCCD], heavy metals to air [mg Ni eq.], Polycyclic Aromatic Hydrocarbons [mg Ni eq.], Particulate Matter [mg PM10 eq.], heavy metals and PAH emissions to water [mg Hg/20 eq.] and eutrophication [mg PO_4 eq.]. An indicator on critical raw materials is moreover proposed.

From the analysis it was concluded that the MEErP methodology is relevant for HarWin because windows are typical ErP belonging to the scope of the Ecodesign Directive. The MEErP methodology has however been developed for policy purposes and therefore may not be suitable to be used as such in a product development process. The main reason is that it concerns a simplified environmental impact assessment method that is not compliant with the ILCD recommendations. Nevertheless, the MEErP approach to identify a base-case, BAT and BNAT; and to calculate the benefits of an improved product compared to the base case both at the product level and setting up a stock model for environmental analysis is useful for the HarWin project.

2.4 Resource Efficiency Assessment of Products (REAPro)

In 2011 the European Commission (EC) published its "Roadmap to a Resource Efficient Europe" indicating objectives, strategies, milestones and actions to be undertaken in order to improve the resource efficiency of the European Union [20]. In line with this policy initiative, the REAPro method has been developed by the JRC upon mandate from DG Environment, between 2009 and 2012. It has been developed to be used in the framework of various product policies, including the EcoDesign Directive [19], EU Ecolabel [21] and Green Public Procurement [22].

The REAPro method was developed to support transparent identification of potential resource efficiency measures for products and assessment of their improvements potentials on a life cycle perspective. The REAPro method aims at assessing the performances of products according to six resource efficiency and waste management criteria and at using results to identify relevant improvement product measures [14]. The criteria address the recycled content rate, the re-usability, recyclability, recoverability rate of a product; the use of hazardous substances in a product and the durability of a product.

From the analysis it was concluded that the REAPro method seems appropriate to be applied to the HarWin windows for its specific focus on resource efficiency, which is not the case for any of the other considered methods. Its application would allow to identify trade-offs between material efficiency performances during production and EoL stages with energy efficiency during the use stage. Its recyclability and durability indices could also be used to explore windows' design opportunities to improve its recyclability and remanufacturability. Although the REAPro is a multi-

criteria life cycle approach in line with the ILCD recommendations, it does not comprise data quality requirements and is not as prescriptive as for example the PEF method.

3. LCEA method for HarWin and its implementation during the design phase

3.1 Proposed LCEA method for HarWin

Based on the conclusions of the analysis, a hybrid (i.e. based on a combination of features of the different methods studied) LCEA approach has been proposed for HarWin. The most important characteristics of the proposed LCEA $_{HARWIN}$ method are the following (referring to the original method for each specific feature):

- the method is life cycle based: it considers the life cycle of the window from extraction of resources to end-of-life treatment (ISO 14040 and ISO 14044);
- the method comprises a multi-criteria environmental impact assessment in line with the PEF method. Moreover, additional environmental information is proposed for four impact categories (mineral resource depletion, eutrophication, photochemical ozone formation, and fossil resource depletion) using the EN 15804 recommended indicators and impact assessment models so that EPDs can easily be developed;
- the method includes indicators of material efficiency (REAPro method);
- the method is based on an iterative assessment process (PEF method) which allows:
  - a screening assessment (based on generic data)
  - a detailed assessment (based on specific data and revised/refined building and window models);
  - a final assessment (based on final specific data and final building and window models);
- the method consists of a comparison of the new developed innovative window with a base case window and BAT window (MEErP methodology),
- the method allows to draw conclusions on the macro-scale (i.e. European continent) based on the results of the assessment of performances at the product level (MEErP methodology).

In previous studies the use stage was identified as very important in the life cycle environmental impact of windows due to its integration in the building and related heat losses/gains resulting in an energy demand for heating and/or cooling, and because of energy demand for lighting when not enough daylight is provided. In consequence, particular attention needs to go to the estimation of the operational energy use and the determination of the part to be assigned to the windows. Hence, the impact of implementing HarWin windows on the building energy consumptions will be investigated by using dynamic computational simulations. A state-of-the-art energy modelling tool, IES <VE> [24] will be employed to carry out the investigation. The IES <VE> is a suite of building performance modelling tools based around a single integrated data model. It is comprised of a series of individual modules including climate, geometric modelling, solar shading, energy and carbon, lighting, airflow, value/cost and egress modules, linked by a Common User Interface (CUI) and a single Integrated Data Model (IDM), which allows data input being passed among different applications. In addition, three building types have been identified as the baseline building models, which are an office building, a secondary school and two residential buildings (i.e. a detached house and an apartment building). A series of climatic locations will also be selected in the simulations to represent the typical climate zones in Europe. Two types of simulations will be conducted with an attempt to better understanding the HarWin windows impact; one is the steady-state simulation to provide the heating and cooling loads and the other is dynamical simulation to provide detailed information from the component level up to the building level.

3.2 Implementation during the development process of innovative windows

The $LCEA_{HarWin}$ method will support key development decisions and dissemination activities. In particular, it is proposed that the $LCEA_{HarWin}$ method will be used in the development phases of the HarWin R&D project (See Fig. 1). Integrating environmental aspects during the design process, often called ‘ecodesign’, has been widely discussed in the literature during the last two decades

(see e.g. [25], [26], [27], [28], [29], [30], [31]). The technical report ISO/DTR 14062:2002 "describes concepts and current practices relating to the integration of environmental aspects into product design and development" and discusses several models of integration [31]. One model, based on the so-called "Pahl&Beitz model" proposed in the nineties by the "Design for X" community [32], aims at proposing various actions (e.g. definition of objectives, analysis, decisions) to be carried out at each phase of the development process (i.e., Planning; Conceptual design; Detailed design; Testing/Prototyping; Market launch; Product review [31]) in order to improve the product environmental performances.

Based on this generic model, the $LCEA_{HarWin}$ method will be applied in the context of the HarWin project for different purposes during the four main phases of the development process of the innovative windows:

- During the planning phase (Phase 1): to identify the key environmental performances that should present the innovative window (based on the simplified application of the method to state of the art windows and on the literature);
- During the conceptual design phase (Phase 2): to analyse the environmental impacts of design concepts alternatives of the new window (e.g. concerning architecture, typology of materials in frame and glazing) and to help partners making informed choices;
- During the detailed design phase/Testing/Prototyping (Phase 3): to analyse the environmental impact of technical design alternatives (e.g. thickness of glazing, exact reference of materials, manufacturing process) and to allow partners on informed decisions;
- For the closure of the project (corresponding to the "market-launch" and "product-review" phases for the ISO 14062 model) (Phase 4): to analyse global performances so that they can be communicated and that further developments can be identified.

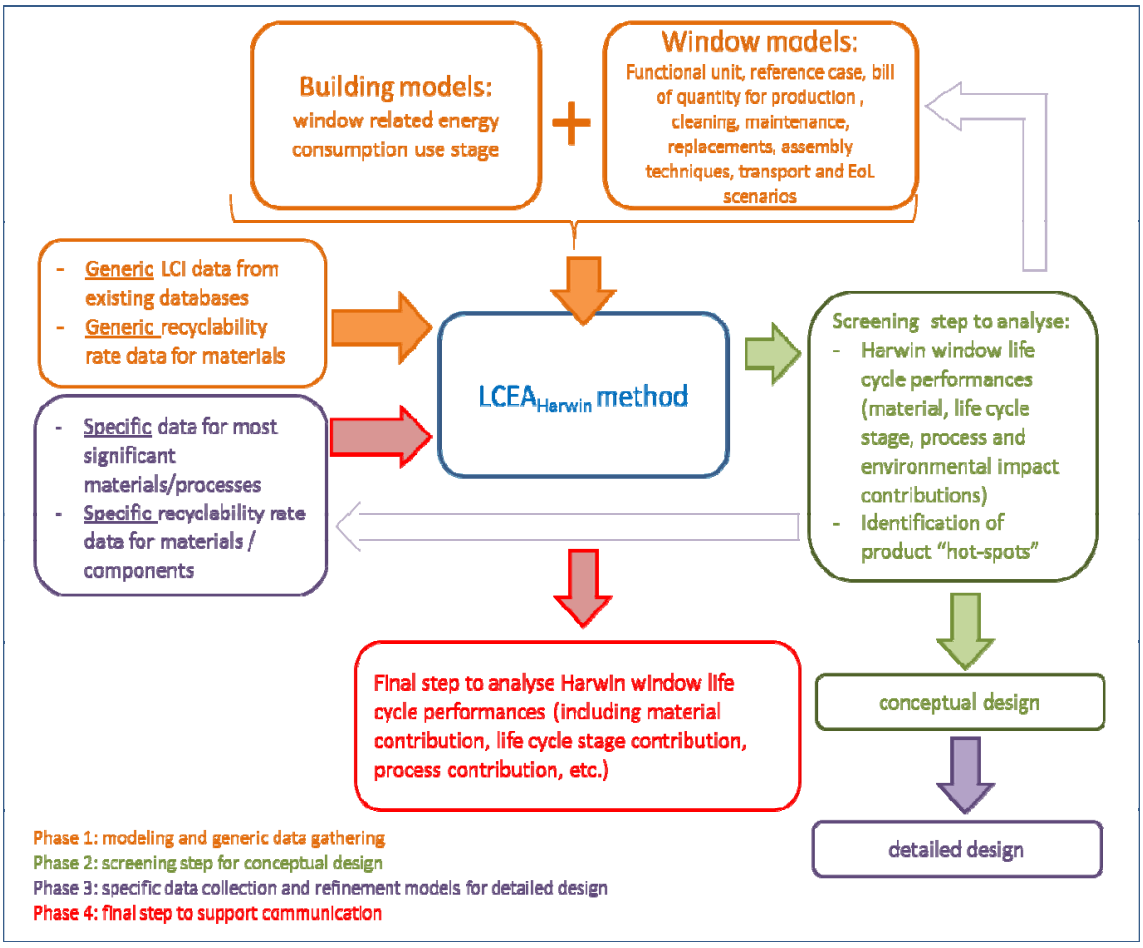

Fig. 1 Schematic representation of the implementation of the $LCEA_{HarWin}$ method for the development of innovative windows

4. Conclusions and steps forward

Based on the analysis of existing initiatives to assess the life cycle environmental impact of windows, a hybrid method was proposed combining the strengths of each of these methods within the context of the HarWin project. The result is a life cycle multi-criteria environmental impact assessment method, entitled $LCEA_{HarWin}$ method, based on an iterative LCA approach, with the robustness of following the recommendations of ILCD. Additionally, the $LCEA_{HarWin}$ method comprises material efficiency indicators to assess the recycled content, recyclablility, recoverability and durability of the windows. The method moreover allows for drawing conclusions on the macro-scale. The next steps of the HarWin project comprise the building modelling and related approaches for allocating energy losses of the building to the window; and related data gathering. The proposed LCEA method will then be tested on state of the art windows and during the design process of the innovative windows and will be used to take decisions related to the development of the innovative window.

Carbon footprint of green roofs in Singapore

Dr. Nalanie

Dr. Nalanie Mithraratne, Department of Architecture, School of Design and Environment, National University of Singapore, Singapore, akimnsm@nus.edu.sg

Short Summary

Due partly to the government incentives introduced under the sky rise greenery initiative, green roofs are common in the tropical Singapore compared with the other eco-roof types. With limited land and natural resources within national boundaries Singapore is unique, as most system components for green roofs have to be imported from elsewhere while waste has to be incinerated. The main focus of green roof studies in this unique Singapore setting so far has been the in-use performance benefits in terms of cost, energy and water savings without considering the life time performance. However, resource costs as well as benefits need to be considered in the decision to promote any strategy.

This paper discusses preliminary results from a study that aims to develop a life cycle carbon footprint based decision framework for selecting eco-roof strategies. The results indicate that the carbon footprint of green roofs depends on the construction details and system components used. The end-of-life waste disposal contributes significantly to the carbon footprint, even with system expansion to include avoided electricity generation as a result of green roof waste incineration, main method used for waste management in Singapore.

Keywords: green roofs, life cycle assessment, carbon footprint, tropical climate, Singapore

1. Introduction

Rooftops represent approximately 50% of impermeable surfaces in urban areas. The potential use of rooftops to moderate the effects of climate change, such as extreme rainfall and temperature, has introduced three eco-roof strategies; green (living), blue (water managing) and white (heat reflecting). While a green roof is a conventional roof covered with a layer of vegetation, blue roof stores water using flow controls, such as downpipe valves, gutter storage systems and cisterns. A white or a cool roof is designed to maintain a lower roof temperature compared to a traditional roof by painting white or applying a reflective coating. The benefit of white roof is limited to temperature modifications while both green and blue roofs can, in addition, provide storm water management. Green roofs can also improve air quality and provide biodiversity through habitat creation.

Singapore is a thriving world class city with over 5million population living in high-density housing in a land area of around 700km^2. Despite land constraints, Singapore is covered in

a high level of greenery due mainly to conscientious planning over decades. Making optimum use of land, while ensuring green space is maintained at 8m^2/person and increasing greenery in high-rise buildings to 50ha by 2030 are goals of the Singapore Sustainable Development Blueprint [1]. With therapeutic value of greenery in reducing stress already established [2, 3], green roofs are an established strategy used commonly in Singapore to soften the harsh urban environment and to improve the quality of life.

Increased roof insulation due to plants and substrate layers of a green roof could reduce the building cooling loads [4-6] while protecting the roof layers otherwise exposed to the natural elements [7, 8]. The potential reduction in urban heat island effect by introducing green roofs has already been established [9, 10]. However, concerns over increased first cost and structural loading were reported as hindering wider uptake of green roofs in Singapore irrespective of the conducive climate [11]. Skyrise Greenery Incentive Scheme introduced by the Singapore government agency NParks aims to address this issue by funding up to 50% of the installation cost of green roofs (and green walls). Since its inception in 2009, over 200 developments have been funded by the scheme.

Current green roof research internationally and in Singapore concentrate mainly on the performance benefits in terms of cost, energy, water savings and carbon reduction [12, 13]. However, for a holistic evaluation of any strategy, resource costs as well as benefits accrued over the lifetime needs to be considered prior to incentives to promote their wider uptake. Bianchini and Hewage [14] in a life cycle assessment study of green roof materials highlighted the need to find alternatives to current materials in order to lower the associated environmental impact. This is especially applicable in resource constrained Singapore where all materials used in green roofs are imported from elsewhere.

1.1 Background

This paper considers the life-cycle performance of alternative green roof systems commonly used in Singapore with concrete roof slabs. While acknowledging the broad range of benefits from green roofs such as reduction in storm water runoff and urban heat island effect, improvements in habitat and urban air quality, reduction in noise and energy use in buildings, the paper is limited to implications of building energy use. Green roofs in Singapore have been reported to reduce the annual energy consumption by up to 15% [11]. While the energy savings depend very much on the baseline selected for the study, the above estimates were based on the u-value of the green roof options, without the effect of soil moisture and the plant shading. While soil moisture could increase the thermal conductance, plant shading could reduce the solar gain and the roof surface temperature.

Accessible, intensive green roofs which are also known as roof gardens are more common in Singapore compared with extensive roof gardens which are inaccessible. While roof gardens are built on-site layer by layer, and therefore tend to be continuous in construction, extensive green roofs can be either build-up or use modular systems that generate an instant effect. Although a modular system provides easy access to the roof structure in case of water damage or alternative use at a later stage compared with the build-up system, the resource use of the two systems, modular and continuous, vary widely.

2. Life cycle assessment of alternative green roof options in Singapore

To assess lifetime environmental performance of alternative green roof options in Singapore based on wider environmental considerations such as energy use and carbon emissions, three green roof systems commonly used on concrete slab roofs are considered; continuous intensive, continuous extensive and modular extensive.

First, the data on material sourcing, typical construction details, maintenance practices and waste disposal scenarios for these systems were collated from industry sources and a

streamlined life cycle assessment (LCA) was conducted. Established databases on materials and products used in construction sector are not available in the Asian region unlike in Europe, New Zealand and Australia. Therefore, the LCA in this study relied mainly on literature and where overseas databases are used these have been modified to reflect the local conditions.

Then, the reduction in cooling energy use as a result of different green roof options was modelled using *EnergyPlus* (version 7.2) thermal simulation software. To estimate the relative overall benefit of green roof, an exposed roof with a PVC water proofing membrane was used as the base case.

Finally, a sensitivity analysis was conducted to assess the validity of the assumptions used in the assessment and their impact on the results of the study.

2.1 Continuous intensive green roof system

Commonly known as roof gardens, typical substrate thickness of this system varies from 250–1200mm. For this assessment, a green roof with 700mm thick substrate layer is selected. While 80% of the roof area is covered with shrubs (roughly 0.5m high) the rest is covered with ground cover plants.

2.2 Continuous extensive green roof system

An extensive green roof with a 100mm thick substrate layer with ground cover plants is considered.

2.3 Modular extensive green roof system

A light weight polypropylene tray system with 70mm thick substrate layer and ground cover plants is selected.

Maintenance of extensive system involves weeding, pruning and fertilising three times a year, while around 10% of the plants need to be replaced annually. Watering needs depend on the type of planting with up to 5l/m^2/day and 12l/m^2/day for ground covers and turfing, respectively.

Unlike extensive green roofs, regular maintenance is necessary for intensive green roofs and the maintenance frequency could vary from daily to fortnightly depending on the building. The plant replacement rate is about 20% per annum while daily water demand could be as high as 25l/m^2 for medium size trees. Either a full-time or a part-time gardener would be necessary due to the need for frequent stability and pest attack tests of shrubs and trees, higher fertilizer demand and for watering.

The end-of-life waste disposal practices for green roofs are not established in Singapore. Although it is possible to recover most components, the waste handling scenarios suggested varied from one supplier to the other. While it is likely to reclaim the drainage layer and substrate materials, the low value products of the remaining layers mixed with dirt are likely to be sent to landfill. The plants and plant media removed are likely to be taken back to the nursery for composting and re-use, respectively. According to industry sources, trays last only for 5–6 years. Although the plant tray can be re-used the supplier indicated that once removed trays are currently sent to landfill.

In Singapore incineration is the main waste management method used due to lack of landfill space. Tan et al. [15] reported that the waste incineration process releases 1.6kgCO_2/kg of waste incinerated, although the energy use for the same was not indicated. In 2008, waste-to-energy plants in Singapore incinerated 2.45million tonnes of waste [16] and generated 1.048millionMWh of electricity [17]. On this basis, waste-to-electricity generation is

427.8kWh/tonne. While 20% of the electricity thus generated is used in the incineration process, diesel use to initiate the incineration process in the year 2008 was 0.005kg/kg according to National Environment Agency [18]. Currently less than 3% of total electricity generation in Singapore comes from waste incineration. Although, electricity generated by waste-to-energy releases higher emissions relative to other electricity generation methods being used, it eliminates the dependence on imported fossil fuels.

3. Methodology and assumptions

An assessment of the energy consumption and waste production associated with acquiring the raw materials, producing the green roof materials, transporting the materials to the construction site, constructing the green roof, maintaining the green roof, and disposing the materials at the end of the life span for three strategies were conducted using life cycle assessment methodology to establish energy and carbon footprint. This is limited only to the parts of the building and roof that are affected by the change in materials across the roof types. The green roofs are assumed to be established on a hypothetical five-storey office building with a 1000m^2 roof area.

3.1 Green roof system resource use

3.1.1 Useful life

The useful life of green roof systems in Singapore is not established yet, as the systems are a recent development in Singapore. Wong [11] in his study used 40years as the useful life of green roofs in Singapore, while Kosareo and Ries [7] used 45years for green roofs in the USA. Considering that the buildings in Singapore are demolished long before the end of their useful life, to accommodate changing building demands, a shorter useful life of 20years is used in this study.

3.1.2 Modular tray

Trays used in the modular construction system are produced in Singapore using recycled polypropylene. Although the use of recycled plastics eliminate the resource use associated with oil extraction and polymer manufacture, there is a resource cost associated with recycling and recovery process. Due to lack of data on recycled polypropylene tray manufacturing process in Singapore, inventory data from literature [19] are used with current Singapore specific waste management practices [20] and electricity data [15] for production of recycled polypropelene pellets. Resource requirements for plastic moulding has been added to this based on ecoinvent data modified to represent Singapore grid electricity. It is assumed that the trays are replaced at 5-year intervals.

3.1.3 Origin of materials and components

Most materials used in green roof systems such as drainage layers, filter layers, substrate and plants are sourced from overseas. Although the substrate composition can vary from one green roof supplier to the other, main ingredients are, recycled construction waste (bricks/clay tiles), pumice, minerals and organics. Substrate materials are predominantly sourced from Malaysia and Indonesia. Seedlings grown in polyethelene bags generally come from Malaysia. Green roof drainage components, filtering and roof protection layers used in Singapore are mainly sourced from Germany.

3.1.4 Transport

For imported products and materials, land transport within the source country, shipping to Singapore, and lorry transport within Singapore are included. It is assumed that the return trip for land transport is empty while ships carry other goods on their return journey. A 25km

distance by lorry from green roof site to supplier's yard and from yard to waste management facility at the end of useful life is also included [21].

3.1.5 Waste management

Due to lack of established practices for end-of-life waste management the following scenario was used based on suppliers' data. All materials and components removed are transported to the supplier's yard. The drainage layer and substrate material are washed and cleaned for re-use. All the other under layer products used in build-up system along with modular trays (except drainage system) are sent to waste management facility. It is assumed that 10% of drainage layer (due to odd-sizes) and substrate material are also sent to waste management facility. Plants are chopped and composted at the supplier's yard. Plant media is re-used at the supplier's yard.

3.1.6 Data sources used

Embodied energy and CO_2 emissions of drainage materials, filtering and roof protection layers are based on *ecoinvent* (version 2.1) data. Since recycled waste is the main ingredient in substrate, resources use for substrate is considered to be limited to transport (shipping and road transport). Resource uses for seedlings are considered to be limited to polyethelene bags and road transport. Energy and emissions of fertilisers are based on New Zealand data [22]. All diesel vehicles used in Singapore are assumed to conform to EURO 4 emissions standards [23] and modelled using *ecoinvent* data.

Energy intensity of current grid electricity in Singapore is not published. This was established using electricity mix data reported by Tan et al. [15], data on electrcity generation technologies reported by Kannan et al. [24] and waste-to-energy data from National Environment Agency [18].

3.2 Green roof system cooling energy benefit

In order to estimate the reduction in cooling energy requirement of a building, due to the addition of the different green roofs, a hypothetical 5-storey office building located in Singapore was modelled for annual energy requirement to maintain 24^{o}C internal temperature, between 7am and 9pm during the weekdays using *EnergyPlus* (version 7.2) [25] simulation software with the earth roof module. The benefit of cooling due to the green roof system is considered to be limited to the floor directly beneath the green roof.

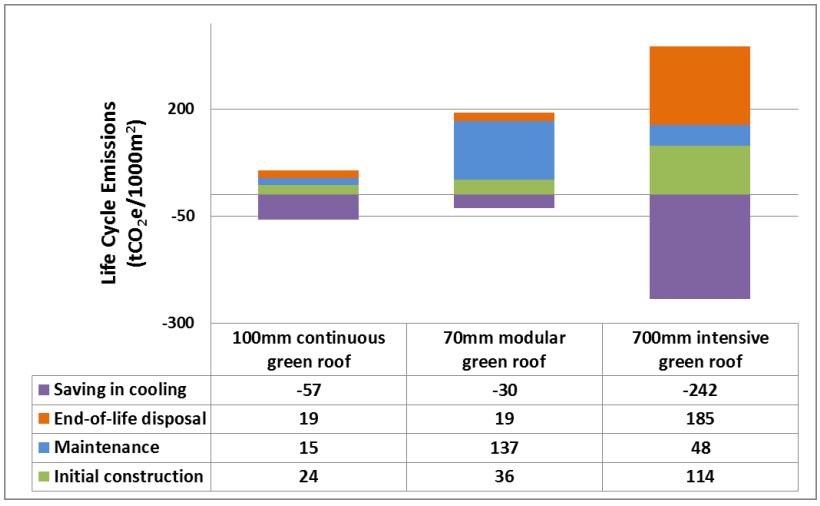
3.3 Sensitivity analysis

To validate the results of the life cycle assessment two variations to the base case are considered:
Scenario1: green roof useful life is 30 years
Scenario 2: tray system is replaced at 7 year intervals rather than 5 years.

4. Results and Discussion

For a holistic evaluation of the benefit of green roofs, it is necessary to identify the energy and emissions avoided due to reduction in grid electricity use. As a first step, the energy intensity of current waste incineration process which supply 2.3% (in 2008) of grid electricity used in Singapore was established.

4.1 Energy intensity of Singapore electricity



Based on National Environment Agency data in 2008, 1kg of waste incineration used 0.35MJ of primary energy. Therefore, a kWh of electricity generated from waste incineration uses

0.82MJ/kWh. Based on a fuel mix which uses 75.8% natural gas, 21.6% fuel oil, 0.3% diesel and 2.3% waste [15], the primary energy of Singapore's grid electricity would be 8.28MJ/kWh. If the transmission network losses which have been estimated to be 2.5% on average [15], are included energy intensity of Singapore grid electricity increases to 8.49MJ/kWh.

Therefore a unit of electricity saved as a result of green roof would save 8.49MJ of primary energy while also avoiding 601gCO_2eq emissions. However, the resource uses for establishment, maintenance and end-of-life disposal would entail energy and emissions costs. These are discussed next.

4.2 Carbon footprint of green roof systems used in Singapore

The results indicate that the life stage responsible for the majority of carbon emissions depends on the green roof construction system; continuous or modular. For continuous construction, the majority (over 70% of the total) of emissions are a result of initial construction, irrespective of whether it is an accessible or inaccessible green roof. For modular construction system the maintenance contributes the most emissions with around 90% of the total. This could be expected due to the short useful life of the tray, even though the trays are produced of recycled polypropylene in Singapore. Total emissions associated with the modular extensive green roof system are three times that of continuous extensive green roof while emissions of intensive green roof system are six times that of continuous extensive green roof. The total emissions due to different green roof systems including the reduction in cooling energy requirement as a result of green roof are shown in Figure 1.

	100mm continuous green roof	70mm modular green roof	700mm intensive green roof
Saving in cooling	-57	-30	-242
End-of-life disposal	19	19	185
Maintenance	15	137	48
Initial construction	24	36	114

Figure 1: Lifetime emissions associated with common green roof systems used in Singapore including the benefit in cooling energy savings (without system expansion)

During the 20-year useful life considered in this study, only continuous extensive green roof system saves sufficient electricity to pay off the emissions released as a result of green roof system. The cooling energy savings are only 15% and 70% respectively for extensive modular tray and intensive green roof systems related emissions. However, any waste generated as a result of establishment, maintenance and end-of-life disposal of green roof system components can result in avoided electricity generation using other fossil fuel sources. Even if the system boundary considered for green roof systems is expanded to include the waste-to-electricity generation, the performance of both extensive modular tray and intensive green roof systems improve marginally, with only 17% and 75% of the lifetime emissions recovered during the 20-year period as avoided emissions due to energy savings. Although waste-to-electricity generation avoids generation using imported fossil fuels the process is emissions intensive.

4.3 Performance with longer useful life

Although only a 20-year period was considered as the useful life in this case, previous green roof studies have considered a longer useful life of 40–45 years due to the ability of green roofs to extend the useful life of roof membranes. If the useful life of green roof systems in Singapore is considered to be 30-years, then the embodied emissions of the intensive green roof system can be recovered as avoided electricity emissions due to cooling energy savings over this period. However, due to relatively short useful life of trays which leads to higher embodied emissions, the modular tray green roof system does not pay back even over the longer 30-year period.

4.4 Performance with longer replacement cycle for modular tray system

Even with a longer replacement cycle of 7years instead of 5years considered in the base case, the embodied emissions of modular tray extensive green roof system cannot be recovered over the extended 30-year useful life. Although the contribution to the total by the maintenance stage is now reduced to 63% of the total from initial 90%, the cooling benefit provided by the roof is not sufficient to pay back the emissions associated with the system.

5. Conclusions

This paper considered the carbon footprint of different green roof construction systems used in Singapore. The study suggests that the total carbon footprint and the life stage at which most emissions are released depend on the green roof construction system used. The results also indicate that the modular tray system, which is popular in Singapore due to the instant effect, is not a sustainable practice in terms of carbon footprint as the emissions investment cannot be recovered.

This research, however, was limited to cooling energy benefit of green roof systems. The advantages of using green roofs extend beyond cooling energy reduction, which were not considered here. For a true evaluation of environmental performance of green roof systems, the impacts on stormwater management also need to be included.

Life Cycle Energy Performance of Semi-Transparent Building-Integrated Photovoltaic (BIPV) Windows in Tropical Singapore

	Poh Khai NG PhD Candidate National University of Singapore pohkhai@nus.edu.sg			Dr. Nalanie MITHRARATNE Associate Professor National University of Singapore akimnsm@nus.edu.sg

Short Summary

Sustainable buildings seek not only to increase energy efficiency, but also to adopt renewable technologies in its design. As such, semi-transparent building-integrated photovoltaic (BIPV) is gaining popularity among architects and building designers, mainly due to its ability to contribute towards a zero-(or even plus) energy building. Semi-transparent BIPV windows not only generate electricity but also allow daylight into the building and reduce the need for artificial lighting. As with other window façade elements, their incorporation will however, increase the cooling load due to solar heat gains. This is even more pertinent in tropical climates where temperatures are high all year round.

This paper examines the life cycle environmental performance of a commercially available double-glazed semi-transparent BIPV module for window application under the tropical conditions of Singapore. Energy simulations were performed in *EnergyPlus* with measured data on optical, thermal and electrical properties of the semi-transparent BIPV glazing in tropical conditions. Subsequently, a life cycle assessment was conducted to determine the long term performance in terms of energy and carbon emissions.

Keywords: building-integrated photovoltaic (BIPV); solar windows; energy performance; life cycle assessment; tropical climate

1. Introduction

Improving the energy performance of façade elements is a key challenge in improving building energy efficiency, because they are the interface between indoor and outdoor environments. In addition, adopting renewable technologies such as solar photovoltaic is becoming more popular due to the shift away from consuming fossil fuels. As such, building-integrated photovoltaic (BIPV) is considered to be an emerging glazing technology for building façade elements [1,2]. When fully integrated with the building, BIPV is able to replace conventional building materials and also to generate electricity. As part of the building façade, semi-transparent BIPV not only affects building energy efficiency through power generation, but also via its thermal properties and daylight transmission. Several researchers have studied their application and combined energy savings potential in different climatic regions [3-6]. Considering that semi-transparent BIPV has multifunctional capabilities, its design and application will require optimization to ensure that the installed systems achieve maximum outcome. Such optimization will also strive to encourage real-life adoption of semi-transparent BIPV, considering that the current costs of BIPV systems are high. Due to relatively long lifespan (typically 25 years) of BIPV systems, long-term implications should also be taken into account when designing for such systems.

In this study, the integration of a commercially-available double-glazed semi-transparent BIPV module in an office building window was studied through a computer simulation under Singapore's tropical climate. The potential electricity savings, due to electricity generation and daylight transmission, when installed in an office building was estimated and compared with that of conventional double-glazed windows. In adopting a long term view in designing of renewable systems, a life-cycle perspective was used to study its energy and carbon emissions, in terms of GHG emissions intensity (gCO_2eq/kWh), energy payback time (years) and energy return on energy investment.

2. Research methodology

This research was conducted in two stages: building energy study and life cycle environmental performance study. First, a simulation study was conducted to identify the potential energy savings of semi-transparent BIPV windows using Singapore's typical meteorological year weather file. The simulation was performed in *EnergyPlus*, which is a building energy simulation software developed by the United States Department of Energy [7]. *EnergyPlus* has various program modules capable of simulating building cooling/heating loads, daylighting and photovoltaic systems. *EnergyPlus* results have been validated through analytical, comparative and empirical tests to ensure reliability [8,9]. For this study, "*EnergyPlus* v7.0" was used.

The life cycle assessment (LCA) performed in this study evaluated the production, maintenance, use and end-of-life disposal of the double-glazed semi-transparent BIPV module in accordance with the recommendations by the International Energy Agency [10]. Although the generic framework of LCA has long been established under the International Organisation for Standardisation [11,12], it was only recently that a methodology guideline specifically for LCA of photovoltaic systems was introduced. The guidance published by International Energy Agency (IEA) includes photovoltaic-specific parameters used as inputs in LCA, choices and assumptions in the life cycle inventory data analysis and modelling approaches. The specific indicators, as recommended by IEA, used in this study are: greenhouse gas emissions (GHG) and cumulative energy demand (CED). The GHG emissions during the life-cycle stages of the BIPV system were estimated as an equivalent of CO_2 (denoted as $kgCO_2eq$) using an integrated 100-year time horizon using the global warming potential factors published by the Intergovernmental Panel on Climate Change (IPCC) [13]. The CED describes the consumption of fossil, nuclear and renewable energy sources along the life-cycle of a good or a service. The energy sources included in the CED indicator result are: fossil, nuclear, biomass, hydro, primary forest, wind and solar.

The impact indicators were further processed into GHG emissions intensity of BIPV electricity, energy payback time (EPBT) and energy return on energy investment (EROEI). EPBT, measured in years, was calculated relative to the average grid electricity currently used in Singapore. EROEI, expressed as energy generation per unit of energy input, denotes the units of energy for each unit invested in the production process.

2.1 Building energy study

A mid-floor plan of an office building was defined with building geometry, façade properties, climate and main orientations as shown in Table 1. *EnergyPlus* simulations were used to determine annual cooling load, artificial lighting requirements and photovoltaic electricity generation. The characteristics of the double-glazed semi-transparent photovoltaic modules used for the calculation of electricity output, daylight transmission and thermal calculations are shown in Table 2. As Singapore's topical climate results in buildings being dominated by cooling due to high ambient temperatures all year round, heating was not considered in the study. A central cooling system with a 3.37 coefficient of performance (COP) was chosen for the building to comply with local building legislation requirements [14,15]. This COP was used with the cooling loads, as indicated by the simulation, to determine the electricity consumption of the cooling system. The Window-Wall-Ratio (WWR) was varied from 10-100% on all four façade orientations to derive the optimum WWR. The details of this study have already been published elsewhere and readers are referred to that study

for further details [16]. The annual energy simulation results thus obtained were compared to a totally opaque wall (0% WWR) to derive the respective net electrical benefit.

Table 1: Description of office building model for EnergyPlus simulations

Parameters	
Total simulated area	800 m^2
Floor-to-ceiling height	3.0 m
Window aspect ratio (height: length)	1:10
Window-to-wall ratio (WWR)	10 – 100 %
Illuminance setpoint	500 lux
HVAC temperature setpoint	22 °C
Occupancy	0.2 person/m^2
Lighting	10 W/m^2
Equipment	8 W/m2
Infiltration rate	0.1 air changes per hour
Ventilation rate	3.0 m^3/(s.m^2)
Operational hours	0900 – 1800 hrs (weekdays only)

Table 2: Characteristics of double-glazed semi-transparent BIPV module system

Pamameters	
Module area (mm x mm)	989 x 930
Efficiency [%]	5.01
SHGC	0.154
U-value [W/(m^2K)]	1.67
Visible light transmittance [%]	6.91
Photovoltaic technology	a-Si
Construction assembly	Double glazed unit
Appearance	Standard
Country of Manufacture	Germany
BOS efficiency	0.90

2.2 Life cycle environmental performance study

The study's main focus is the life cycle assessment of production, installation, maintenance, use and end-of-life disposal of a double-glazed semi-transparent BIPV system. The photovoltaic system studied with 3.8 kWp (90% WWR) was assumed to be installed in an office building in Singapore. The module's manufacturing phase resource uses were obtained from the *ecoinvent* (v2.1) database [17,18] and was modified to represent the actual scenario. Representative inverter and balance of system components were also selected from the same database. Singapore's grid electricity mix was considered for the study. Electrical generation supplied to Singapore's national grid comes from 75.8% natural gas, 21.6% fuel oil, 0.3% diesel oil and 2.3% waste incineration [19]. With 2.5% transmission losses included, the carbon emissions of Singapore's grid electricity are 601.0 gCO_2eq/kWh [20]. This highlights an added benefit of BIPV, which is avoiding the national electricity grid transmission losses due to on-site electricity generation.

The following assumptions were used to facilitate modelling.

i. As the module used in this study was manufactured in Germany, the electricity use for manufacturing process was replaced with German medium voltage electricity data extracted from *ecoinvent* database;
ii. The lifetime of the module was assumed to be 25 years. This is the warranty provided by the manufacturer and is also in accordance with the IEA recommended life expectancy;
iii. The degradation of the module over time reduces the module electricity conversion efficiency. Therefore a linear degradation reaching 80% of the initial efficiency at the end of the 25 years life time was used;

iv. The inverter life was assumed to be 15 years and therefore one replacement with an identical inverter during the BIPV system life time was included;
v. The remaining Balance of System (BOS) included the façade installation, mounting energy use and electric installation on-site (Singapore). These were modified with Singapore grid electricity data.
vi. Transportation of module from Germany to Singapore using shipping was included, with the shipping distance obtained from an online shipping distance calculator [21];
vii. The solar cell modules were deemed to be non-recyclable due to lack of reliable scientific data and were considered to be disposed as solid waste in Singapore.

3. Results and Discussion

3.1 Building energy study results

A parametric analysis on the WWR was conducted to investigate the effect of the double-glazed semi-transparent BIPV module on the building's energy efficiency, as compared to a totally opaque wall (0% WWR). The net total electricity saving for each individual WWR was calculated by subtracting the cooling demand increase, from both the photovoltaic electricity generation and lighting energy savings.

Figures 1 and 2 illustrate the energy simulation results for the east and west orientations. With both east and west within the direct sun path of Singapore, the photovoltaic electricity generation increases considerably with increasing WWR. This phenomenon is also encountered for the lighting electricity savings as more light is transmitted to reduce the need for artificial lighting. Higher WWR also increases the solar heat gain through the façade which increases the cooling demand required to maintain the zone at the desired temperature. The net total savings, which are almost linear, increase on average at 1.8 kWh/m^2/yr and achieve 18.0 kWh/m^2/yr maximum for both east and west orientations.

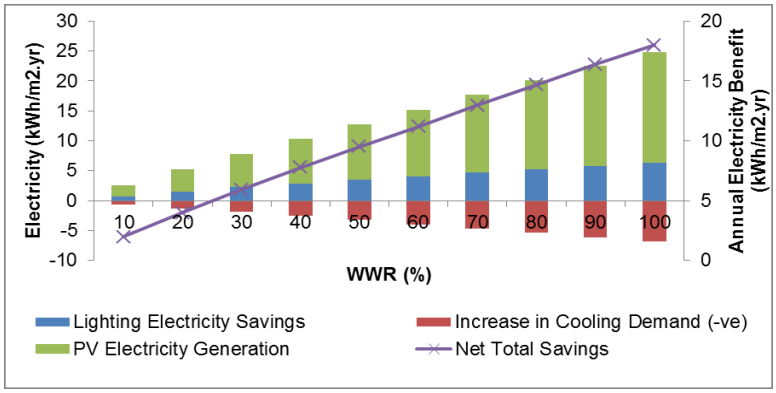

Figure 1: Annual electricity performance and benefit for east orientation

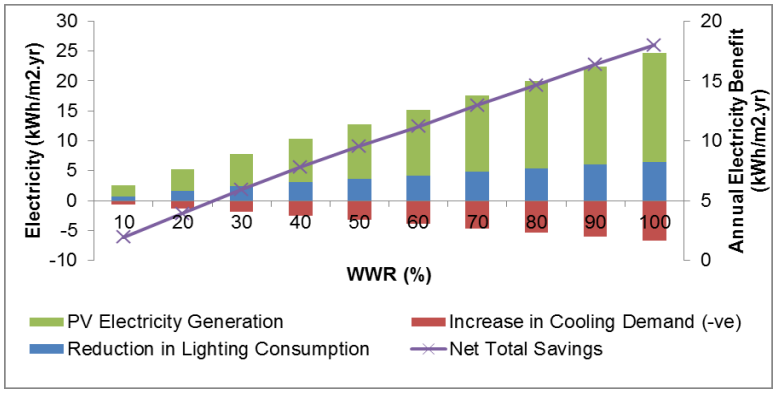

Figure 2: Annual electricity performance and benefit for west orientation

Energy simulation results for north and south orientations are shown in Figure 3 and 4, respectively. The results show a similar linear trend to that of east and west orientations. The net total savings increase at approximately 1.6 kWh/m^2/yr for each 10% increase in WWR, and peak at 100% WWR, with 16.0 and 16.4 kWh/m^2/yr, respectively. These results indicate the potential of installing semi-transparent BIPV modules on facades which are not directly in Singapore's sun path. Photovoltaic electricity generation on these facades is comparable to the east and west orientations as Singapore's highly diffused sky conditions allow north and south orientations also to receive a considerable amount of sunlight. The increase in cooling demand is also lower due to reduced direct solar radiation. Thermal gains due to diffused light, that is deemed 'cooler', are lower.

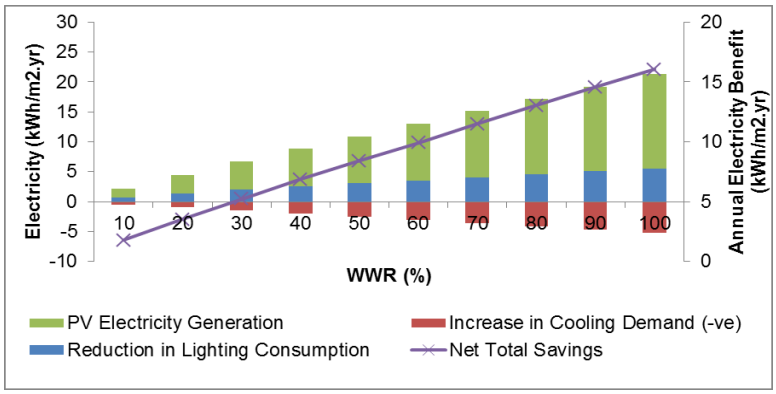

Figure 3: Annual electricity performance and benefit for north orientation

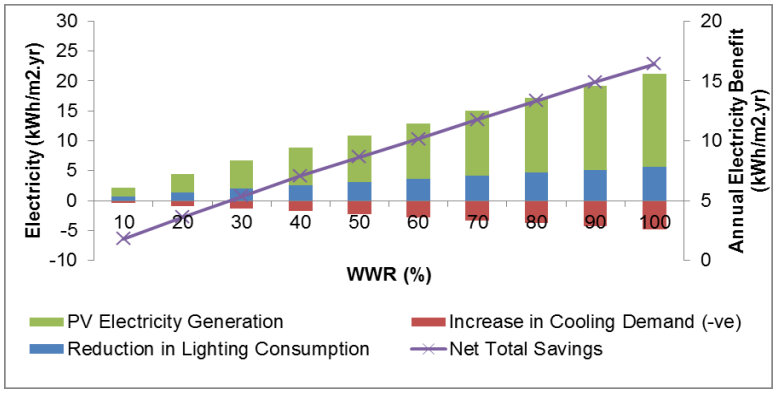

Figure 4: Annual electricity performance and benefit for south orientation

These results indicate that double-glazed semi-transparent BIPV has the potential to be widely adopted on all orientations in Singapore's context. While it would be theoretically ideal to use 100% WWR in buildings, it might not be feasible even in highly-glazed buildings. WWR could be limited in actual installations due to framing, wiring and trunking requirements for BIPV systems. As such, a reduced WWR of 90% was adopted for the subsequent LCA study. The annual electricity benefit for east, west, north and south orientations with 90% WWR are 16.4, 16.3, 14.6 and 14.9 kWh/m^2/yr, respectively.

3.2 Life cycle environmental performance study results

The life cycle emissions and life cycle energy demand of the 3.8 kWp BIPV system components are presented in Table 3. End-of-life disposal of individual components is included in these estimates.

Table 3: Life cycle emissions and energy of 3.8 kWp BIPV system

	GHG emissions ($kgCO_2eq$)	Cumulative Energy Demand (MJ)
Double-glazed BIPV modules	4744	87533
Integrated facade construction	3239	51905
Module installation	2	27
Electrical system installation	219	2850
Inverter (including replacement)	738	13061
Total	8942	155,376

The total life time electricity benefit for the BIPV system if installed on four main orientations, as obtained from the simulation and adjusted to account for module degradation, is shown in Table 4. The BIPV system considered here is capable of generating 65.8–73.6 kWh of electricity over its 25-year lifetime, depending on the orientation of the façade. In addition, the system has a cumulative energy cost of 155GJ in terms of primary energy as shown in Table 3.

Table 4: Total life time electricity generation of BIPV system

	Annual Electricity Benefit			
Year	East	West	North	South

Total (kWh)	73633	73684	65806	67568

*Note: Values may not add up due to rounding

The GHG emission intensity of BIPV generated electricity on the various orientations is presented in Figure 5. East and west orientations' emission intensities are similar at 118 gCO_2eq/kWh each whereas the values are 133 and 129 gCO_2eq/kWh for north and south orientations, respectively. The results are slightly higher compared with previous a-Si PV system studies where GHG emission intensities were reported to be between 18–50 gCO_2eq/kWh [22]. The emissions intensity depends not only on the PV module efficiency but also on the national transmission grid losses of the location. Singapore being a small land area electricity distribution loss is relatively low at 2.5%.

However, the emissions intensity of PV generated electricity is less than a quarter of the current gird electricity (601g/kWh) in Singapore.

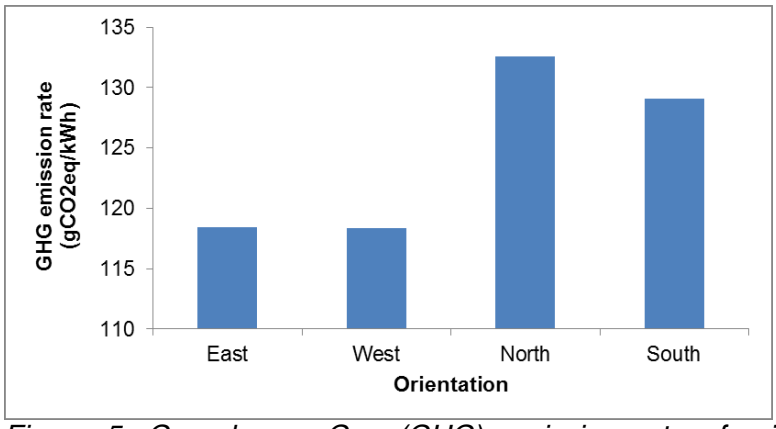

Figure 5: Greenhouse Gas (GHG) emission rates for investigation BIPV system for various orientations

Figure 6 illustrates the results of the energy payback times (EPBTs) of the investigated BIPV system adopting double-glazed semi-transparent modules over 25 years. The simple EPBT indicate a range of approximately 5.8-6.6 years for the payback. And, if avoided transmission grid losses are included (BIPV provides on-site generation), the EPBT values will be even lower at 5.7-6.4 years. East and west orientations achieved EPBT of 5.7 years where as north and south values were slightly higher at 6.4 and 6.3 years respectively. As compared with previous studies where EPBT for a-Si PV systems ranged between 1.8–3.5 years [22], the values obtained for the investigated BIPV system are higher which is due to the non-optimum module tilt and modules not facing the location's sun path directly.

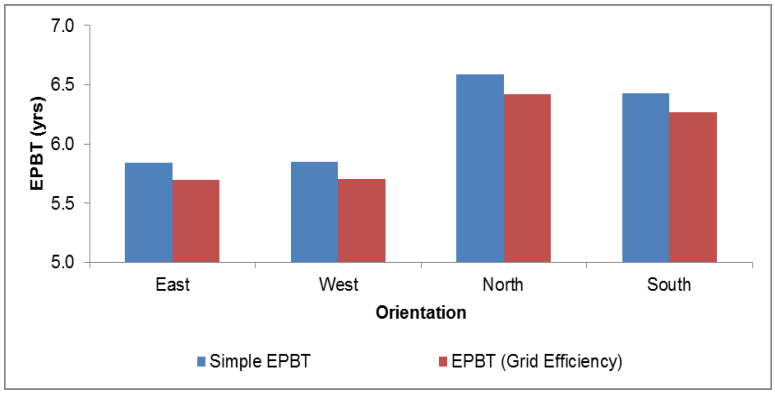

Figure 6: Energy payback times (EPBT) comparison (including and excluding grid efficiency) for BIPV system facing four main orientations

Figure 7 presents the EROEI ratios for the investigated BIPV system's four façade orientations. As expected, east and west achieved the highest EROEI ratios of 4.0. The south façade is next at 3.7 and the north façade obtained the lowest EROEI of 3.6.

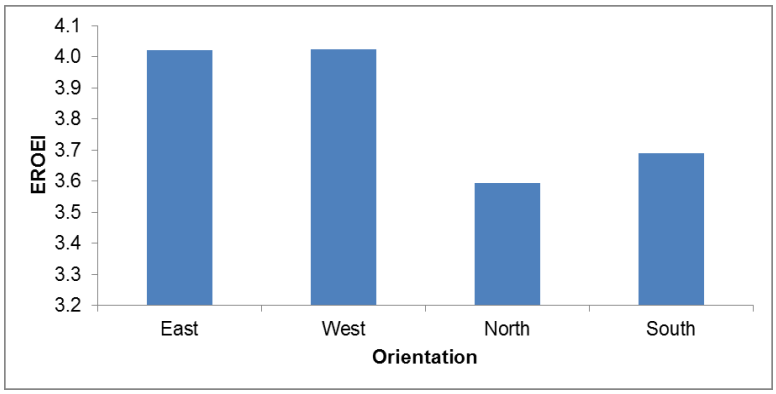

Figure 7: Energy Return on Energy Investment (EROEI) ratios for investigation BIPV system for various orientations

4. Conclusions

This paper considered the long term environmental benefits of applying double-glazed semi-transparent BIPV windows in Singapore at the single-building scale. The results suggest that semi-transparent BIPV windows are feasible on all facades in Singapore, due to the highly diffused nature of the skylight. A streamlined life cycle assessment considering energy and carbon emissions was also performed, for a highly glazed building with 90% WWR. The GHG emission intensity of PV generated electricity is at most a quarter of the emission intensity of current grid electricity in Singapore. The energy invested in the BIPV system is recovered in six years if the current grid transmission losses are considered. The energy return from the BIPV system considered is around four times the energy investment for the system.

The study reveals that there is significant potential for semi-transparent BIPV windows to be applied in Singapore's buildings. The potential areas for practical application go beyond orientations that fall within the direct sun path to those that do not.

5. Acknowledgments

This research was funded by Singapore's National Research Foundation (NRF) through the Clean Energy Program Office (CEPO) under the project: "Multifunctional Photovoltaic facades with integrated innovative Thin-film and selected emerging PV technologies for energy generation & conservation (MPVF)" (NRF2007EWT-CERP001-0640). Short Summary

The Australian construction sector contributes almost a quarter of the nations carbon emissions and the main strategy to address this has been to reduce the operating energy of existing buildings and by regulating energy consumption of new buildings. However there has been less focus on minimising the embodied energy of new construction projects. Engineered timber products have been used in a number of large building projects to replace heavier materials as a structural alternative whilst providing benefits such as aesthetics and the capacity to store carbon. Cross-laminated timber (CLT) has found a market in apartment buildings in Europe with a growing number of projects using the product for both structural floors and walls up to 9 storeys high. Australia's first major CLT building stands 10 storeys high and is currently being marketed as a sustainable city apartment alternative to reinforced concrete. This paper looks at the perception of consumers towards this new construction innovation in an attempt to understand whether Australian residents will accept sustainable timber use in apartment living.

Keywords: Cross-laminated timber; apartments; embodied-energy; sustainable construction.

1. Introduction

Australians are gaining an increasing awareness of environmental issues and sustainable construction due to continued publicised debate and recently implemented carbon tax, rising energy prices and a string of government subsidies provided to homeowners for energy saving technologies [1][2]. Whilst much of the focus in reducing the construction industries' environmental impact has been on operating energy, there is a growing importance to minimise the embodied energy in homes and apartment buildings [3][4]. Building legislation currently controls issues relating to operating energy but it has no restrictions on the energy embodied in a new building's construction materials [5]. Shortage of land for detached dwellings in the city of Sydney (New South Wales) and the high cost of providing infrastructure to a spreading city have lead to the government encouraging high-density apartment living through both state and local government policy changes and land use rezoning [6]. Apartment projects make up the majority of revenue in Australia's new construction market and this is expected to continue in the near future [7]. Apartment buildings in Sydney are predominantly built with a structure of reinforced concrete columns and floor slabs with a variety of materials used for dividing walls and facades [8]. The recent completion of Australia's first and the world's tallest structural timber apartment block has provided a reduced embodied energy option when compared to the typical concrete construction methodology [9]. It has also been marketed for its sustainable attributes whilst providing equivalent or greater facilities, aesthetics and comfort compared to inner city concrete apartments.

This paper examines the opinion of NSW residents towards environmental sustainability, the use of timber as a sustainable material in new residential construction, and their willingness to live or purchase an apartment in a medium-rise timber structural building. This paper also presents the process of data collection and analysis of an online survey. The results of the survey reveal that most of the participants prefer concrete construction in apartments even though they believe there should be an increase in the use of sustainable materials and that timber is a more environmentally sustainable material. Finally, this paper presents strategies for increasing the acceptance of timber both as a sustainable building material and as an alternative structural solution to reinforced concrete apartment construction.

2. Timber apartment construction

2.1 Australian apartment construction

Structural timber apartment construction is limited in Australia due the market dominance of materials such as steel, reinforced concrete and masonry used in these projects. Increasing population densities requiring taller buildings, stricter building codes and standards as well as an established workforce and technologies all support the use of heavy materials in medium and high-rise apartment construction. The majority of apartment projects in NSW are built with reinforced concrete floor plates and columns. The national code of construction does not permit apartments greater than three storeys to be built out of structural timber elements so alternate design solutions are required to achieve compliance [5]. This costly and time consuming process in addition to the strict fire and acoustic performance requirements for apartment buildings has resulted in heavy material utilisation in these types of projects until recently. Timber research and testing has shown that engineered timbers such as CLT have the capacity to perform predictably in fires in addition to providing acoustic performance that satisfies local regulations with the addition of some simple cement screeds to the floor, insulation systems and floor coverings [10][11][12]. The increased speed of construction compared to reinforced concrete has made medium-rise apartments using CLT panels appealing to developers for financial and time saving reasons. Reduced site manpower will also assist building companies to decrease the risk of site injuries and the cost of safety compliance [13]. In addition to time, cost and safety benefits the opportunity to source CLT panels from sustainable plantations and its capacity to store carbon during its life cycle is motivating construction companies in Europe and Australia to implement this innovative construction methodology [14][15][16].

2.2 Cross-laminated timber apartments

A few years after the erection of the eight and nine-storey CLT apartment structures named ‘Bridport house’ and ‘Stadhaus’ in London the construction of ‘Forte’ has recently been completed. Forte is a ten-storey CLT apartment building in the Docklands area of the city of Melbourne, Australia. Despite being slightly taller than the preceding CLT apartment blocks one of its main differences is it’s positioning in the private apartment market where it competes against similar luxury grade concrete apartments rather than in the affordable/public housing market. The adoption for this timber building innovation in the private housing market will depend not only on providing financial benefits to developers but also on the dynamic preferences and choices of prospective investors and occupants [17]. Research in Europe has found that cost premiums associated with sustainable construction provide disincentives to purchasers whereas a recent Australian study revealed that homeowners would pay extra for sustainable materials in new detached dwellings [18]. Housing material research reveal that consumers desire the warm and aesthetic attributes of timber but are still concerned with its perceived structural, safety and longevity issues when comparing timber with heavy materials such as concrete and masonry products [19]. Despite the existing data covering some aspects of consumer perception towards sustainability and the use of timber in residential housing the completion of Australia’s first structural CLT apartment block presents an opportunity to test how the market will view this innovative construction methodology.

3. Research method

The purpose of the research was to obtain data that reflected NSW resident's perception of sustainability in residential building, their understanding of timber as an environmentally beneficial material and their inclination towards occupying and owning medium-rise timber apartments. The data would be analysed and results used to develop strategies to increase the acceptance of timber as an environmentally sustainable alternative for heavy building materials in apartment construction. Online questionnaire surveys were used to allow for rapid distribution, wider coverage and to increase the efficiency of data collation and analysis. The sample group was chosen to provide a mix of residents occupying and/or owning units or detached dwellings and having a background of either construction or non-construction related employment. Construction related participants were contacted through construction companies, industry associations and professional affiliations. Non-construction workers were accessed through friends, family and work colleagues and snowballing technique was used to increase the size of this group. The survey was distributed via a link embedded in an email sent to participants to enable completion of the surveys at their own convenience and to maintain anonymity. The potential participants were then reminded 2 weeks after initial distribution by email, phone and personal contact except in the case of surveys distributed through industry associations and snowballing. Final response rate was estimated at 15% with 310 responses received. The questionnaire included sections on demographics, attitudes to sustainable construction, material preferences for medium-rise units and willingness to pay a premium for these dwellings. The survey commenced in December 2012 and data was collected for approximately 3 months.

4. Observation and analysis

Participants in the questionnaire were occupants and residents of both units and detached dwellings in NSW with the majority coming from suburban areas surrounding the city of Sydney (84%). This figure was made up of those living in inner Sydney (59%) and outer Sydney (41%). Close to half of the participants came from a construction related profession (48%) and the remaining 52% had no construction background. Construction professions/workers included project managers, property professionals, developers, architects, engineers, builders, quantity surveyors and trades in order of greatest representation to least. Females were underrepresented as they made up only 35% of participants whereas there is an equal amount of men and women in NSW between the ages of 18 and 64 [20]. A comparison of the age distribution of the survey participants with the NSW population shows a similar percentage spread and this is presented graphically in Figure 1.

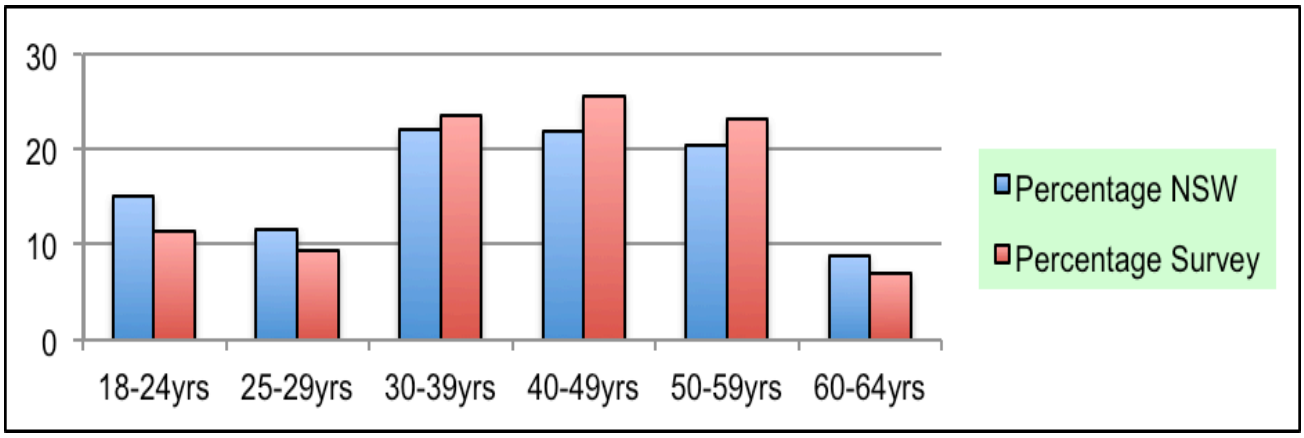

Figure. 1: Age distribution comparison between survey participants and NSW population

4.1 Sustainability and sustainable building materials

Participants were asked whether society should focus more on sustainability and whether there should be an increase the use of sustainable building materials in residential construction. They were also asked if they believed that timber was an environmentally sustainable building material.

There was almost full agreement that society should focus more on sustainability (90%) and that sustainable materials should used to build new residences (94%). Undecided votes for these questions were 7% and 4% respectively with negative responses for each question totalling just 3%. Two thirds (65%) of participants favoured timber as an environmentally sustainable building material with 29% unsure and 6% rejecting the proposition. Age, gender, construction background made little difference to the responses with a maximum variation of 9% above or below the mean.

4.2 Home occupants attitudes towards medium-rise structural timber units

Participants were also asked seven questions specifically about their perception of living and owning a unit in a ten-storey structural timber apartment. These included the reasons for preferring to live in a concrete or timber unit and some of the benefits and concerns they would have about the timber structure. They were also requested to nominate whether they would expect to pay more for a unit in a timber residential apartment block or a typical reinforced concrete apartment block and how much extra they would expect to pay.

4.2.1 Willingness to live or purchase a unit in a timber apartment block

21% of respondents would prefer to live in a 10-storey timber structural unit over one built with reinforced concrete which is just over double the proportion of people willing to purchase a unit in a timber apartment block (10%). 36% of the females surveyed were willing to live in a timber unit but only 12% of the males. This percentage gap increased when it came to purchasing, with 20% of females and just 6% of males willing to buy into medium-rise timber construction. Participants with a construction background were less willing to live in a timber unit block (16%) and even less would like to purchase (7%) whereas 26% of non-construction workers would live in timber units and 14% would buy. Age groupings also provided different rates of willingness to live and buy timber units with both the 25-29yr and 60-64yr age groups varying significantly from other age groups. These results along with those mentioned above are found in Table 1.

Table 1: NSW residents' preference for timber over concrete units.

Demographic group	**Prefer to live in timber medium rise unit to a concrete unit (%)**		**Prefer to purchase a timber medium rise unit to a concrete unit (%)**	
	Timber	Concrete	Timber	Concrete
All responses	21	79	10	90
Male	12	88	6	94
Female	36	64	20	80
Construction	16	84	7	93
Non-construct.	26	74	14	86
Age group				
18-24	19	81	8	92
25-29	5	95	11	89
30-39	25	75	9	91
40-49	23	77	12	88
50-59	25	75	14	86
60-64	16	84	6	94

4.2.2 Willingness to live or purchase a unit in a timber apartment block

As recorded in Table 1 there were only a small percentage of participants willing to purchase a timber apartment (10%). Reasons provided for the choice of buying a unit with a structure composed of timber over concrete included sustainability, aesthetics and acoustics. The reason for participants choosing concrete structure for units is listed in Figure 2 and these have also been

analysed by work background. The top three reasons for all participants to choose concrete units were structural performance, fire resistance and its tested performance. Participants with construction background showed the greatest concern for the fire resistance, tested product, financial and acoustic characteristics. Non-construction workers selected structural capability, maintenance, durability and insect resistance as the most important characteristics.

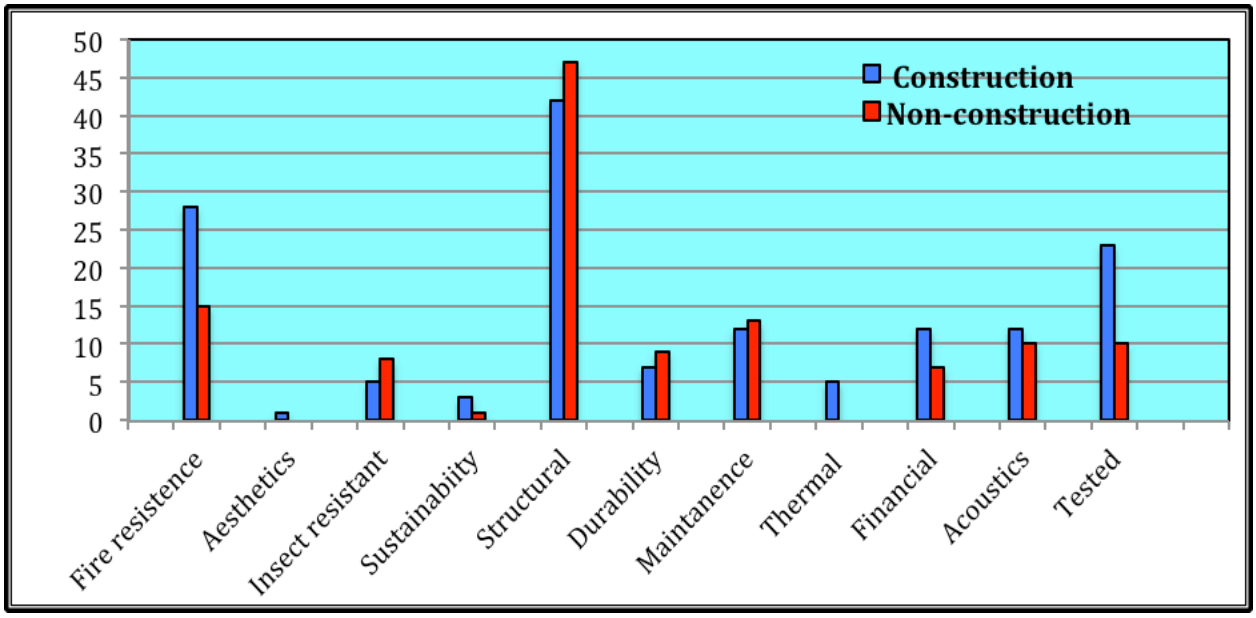

Fig. 2: Reasons to purchase concrete over timber structure in medium-rise apartments (by number)-Comparison by construction or non-construction industry background.

4.2.3 Benefits and concerns of living in a timber apartment

Participant's opinions of some of the benefits and concerns associated with living in a ten storey timber unit block was analysed, with sustainability, aesthetics and less expensive being the most commonly chosen benefits. Following these came indoor air quality, acoustics and structural attributes. Other benefits mentioned included pioneering project, innovation, and thermal comfort. The top three concerns for prospective occupants were fire resistance, insect attack and structural stability, and to a lesser degree water damage, purchase price and acoustics. Participants raised maintenance, deforestation, thermal mass capabilities and high strata levies as other concerns of less importance. These results are presented in Table 2.

Table 2: Main benefits and concerns of potential occupants of a tall timber apartment.

Benefits	**No. Chosen**	**%**	**Concerns**	**No. Chosen**	**%**
Sustainability	163	35	Fire resistance	173	34
Aesthetics	158	34	Insect	118	23
Inexpensive	65	14	Structural	106	21
Indoor air quality	48	10	Water damage	46	9
Acoustics	24	5	Expensive	24	5
Structural	10	2	Acoustics	8	8
TOTAL	**468**	**100**	**TOTAL**	**508**	**100**

In regards to participants expectations of whether timber units should be cost comparable to concrete units there was little difference between the percentage of those who believed that timber should cost more (37%) and those that thought concrete should be more expensive (38%). The remaining 25% considered that the unit cost should be the same regardless of the structural material. These proportions are presented in Figure 3.

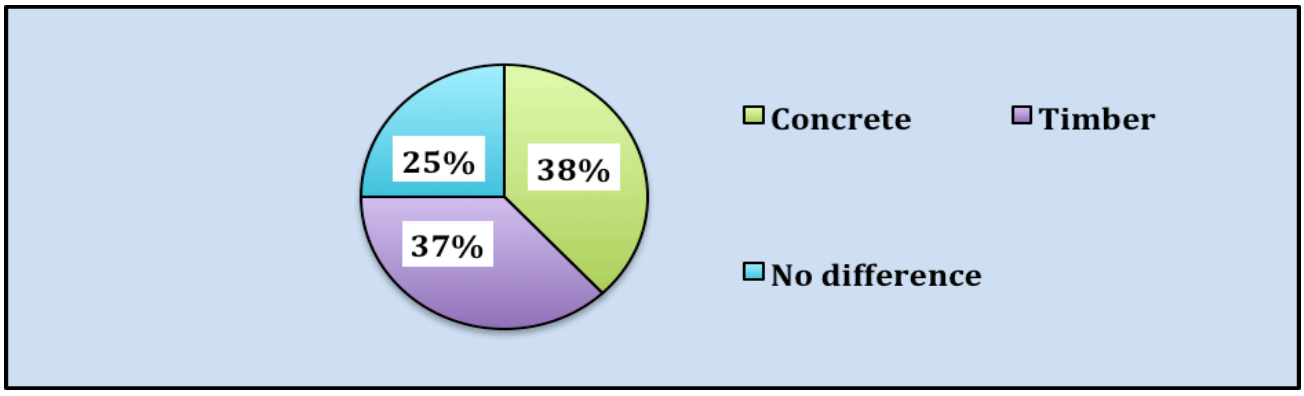

Fig. 3: Would you expect to pay more for a timber or concrete unit

The participants who chose either timber or concrete units to be more expensive to purchase were also asked how much extra they would expect to pay for that type of unit. They were given 7 options: these included $5000, $10,000, $15,000, $20,000, $25,000, $30,000 and a participant-determined premium. Only the first 5 options were selected and the percentages of each selection are shown in Table 3. The median expected additional cost for both the timber unit and concrete unit was similar with figures of $15,600 and $16,000 despite dissimilar distributions around the mean.

Table 3: Additional amount expected to be paid for a concrete or timber unit

Amount above typical unit price	**Concrete %**	**Timber %**
$5000	13	4
$10,000	15	32
$15,000	20	24
$20,000	43	28
$25,000	9	12
$30,000	0	0
Other amount	0	0
TOTAL	**100**	**100**

5. Discussion

A mixed section of NSW home occupants with both construction and non-construction work backgrounds are strongly in favour of increasing societies' action on sustainability in general and specifically increasing the use of sustainable materials for residential building. The majority believe that timber is an environmentally sustainable building material however they demonstrated a reluctance to either live or purchase a unit in a medium-rise structural timber apartment block in favour of the traditional reinforced concrete structure. This represents a separation between their ideals and their intended actions. This could be related to a number of the factors listed below.

- Misperceptions surrounding structural adequacy of timber in taller buildings due to the lack of information distributed about medium-rise timber construction technologies.
- Fear of the combustible nature of timber in tall buildings despite legislative requirements related to the protection and escape of occupants being mandatory in all Australian apartment buildings.
- Familiarity and acceptance by the construction industry and general public of reinforced concrete apartment construction which has been proven to fulfill all building codes and standards and has predictable costs, experienced designers and trades people in the market.

- Projection of common negative perceptions of residential timber performance such as insect and water damage onto larger residential timber construction projects.

In addition to these issues potential occupants, investors and owners need to be assured that they will not pay increased maintenance costs, strata levies and receive an acceptable return on their investment. A number of strategies are suggested below to address the fore mentioned barriers to the acceptance of medium-rise structural timber construction.

1. Increase marketing to educate the demand side of the market about the structural capacity, fire resistance, acoustic and thermal benefits and suitability of timber for use in apartment construction to compliment the recent media campaign that promotes the aesthetic and environmental benefits of timber.
2. Produce a clear and simple report on the effects of carbon tax on the price of timber, concrete, steel and other heavy materials used in the residential building industry.
3. Publicly showcase innovative construction methods that seek to reduce the environmental impact of the construction industry.
4. Include innovative timber building design and construction technologies into university curriculum to educate future construction professionals on sustainable building options.

All these strategies aim to increase the education of both construction professionals and the general public regarding the benefits of timber use in medium-rise apartment construction in order to help dispel persistent misconceptions about negative timber characteristics. They also reveal the need to address the embodied energy issues in construction to compliment the continuing efforts to reduce the operating energy in Australia's building stock as part of the nations carbon reduction strategy. This study will be followed by a set of qualitative interviews that target the supply side of the apartment market with interviews to a broad range of construction professionals.

7. Conclusion

Heavy materials such as steel, concrete and masonry dominate the current market for medium and high-rise apartment construction in Australia. Advances in engineered timber and innovative design has seen CLT used in a growing number of projects in Europe and the first ten-storey timber apartment block in Australia. Although CLT construction has been shown to deliver advantages of speed, safety, cost and carbon reduction when compared to reinforced concrete, the private consumer market for apartments built of timber is yet to be convinced of these benefits. Ongoing education on the benefits of timber to both the general public and construction professionals is required if structural timber apartment construction is to become a long-term environmentally sustainable alternative to current construction methods.

Short Summary

In several research projects of the Department of Structural Design and Timber Engineering (ITI) at the Vienna University of Technology (VUT) the combination of timber products with other conventional building materials and components, e.g. glass, steel and lightweight wood particle concrete was explored with the purpose to optimize structural performance, usability energy-efficient and ecological profile of composite systems [1, 2, 3, 4]. A number of show cases mixing different material elements are presented e.g. timber-glass, timber-steel and timber-lightweight concrete, use for beam, columns, shear walls and floor constructions.

Keywords: Sustainable building, sustainable redevelopment, wood based structural elements, resource efficiency

1. Introduction

The global population is expected to have grown by 30% to around 9 billion by 2050, and people in developing and emerging economies will legitimately aspire to the welfare and consumption levels of developed countries. 70% of the 9 billion people that are predicted to live on Earth in 2050 are expected to live in urban areas [5]. Driven by population growth and urbanization, the building sector has a huge impact on the gross domestic product (GDP), on the job market, on the quality of life, etc. At the same time, the construction industry adds to the shortage of resources, to waste production, and water and air pollution.

Developed countries currently account for the majority of the world's existing building-related energy demand and CO_2 emissions. The construction sector is the largest consumer of raw materials in the EU and construction and demolition activities account for about 33% of waste generated annually [6].

Buildings play an important role when it comes to controlling climatic change through the reduction of CO_2 emissions in the production of building materials; during the construction phase itself; during the use of the buildings; during the recycling and destruction process; and in deposits. Unless the maintenance and exploitation of buildings as well as the construction of new buildings changes fundamentally, the EU objectives to reduce CO_2 emissions and the consumption of non-renewable resources may not be reached [7].

Nowadays, construction techniques in Europe are mainly based on the use of industrially produced materials such as steel, reinforced concrete, bricks, plasterboards, etc. Especially during the past two centuries, they have largely replaced natural materials that had been used for thousands of years, including wood, stone, and clay. In Europe, more than 80% of all buildings consist of reinforced concrete. At the same time, European forests were over-exploited in the past centuries. They have only been protected by forestry laws since the end of the 19th century. These laws target

a sustainable forestry management, and forests have indeed fully recovered thanks to reforestation. As a matter of fact, they could produce 30 to 50% more wooden raw material than is harvested today.

The European countries have to face profound changes in the demand for buildings (e.g. quantity, high living quality, size, functionality, flexibility, expected lifetime and low energy consumption). The technical possibilities have multiplied, new materials and new construction methods appeared and finally a set of completely new requirements concerning environmental aspects and criteria of sustainability has to be translated into the built reality. Wood as a sustainable and an ecological material has an excellent chance to be an alternative construction material in urban areas.

2. Motivation

In the past ten years, an increasing demand for flexibility has been observed when it comes to the use of buildings; for fast construction processes; revitalization and restoration of existing stock; and also for the aesthetic quality of buildings. Many professionals argue that current mineral-based and heavy on-site construction techniques may not fully meet these requirements and search for alternatives that use a higher percentage of lightweight and pre-fabricated materials with better ecological profiles.

Cultivated forests that are exploited on the basis of sustainable forestry can deliver a whole range of products - from cellulose, paper and pellets to wood-based hybrid building elements and high quality visible wood products with a high added value -, thus stimulating local industries, reducing the consumption of fossil-based energies and the emission of greenhouse gases.

The building market has always been the most important mass market for timber products. In the past few years, an increasing number of wood-based buildings have been constructed in Central and Western Europe (e.g., single-family houses, multi-story condominiums, schools, hospitals and office buildings). Timber constructions with more than two stories make up less than 5% of the building market in Austria [8]. The European countries have to face profound changes in the demand for buildings. The building codes are in constant revision, actually nearly all European countries allow at least 4 stories buildings in timber as regular solutions and pilot projects had been built up to 10 stories.

The renewable raw material “wood” is available in a sustainable way; the basic technologies are well known and good examples of wood-based building already exist. However, the potential of using wood in the building sector is still highly underestimated. Wood as a sustainable and an ecological material has an excellent chance to be an alternative construction material in urban areas. So from 1996 to 2009 the world production capacity of glue laminated products increased from 1 Mio. m^3 to nearly 5 Mio. m^3. Austria holds a leading position with regard to the export of sawn wood and timber industry products. More than 50% of the world production comes from Germany and Austria.

The technical possibilities have multiplied, new materials and new construction methods appeared and finally a set of completely new requirements concerning environmental aspects and criteria of sustainability has to be translated into the built reality.

In several research projects of the Department of Structural Design and Timber Engineering (ITI) at the Vienna University of Technology (VUT) the combination of timber products with other conventional building materials and components, e.g. glass, steel and lightweight wood particle concrete was explored with the purpose to optimize structural performance, usability energy-efficient and ecological profile of composite systems [1, 2, 3, 4].

The developments focus on wood as renewable resources, waste and manufactured products of the forest industry. These technologies provide structurally efficient components for low-energy constructions, supporting rapid-assembly modular construction with increased efficiency through the use of prefabricated dry elements, thereby opening opportunities to reduce carbon emissions.

The ecological impact of the most performing structural elements was analyzed in case studies with regard to life-cycle analysis, following the whole fabrication chain of all components, and comparing

the results to conventional ways of construction in order to demonstrate the competiveness of the developed wood-based systems. Consequently, further improvements with regard to life-cycle costs are tracked down. To check on the potential for future market implementation, the ecological impact and the economic feasibility were also analyzed.

A cost optimization is possible by replacing parts of the expensive timber material by mineral-based materials as cement, anhydride, magnesia, clay or dry sand and to combine these mineral layers with the timber parts to structural elements. These should be prefabricated and allow a rapid erection without use of much water.

The research project results benefit at several levels of the European industry. Firstly, it offers utilization for waste products of the wood industry, thereby improving the exploitation of the utilization chain of forest products. Secondly, it provides a marketable component system for building construction that optimally uses timber sections. Thirdly, it contributes to reducing carbon emissions by storing forest waste in construction elements for a long period instead of burning it for warmth or energy. The results are especially beneficial to wood rich countries in Europe with wood production chains as well as a concrete tradition. In a larger context, such products support rapid-assembly construction methods that use prefabricated dry elements to increase construction efficiency.

Several show cases of mixing different material elements will be presented e.g. timber-glass, timber-steel and timber-lightweight concrete, use for beam, columns, shear walls and floor constructions.

3. Wood based structural elements

With the purpose to optimize structural performance, usability energy-efficient and ecological profile of composite systems in several research projects of ITI/VUT the combination of timber products with other conventional building materials and components, e.g. glass, steel and lightweight wood particle concrete was explored [1, 2, 3, 4]. The developments focused on wood as renewable resources, waste and manufactured products of the forest industry. They are briefly described in [1, 2, 3, 4] and clarified by an example.

These technologies provide structurally efficient components for low-energy constructions, supporting rapid-assembly modular construction with increased efficiency through the use of prefabricated dry elements, thereby opening opportunities to reduce carbon emissions.

As a representative example for these developments the application of cement bonded wood composites as structural sandwich panels illustrates the extent of the interrelationships involved in the development of complex system solutions to increase resource efficiency.

3.1 Application cement bonded wood composites as structural element

Mixtures of cement and wood-particles have already been developed around 1900, but they found their application mainly in non-structural building material such as insulating boards; many products are on the market using cement-bond wood wool, wood fibers or prefabricated powder for applications in surface finishing. More recent developments deal with wood-concrete bricks, complete walls for housing and wooden chips as insulation material. Many products have been patented and industrialized [9].

The development of these lightweight wood-concrete systems leads to a new, highly competitive generation of polyvalent multi-material building components (*Fig. 1*). The application of wood-based, cement-bonded products could be considerably increased if applicability in structural elements is given. These propose to develop wood-concrete compounds as a structural material, and to combine it with timber components into structural composite floor and wall elements, additionally providing further benefits for building physics and fire safety.

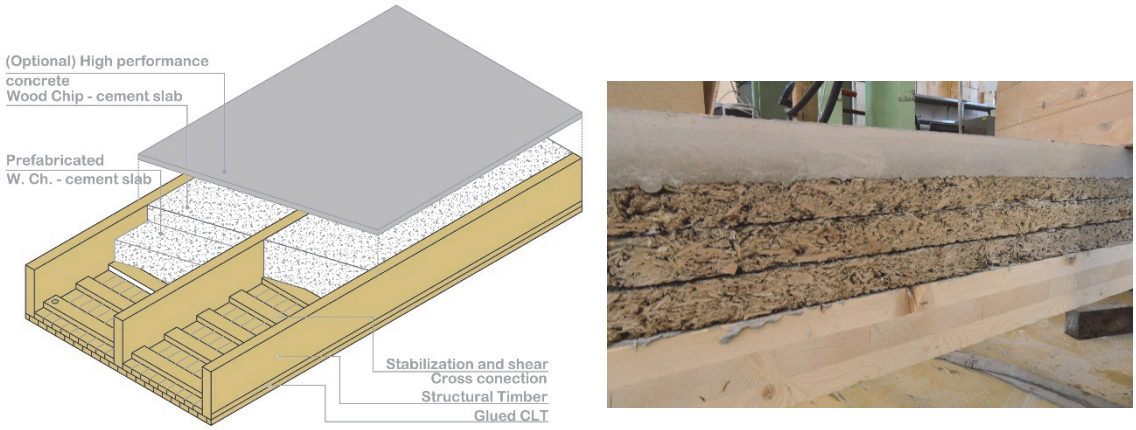

Fig. 1: Lightweight wood-concrete floor element

This technology combines existing concrete tradition with organic renewable resources as an alternative to conventional concrete or masonry, thereby opening opportunities to reduce carbon emissions through the reduction of cement use and increased use of wood for construction since the carbon dioxide stocked in the wood is preserved for several decades instead of burning it.

As a structural model analogy on material level, the wood fibers in different forms, i.e. saw dust, chips, strands, wool etc., in the wood-concrete compound allow for a load-bearing truss embedded in the concrete, being able to transmit compression and also a certain tension (Fig. 2). Different wood-concrete compound compositions can be arranged in the section of a structural element with the result that they provide the necessary structural performance where it is needed: higher compression strength in the compressive (bending) zone where little tensile strength is required; well-balanced tensile and compression strength in the section core to absorb shear forces; higher tensile strength and little compression strength in the tension zone to support the structural timber elements in tension and for absorbing local stress concentrations in shear connections to the timber components.

Fig. 2: Development of lightweight wood-concrete

The use of composite products of timber and lightweight wood-concrete was to be supported and stimulated by comprehensive and scientifically robust background data, which was presented in user-friendly and adapted tools for engineers [1, 2 and 4]. The following stages among others were proposed to achieve relevant results compatible to industrial applications:

- ⇨ Development and optimization of wood light-weight concrete using recycled wood particles and new additives (*Fig. 2*),
- ⇨ Strength tests and evaluation of the physical properties of the lightweight wood-concrete,
- ⇨ Design of structural components made of lightweight concrete connected to timber sections,
- ⇨ Evaluation of the thermal and sound insulation behavior,
- ⇨ Analysis of the experimental results to develop design concepts,
- ⇨ Fire resistance by explorative tests,
- ⇨ Optimization of the manufacturing methods,
- ⇨ Studies regarding the ecological impact.

3.2 Economic feasibility and ecological impact

The first generation of timber based multi-story buildings are characterized by an “abundant” use of massif timber panels (cross-laminated timber - CLT) and a prudent overdesign of additional layers to fulfil or overfill the requirements concerning acoustic and fire behavior [10 and 11]. The structural systems for the floors and the structures for the vertical loads were often not optimized: thick massive floor panels instead of less wood consuming rib or sandwich construction and massive wood panels for all wall elements instead of optimized use of structural columns and the minimum quantity of structural shear walls together with a maximum of light nonstructural separation walls.

Other cost reduction measures could be the use of vertically orientated “balloon” systems (vertical elements more than one story high) instead of horizontal platform systems (one-story high elements, protection needed for the “open” platform).

Further cost optimization is possible by replacing parts of the expensive timber material by mineral-based materials as cement, anhydride, magnesia, clay or dry sand and to combine these mineral layers with the timber parts to structural sandwich elements. These sandwiches should be prefabricated and allow a rapid erection without use of much water. A good example for this kind of composites is the cement bonded wood particleboards (or wood wool boards) which are used and produced since several decades in the European countries [9]. The combination of these cement bonded panels with structural timber panels is a promising strategy to reduce cost, to increase fire resistance and sound protection (mainly impact sound on floors and walls), to increase the thermal storage capacity (24 hours cycle) and to maintain the good recyclability with the possibility to burn the composite after use to profit of the thermal capacity of the wood.

The comparison of today’s market prices for the basic building materials (concrete and sawn timber boards) shows that, in spite of the high energy consumption for production and distribution, the price of 1 m^3 concrete delivered on the site is surprisingly low. On the other hand, sawn timber boards cost 5 times more, representing the real cost (mainly labor for planting and harvesting trees, secondary transformation with a small percentage of non-renewable energy).

In order to recognize the potential for future market implementation and to demonstrate the competiveness of the developed multi-layer systems, the economic feasibility and ecological impact of the most performing structural elements were analyzed in several case studies [12].

Four different variants of floor elements were examined (Fig. 3): variant 1 (components: CLT and three wood chip concrete layers), variant 2 (components: CLT and two wood chip concrete layers), variant 3 (components: CLT, two wood chip concrete layers and reduction of the amount of the screws) and variant 4 (components: wooden planks and two wood chip concrete layers).

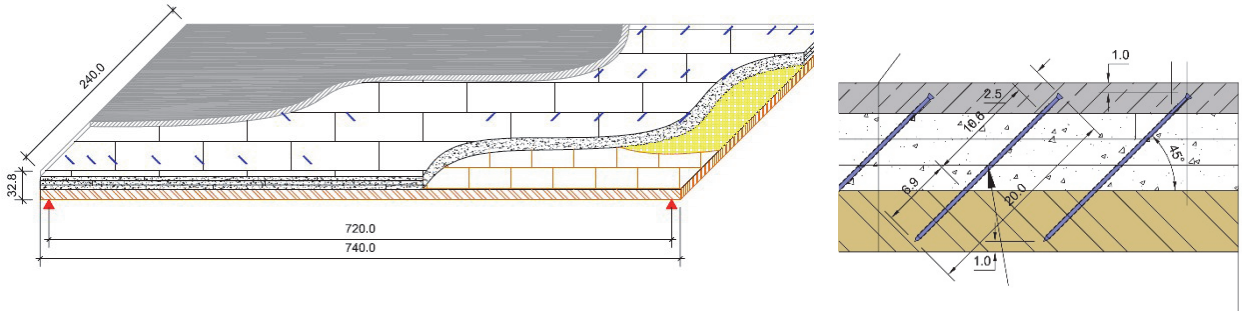

Fig. 3: Different variants of floor elements

The difference between the variants 1 (three wood chip concrete layers) and 2 (two wood chip concrete layers) explains themselves through the reduction of the amount of the glue areas (two instead of three). Variant 4 shows that the reduction of the wood cross-section and the use of simple wooden planks have a large influence on the price (Table 1).

Table 1: Price of different variants

Variant	Wood-concrete layers	Price (€/m²)
1	3	173
2	2	150
3	2	143
4	2	104

From the ecological point of view the lightweight wood-concrete floor elements were examined by two end of life (EOL) scenarios. Two different presumptions were considered. A “standard” scenario expects the commercial way of waste management - demolition of the elements with following burning in a waste incinerating plant and land filling of the ashes. A “best case” scenario expects a prospective way of waste management, more expensive because of the needed equipment. It presumes a profit of the recycling potential, but providing the separability of each main materials of the element during the demolition.

The comparison represents that the lightweight wood-concrete floor elements are an adequate alternative to the massive timber as well as conventional concrete floor elements. On the subject of the ecological index “Acidification Potential (AP, SO_2-eqv.)” the lightweight wood-concrete sandwich floor element variant 4 has particularly better ecological value as the massive timber floor elements (Fig. 4).

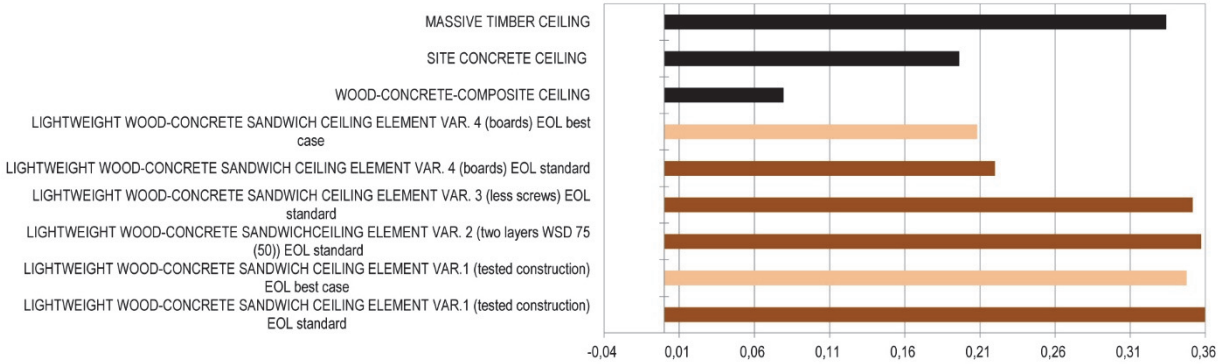

Fig. 4: Ecological index Acidification Potential (AP) of different ceiling element variants

The comparison of the ecological index “Global Warming Potential (GWP 100, CO_2-eqv.)” shows that the lightweight wood-concrete sandwich floor elements variant 3, variant 2 and variant 1 (EOL best case/standard) have a minus value, this means, that they stored more CO_2, than it released during the manufacturing and disposal progress (Fig. 5).

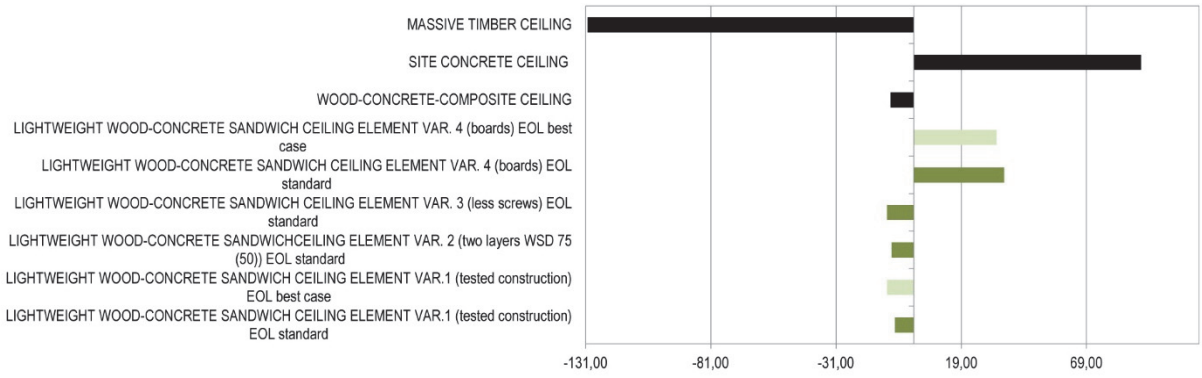

Fig. 5: Ecological index Global Warming Potential (GWP 100) of different ceiling element variants

Concerning the ecological index measure of need for non-renewable energy (PEI ne, MJ) all variants of the lightweight wood-concrete sandwich floor element have a value to 60 MJ for 1m^2, the lightweight wood-concrete sandwich floor element variant 4 (EOL best case) has a value near 0. This means that the amount on non-renewable energy needed for production of this element is nearly the same as the benefit of the end-of-life-processes - Recycling, burning, land filling...- (Fig. 6).

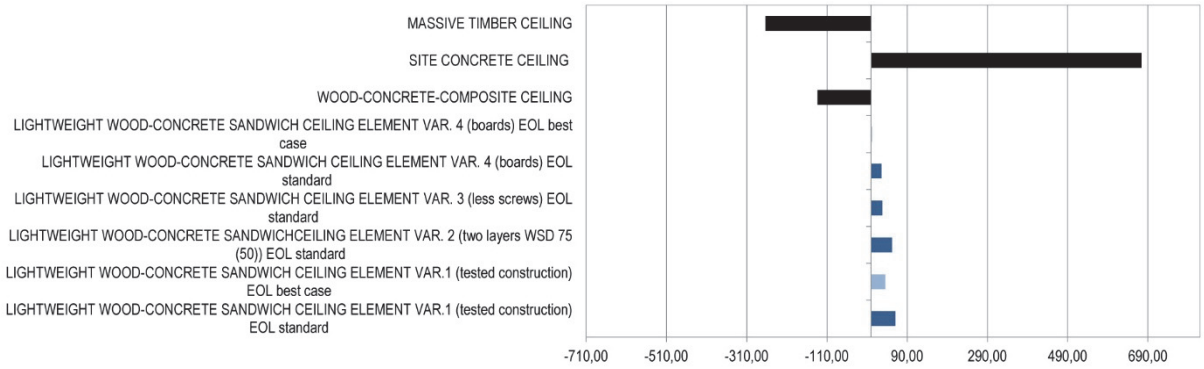

Fig. 6: Ecological index measure of need for non-renewable energy (PEI ne) of different ceiling element variants

Consequently, further improvements were tracked down with regard to life-cycle analysis, following the whole fabrication chain and end-of-life-processes of all components and comparing the results to conventional ways of construction.

4. Conclusions

The research project results benefit at several levels of the European industry. Firstly, it offers utilization for waste products of the wood industry, thereby improving the exploitation of the utilization chain of forest products. Secondly, it provides a marketable component system for building construction. Thirdly, it contributes to reducing carbon emissions by storing forest waste in construction elements for a long period instead of burning it for warmth or energy. In a larger context, such products support rapid-assembly construction methods that use prefabricated dry elements to increase construction efficiency.

To reach a comparable or higher market share in the multi-story sector – necessary to guarantee a constant high demand of timber products able to absorb the production capacity of the reforested forests – timber-based buildings must be economically competitive. The strategies to increase use of timber in multi-story buildings are:

- ⇨ Combination of wood with cheaper, non-combustible mineral materials for cost and fire resistance optimization,
- ⇨ Full use of prefabrication with the goal of reducing erection time,
- ⇨ Increase specific knowledge about timber by professionals, students and builders,
- ⇨ Realize intelligent and attractive pilot projects.

Incontrovertibly, there are also certain pending questions related to the research: manufacturing performance of the multi-layer system and market acceptance of the proposed building technology due to the economic competitiveness. The newly developed system shall be promoted through the initiation of pilot applications. Initiation of pilot projects will provide the possibility to experience the practicality and applicability of the developed composite systems, and create different design and application solutions. Any modification proved to be necessary at architectural and structural design stages may be reached as a result.

Short Summary

Cladding systems performances are considered always more relevant in determining sustainability values of building constructions [1]. Insulating envelopes are the mediating elements between outdoor environment and indoor spaces of a building: they are responsible of heat transfer and regulation of energy flows through the wall [2].
The present work aims to improve the performance of an existing commercial product [3] through the application of smart materials called PCMs (Phase Change Materials). These substances have been applied for many years in building industry because, due to their high heat storage capacity, they help decreasing thermal peaks inside buildings and reducing energy consumption required by cooling systems [4].
Analysis of previous researches on materials insulating properties [5] and on building products requirements [6] has been carried out in order to provide an adequate background and to find a good solution to integrate PCMs into the cladding system.
The new material which has been developed, aimed at improving insulating properties, is a composite panel made of a cellulose fibre matrix (obtained from recycling processes of cardboard) and PCMs as additives in the mixture.
The environmental improvement of the product obtained with the present research consists of the following features:

- the use of widely available waste products such as cardboards as base material [7];
- the development of a new smart material which is able to increase the insulation properties in specific and critical conditions through the use of PCMs;
- the achievement of a product which turns recyclable to obtain a new insulating panel, because the presence of PCMs powder doesn’t contrast the recycling process of paper.

Properties of the new composite material have been tested and compared to those of a commercial insulating panel. Results have shown the possibility to improve in dynamic thermal conditions the insulating properties of building envelopes.

Keywords: PCMs; Thermal Insulation; Cladding System.

1. Introduction

The present work aims to improve the thermal and environmental performances of a building cladding system. [3] Specifically the research focuses on the analysis of the insulation layer and carries on the development of a new composite material suitable to replace the actual products.
The reference product is “PIZ Cladding System” (Fig. 1), a prefabricated envelope for civil and industrial buildings produced by PIZ S.r.l. It is made of double-layered panels installed with dry technique on aluminium anchoring guides. Internal layer is made of 45 mm expanded perlite and has insulating function while external layer is a covering and aesthetical skin made up of a 9 mm fibre-reinforced cement mortar.

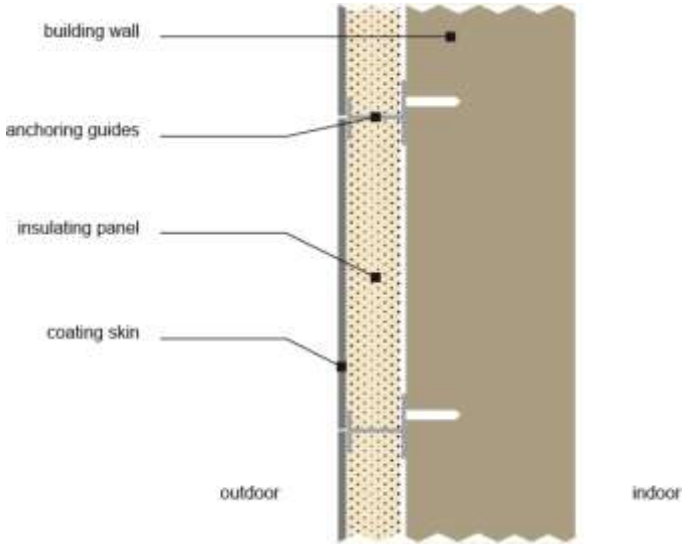

Fig. 1: PIZ Cladding System components

The required properties of a building insulating panel have been selected in order to set adequate tests for the material characterization. Those qualities depends on European normative [6], sustainability requirements [8] and innovations introduced on the market by latest commercial products. The main properties concerns:

- sustainability, which can be improved through the use of waste products as base material for new building components and through the achievement of better insulating and resistance properties;
- static thermal insulation, which can be improved by introducing air particles into the material structures;
- dynamic thermal insulation, which can be improved by increasing walls thickness or achieving high heat storage capacity;
- lightness, which can be improved by introducing air particles into the material structures;
- flexural resistance, which can be improved by high cohesion through the material fibres;
- fire resistance, which can be improved by adding retardant substances;
- water resistance, which can be improved by adding anti-humidity substances.

Experiments on composition and productive process have been done in laboratory scale in order to face each outlined aspects. Afterwards tests have been conducted in order to verify the effectiveness of the processed solutions. Finally comparison between cellulose samples and perlite panels actually employed in “PIZ Cladding Systems” has come to the conclusion that the new composite material developed represents a valid alternative for the sustainable improvement of the product.

2. Materials

2.1 Cardboard scrap

Recycling industry is a crucial resource for international industrial system. In recent years, the market of secondary raw materials has increased, thanks to the improvement of separate collection system.
Regarding the recycling of paper and cardboard, in the last decades the collection of waste products in Italy increased of about 1 millions of tons, while the industrial use of those secondary raw materials increased of just 300.000 tons. [11] This indicates that the current production and collection of waste paper is marked by an oversupply. To develop new products starting form waste materials helps to provide a sustainable answer to this overproduction problem.
Paper recycling is a well consolidated industrial process which gives undeniable economical and environmental advantages. Depending on cellulose fibres properties different kind of products has been produced starting from waste material. In building industry, taking advantage of insulating function of cellulose fibres, paper scraps has been recently employed as thermo-acoustic insulating material. [12]
In the presented work, the thermal insulation quality of cellulose fibre has been investigated and enhanced through the addition of smart materials. The result is the production of a new composite material.

2.2 PCMs

One of the main causes of energy consumption in buildings is the increasing use of indoor heating and cooling systems [13]. Comfort inside architecture spaces can be obtained with well known temperatures and humidity values (about 16-22°C and 40-70% respectively). [14]
The study of insulating system applied on the perimeter walls permits to improve the maintenance of thermohygrometric values needed to carry on indoor activities. For this reason envelope material performances affect the energy consumption and the environmental impact of a building project. In recent years Façade Engineering has acquired an increasingly important role to enrich projects related to new or renovated architectures. [1]
Application of Phase Change Materials (PCMs) in building industry have been studied for many years [4] and has recently proposed on the market in the form of building components by European chemical companies (Basf SE, Rubitherm GmbH). [15] The role of PCMs inside insulating material is to reduce the heat transfer through the perimeter walls. Those substances have high heat storage capacity that can be set at useful temperatures in accordance with their phase transition temperature.
In order to reduce energy consumption in summer, PCMs thermal storage should be activated when temperatures exceeds the comfort zone. For the present work two kinds of Paraffine substances have been selected: Rubitherm PX28HC, with phase transition at 28°C, and Micronal Basf DS600, with phase transition at 26°C. [15]

3. Production process

During this research has been possible to synthesize a new composite material with thermal insulating properties through the mixing of cellulose fibers and PCMs. The first ones give low thermal heat conductivity (suitable for winter periods in static condition), the second ones confer high thermal storage capacity (suitable for summer periods in dynamic condition).
Production process has been reproduced on laboratory scale through the use of a pulper machine which permits to simulate paper recycling. (Fig.2) Cardboards derived from industrial scraps (provided by Ghelfi Ondulati S.p.A.) [16] has been processed with water into the pulper machine (a). A wet pulp has been obtained (b) and chemical substances, in liquid (d) or powder (c) form, has been added into the mixture in order to enhance resistance and insulating properties of cellulose fibers.
The wet pulp chemically modified has been placed into stamps and processed in a heater in order to drain water (e). Settings in time and temperatures vary with material compositions and quantities. As a result a dry solid panel has been obtained (f).

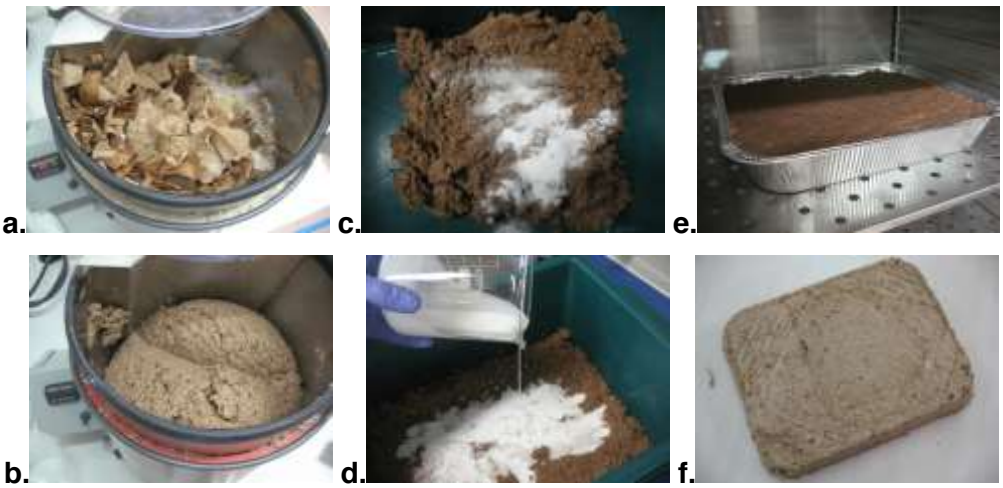

Fig. 2: Composite material production process

4. Properties

4.1 Durability

In order to preserve the sustainability of a product it is necessary to ensure an adequate life time. Resistance properties of materials are related to the durability time of a building components. Following the CPR's requirements [6], specific additives has been selected for their ability to confer water and fire resistance properties to cellulose fibers. The introduction into the cardboard pulp of those substances, which doesn't contrast with the recycling process of the composite material, permits to improve the life cycle of the product.
After laboratory tests the suitable quantities of additives has been chosen. [10] In order to improve fire resistance and confer fungicidal effect, an addiction of 30% of Borate Salts [17] has resulted adequate. In order to improve water resistance, an addiction of 15% of Basoplast Basf [18] has resulted effective.

4.2 Lightness and mechanical resistance

Environmental improvements of a product are achieved also with appropriate physical properties related to its application. Lightness and mechanical resistance are important qualities for building components and a good compromise between those two factors needs to be find in order to produce an effective insulating panel.
Measurements on composite material samples produced for this research demonstrates that the attempts to improve lightness has the effect to reduce flexural strength at the same time. In fact, extremely light samples haven't been considered suitable to be subjected to mechanical test. Anyhow it has been possible to produce cellulose panel with pourous or perforated structures with significant weight loss and good flexural resistance compared to commercial panels.(Fig.3) [9] Weight and flexural strength comparison between the selected materials are listed in Table 1.

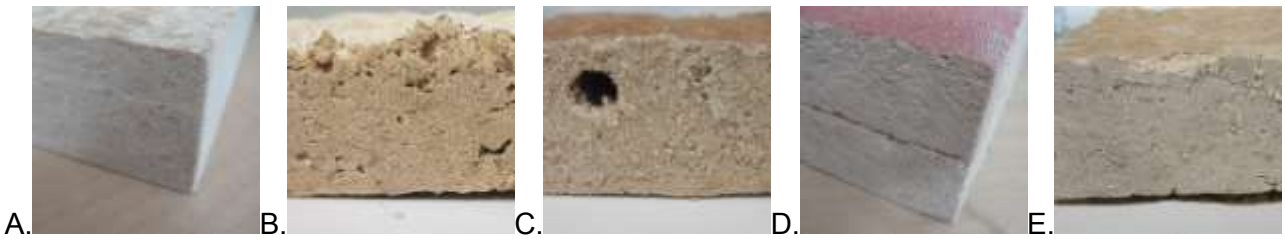

Fig. 3: Materials samples selected for the experimental tests.

Table 1: Physical properties comparison between perlite and cellulose fibre panels

	Material	Density (kg/m^3)	Flexural strength (kPa)
A	Expanded perlite panel with cellulose fibre	145	282.95
B	Pourous panel of cellulose fibre and PCMs	180	170.75
C	Perforated panel of cellulose fibre and PCMs	215	375.80
D	Expanded perlite panel	260	650.50
E	Compact panel of cellulose fibre and PCMs	215	390.25

Those data demonstrate that the new composite material developed with cellulose fibers and PCMs would be an appropriate insulation layer for PIZ cladding systems mechanical requirements.

4.3 Thermal conductivity

The main criterion to certificate the environmental impact of a building is the thermal conductance of its perimeter closures (U value, measured in W/m^2K). This value depends directly to the thermal conductivity of each material that composes stratification into walls (λ, measured in W/mK). [19]
Commercial PIZ Cladding System produced with expanded perlite panels has well known thermal conductance values. Assuming to replace the insulation layer of PIZ Cladding System with the cellulose panels produced with the present research, different thermal conductance properties will be obtained.
Using a heat flux meter test, the λ value of each specimens has been measured and U value of a PIZ Cladding System has been subsequently calculated. Resulted are listed in Table 2.

Table 2: Thermal properties of a PIZ cladding system with different insulating materials

	Insulating material	PIZ U value (W/m^2K)	λ of insulating material (W/mK)
A	Expanded perlite panel with cellulose fibre	1.10	0.050
B	Pourous panel of cellulose fibre and PCMs	1.15	0.052
C	Perforated panel of cellulose fibre and PCMs	1.20	0.055
D	Expanded perlite panel	1.31	0.060
E	Compact panel of cellulose fibre and PCMs	1.38	0.063

Those data demonstrate that the new composite material developed with cellulose fibers and PCMs would be an appropriate insulation layer for PIZ cladding systems thermal requirements.

4.4 Thermal inertia

The most relevant improvement achieved with the new composite material has been conferred by PCMs thermal storage effect. Their power to improve the environmental sustainability during the product working phase has been validated by laboratory tests.
A thermostatic chamber (represented in Fig.3) has been constructed and temperature variation of typical summer days has been reproduced switching a lamp inside it. Samples of insulating material have been placed on the perimeter wall and, using a heat flows probe, the insulating capacity of each panel has been compared.

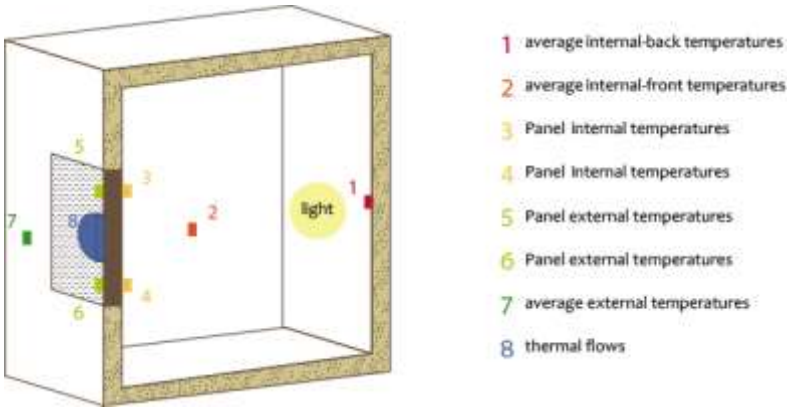

Fig. 3: Thermal flows tests equipments scheme

Thermal test starts when the lamp has been switched on. Temperature inside the chamber starts at 20°C and quickly reaches the value of 35°C in 90 minutes. Once the lamp has been switched off the temperature inside the chamber slowly decreases. Measurements of temperatures [in °C] and thermal flux [in W/m^2] have been represented in Fig. 4. Three material samples with dimensions 200x200x45 mm have been compared:

- Expanded Perlite panel with cellulose fibres;
- Cellulose fibres panel and Micronal Basf PCMs with temperature change at 26°C;
- Cellulose fibres panel and Rubitherm PCMs with temperature change at 28°C.

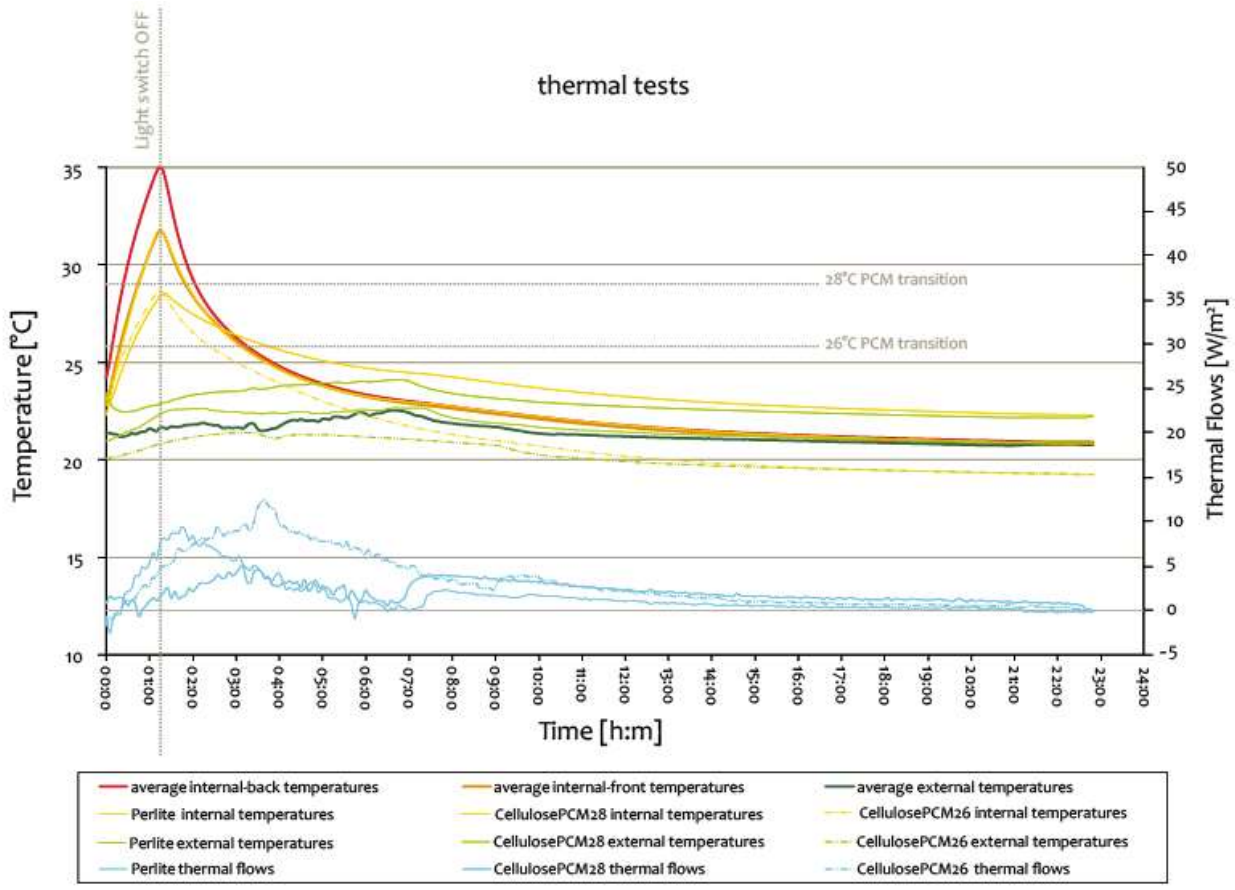

Fig. 4: Thermal flows and temperature measurements

Calculating the area under the thermal flows curves, it is possible to compare the amount of thermal energy which passes through the panel in a definite period time. Area variation during thermal test is represented for each panel in Fig.5 and some significant results are listed in Table 3.

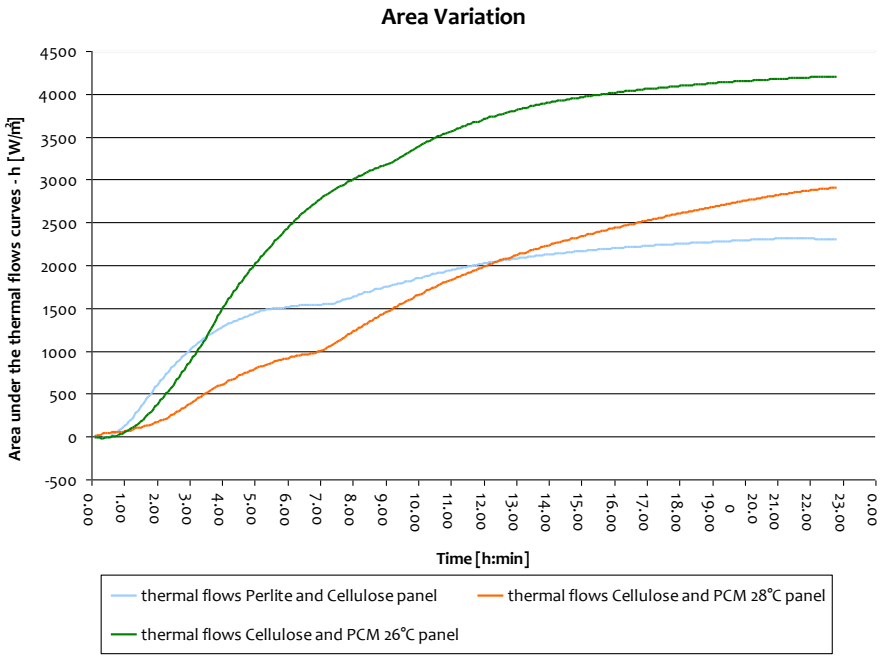

Fig. 5: Area variation under thermal flows curves

Table 3: Area under the thermal flows curves

Insulating material	Area [h(W/m²)] at time *[h:min]*			
	3:30	*6:30*	*12:30*	*18:30*
Perlite	19.26	25.50	34.13	**37.66**
Cellulose PCM 28	**8.33**	**15.87**	**34.10**	43.94
Cellulose PCM 26	18.99	43.53	62.59	68.44

It is possible to notice that Cellulose-PCM panel with phase transition at 28°C has the better performance up to 12:30 hours of thermal test. After that time Perlite panel acquires better results thanks to its better thermal conductivity. Cellulose-PCM panel with phase transition at 26°C gives a good insulation till 3:30 hours of thermal tests when its thermal flows becomes higher than whose of Perlite panel.

5. Conclusion

The method adopted for developing a new building insulating panel in accordance with sustainable requirements has been described. The improvement process starts form the choice of recyclable materials with insulating properties like cellulose fibres, with the aim to find a solution for the cardboard scraps over-collection problem. The enhancement of product lifetime through the maintenance of material resistance properties has been faced with the selection of specific additives which also allow further recycling process. The implementation of insulating properties has been achieved with the addition of PCMs whose operating principles has the effect to reduce the energy consumption of buildings.
All the underlined aspects have been validated by laboratory tests and numerical values. Density, flexural strength, thermal conductivity and conductance of the new composite material developed resulted comparable to those of Perlite actually employed in PIZ Cladding System. While the new product gives better results in dynamic conditions thanks to the thermal storage effect of PCMs which help to reduce the heat transfer when temperature reaches high typical summer values. Those thermal tests suggest that PCMs could be effective for the reduction of cooling systems energy consumption during summer periods.
As stated in the recent European Commission Recommendation of 9 April 2013 (2013/179/UE), measurement and information on the environmental performance of materials, products and

services must comply with the life cycle method. It means that instead of estimating the material impact, it would be more appropriate to estimate the effect that this new material confers to the life cycle of the product in which it is used. As highlighted by recent researches [20], to focus exclusively on the assessment of energy consumption in the use phase involves the shift of environmental impacts to the other phases, with a prevalence on building materials' production. For this reason the application of a building envelope made of secondary raw materials as recycled cardboard should not represent a risk, because it ensure low environmental impact even in the early stages of pre-production and production. These qualitative evaluation on the potential benefits of reducing the impact in the early stages of pre-production, production and use will be verified and quantified with the Life Cyle Assessment.

The environmental footprint of plastic pipe systems within the built environment

Short Summary

The European Plastics Pipes and Fittings Association (TEPPFA) deems it important to have an insight into the integral environmental burdens encountered during the life-span of particular plastic pipe system applications within the built environment. With this framework in mind, TEPPFA has set up a project with the Flemish Institute for Technological Research (VITO). The aim of this project is to carry out several life cycle assessment (LCA) studies from the cradle to the grave. The LCAs of several plastic pipe systems outline the various environmental aspects which accompany the pipe systems, from the primary extraction of raw materials up to and including the end of life (EoL) treatment after their reference service life time. To get a better view on the advantages and disadvantages from an environmental point of view of a pipe system in plastic compared to its main competing non-plastic material, LCA comparisons were made. The conclusions of the comparative LCA studies show that the average environmental impact of plastic pipe systems in general are lower than the average environmental impact of piping systems made out of traditional materials.
This paper reports on the LCA of some specific plastic pipe systems with the final aim of providing a clear environmental product declaration (EPD), thus raise the awareness amongst developers, installers and users, of the potential environmental impacts and benefits over the complete life cycle. In addition some comparisons for the environmental impact category global warming (CO2 footprint) are presented and discussed.

Keywords

Plastic pipe systems, life cycle assessment (LCA), environmental product declaration (EPD), European sector approach, sustainable construction and housing.

1. About TEPPFA

TEPPFA stands for The European Plastic Pipes and Fittings Association. It is a trade association representing the key manufacturers and national associations of plastic pipe systems. TEPPFA is actively involved in the promotion and acceptance of plastic pipe systems for all applications. It has a

voluntary initiative, commitment to develop EPDs for several types of plastic pipe systems. The EPD initiative of TEPPFA aims to measure the environmental impact of plastic pipe systems throughout their entire life cycle and to communicate about the results by means of EPDs.

2. Life Cycle Assessment (LCA) of plastic pipe systems

LCA is a standardized tool that assesses the environmental impact of products, processes and/or systems throughout their entire life cycle. LCA quantifies the potential environmental effects of a product, a process or a system over its entire life cycle, meaning that the extraction of raw materials, the production of materials and the product, the use and the end-of-life treatment are taken into account.

TEPPFA created cradle-to-grave LCAs consistent with ISO 14040 [2], ISO 14044 [3] and the pre and final EN 15804 [4] and EN 15942 [5].norms. The overall objectives of the TEPPFA LCAs are:

- to analyse the environmental impacts of different applications of plastic pipe systems in selected application groups;
- to investigate the relative performance of various plastic pipe systems at the system level in order to show that material choices cannot be made at the product or material level only;
- to use the results of the LCA-studies of the plastic pipe systems for business-to-business communication by means of EPDs;
- to compare the environmental footprint of the plastic pipe systems with the environmental footprint of non-plastic pipe systems.

Within the TEPPFA framework the environmental impact categories as defined in EN 15804 are considered [4].

Table 1: The environmental impact categories considered in the LCAs

Abiotic depletion:	exhaustion of natural resources
Acidification potential:	emissions from manufacturing processes resulting in acid rain
Eutrophication:	over-fertilisation of water and soil
Global warming:	insulating effect of greenhouse gases, such as CO_2 and methane
Ozone layer depletion:	depletion of the ozone layer in the atmosphere caused by emissions of pollutants
Photochemical oxidation:	photochemical reaction of sunlight with primary air pollutants, that leads to chemical smog

3. Environmental Product Declaration (EPD) of plastic pipe systems

The EPDs for plastic piping systems provide LCA-based information from the cradle to the grave. The EPDs are provided in a standard communication format according to the EN 15942 [5]. The EPDs can be downloaded from the TEPPFA website (http://teppfa.eu/sustainability-a-environment/-epd.html). TEPPFA created the EPD framework. The member companies that produce plastic pipes and fittings provided their life cycle inventory (LCI) data to TEPPFA. Then the LCAs are carried out by VITO, critically reviewed by an external and independent expert from Denkstatt and Third Party Reports and EPDs are created and published on the TEPPFA website. The process reflects a European sector approach for EPDs.

4. Overview of the LCAs and EPDs for plastic pipe system applications

- Sewage and drainage applications (non-pressure):
  - PVC-U solid wall sewer pipe system [12]
  - PVC-U multilayer (foamed core) sewer pipe system [13]
  - PVC-U multilayer (core of foam and recyclates) sewer pipe system [14]
  - PP structured (twin) wall sewer pipe system [15]
  - PP solid wall sewer pipe system [20]**
  - PP structured wall multilayer sewer pipe system [20]**
- Water and gas distribution applications (under pressure):
  - PE water pipe system [8]
  - PVC – U water pipe system [9]
  - PVC – O, MRS 31,5 MPa, water pipe system [10]
  - PVC – O, MRS 45 MPa, water pipe system [11]
  - PE gas pipe system [19]**
  - PE water pipe system installed by directional drilling technology **
- Soil and waste applications in the building (non-pressure):
  - PP pipe system [6]
  - PVC-U pipe system [7]
  - PP low noise pipe system [18]**
  - PVC-U low noise pipe system [18]**
- Plumbing, hot & cold applications in the building (pressure):
  - PEX solid wall pipe system [16]
  - Polymer, aluminium, polymer multilayer pipe system [17]
  - PP-R pipe system [21]
  - PB-1 pipe system**
- Rain gutter applications:
  - PVC-U rain gutter system**

5. Some results for plastic pipe systems

5.1. Sewage and drainage applications

The functional unit of the sewer pipe systems that have been studied has been defined as: “the below ground gravity transportation of sewage over a distance of 100 m by a typical public European plastic pipe system and its alternative concrete pipe system from the entrance of a public sewer system to the entrance of the waste water treatment plant, over their complete reference service life of 100 years, calculated per year”.

PVC-U solid wall sewer pipe system
The environmental impacts of the PVC-U solid wall sewer pipe system is mainly caused by the product stage (raw materials) and the construction process stage (excavation of the). When comparing the PVC-U solid wall sewer pipe system with a concrete sewer pipe system fulfilling the same functional unit, we can conclude that for most environmental impact categories the contribution of the concrete pipe system is relatively lower, although the difference is not significant. Only for global warming of the PVC-U solid wall sewer pipe system has a lower contribution (see Figure 1).

PVC-U multilayer (foamed core) sewer pipe system
The technical possibilities of the plastic pipe systems provide excellent tools to fit these systems to many different requirements. A new product in which a reasonable amount of plastic is replaced by air reduces the environmental impacts dramatically in most environmental categories. When considering a multilayer sewer pipe system instead of a solid wall sewer pipe system, the environmental impacts are reduced significantly. At the same time the environmental impacts of a

PVC multilayer foam core pipe system results in a lower contribution in comparison to the environmental impact of a concrete pipe system and this is valid for all environmental impact categories considered. Figure 2 presents the comparison for global warming.

PVC-U multilayer (core of foam and recyclates) sewer pipe system

In this type of PVC-U multilayer pipe system the virgin PVC material in the core of the pipe wall is replaced partly by foamed virgin PVC and recycled PVC. When considering this multilayer sewer pipe system instead of a solid wall sewer pipe system, the environmental impacts are reduced significantly. At the same time the environmental impacts of this multilayer pipe system with a core of foamed PVC and PVC recyclates results in a lower contribution in comparison to the environmental impact of a concrete pipe and this is valid for all environmental impact categories considered. The use of recyclates further reduces the CO2 equivalent. Figure 3 presents the comparison for global warming.

Figure 1: Comparative environmental profiles: PVC-U solid wall versus concrete sewer pipe systems

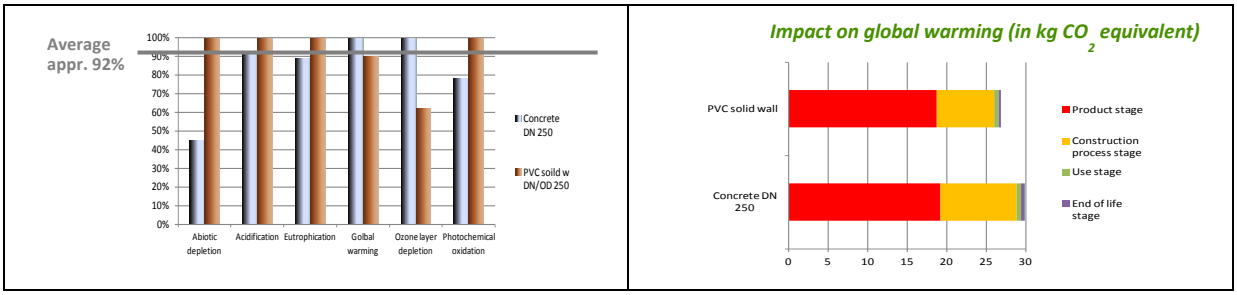

Figure 2: Comparative environmental profiles: PVC-U multilayer (foamed core) versus concrete sewer pipe systems

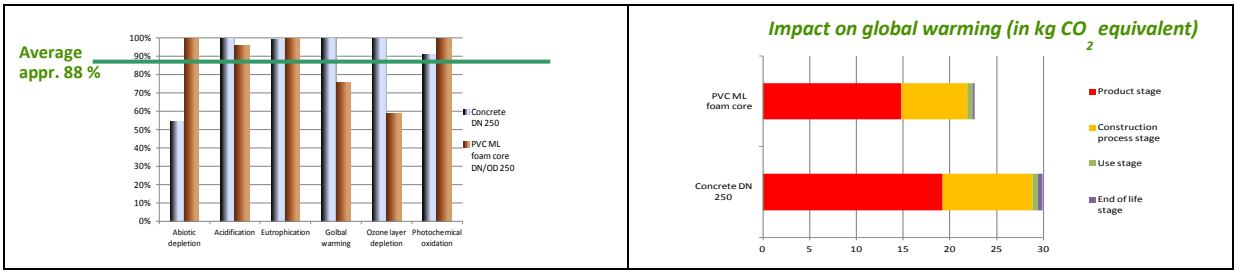

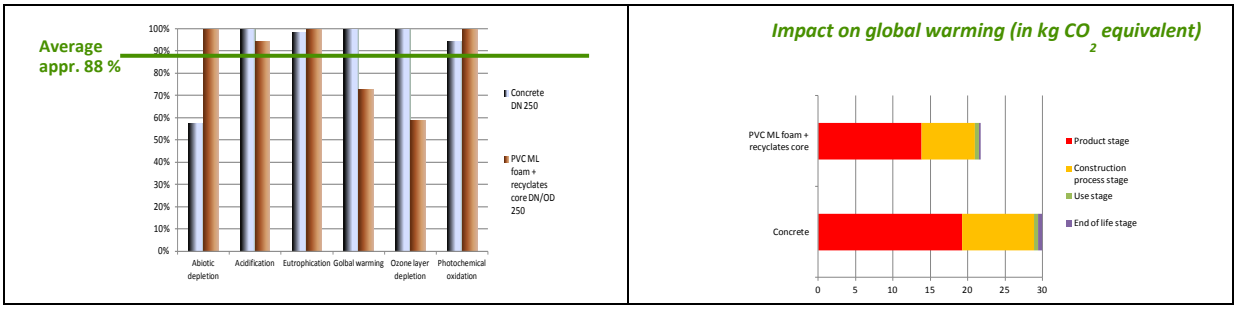

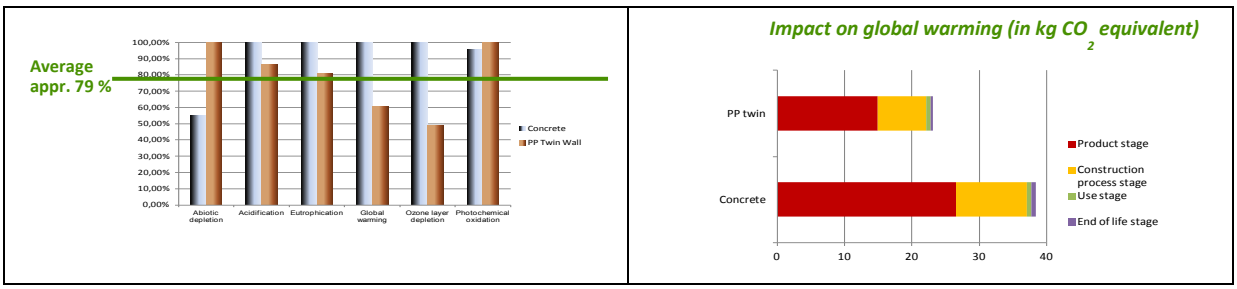

Figure 3: Comparative environmental profiles: PVC-U multilayer (core of foam and recyclates) versus concrete sewer pipe systems

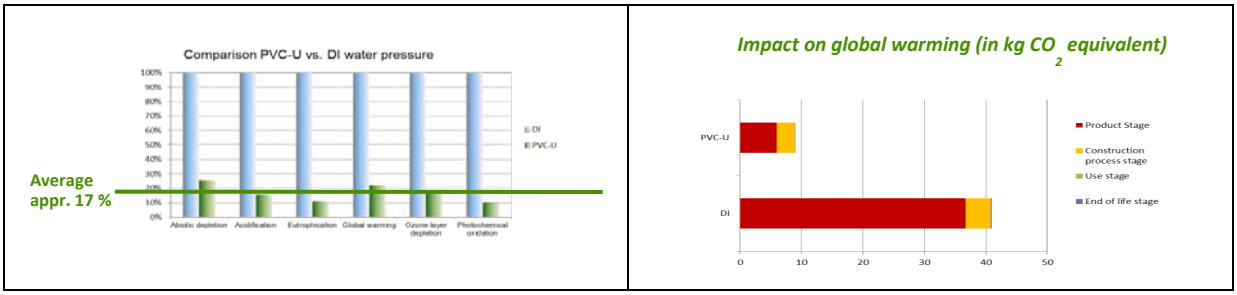
PP structured (twin) wall sewer pipe system

In this LCA study DN/ID 300 PP and DN 300 mm concrete piping systems are compared. When considering a PP sewer pipe system with a structured (twin) wall in comparison to a concrete sewer piping system this results in a relatively lower contribution for all environmental impact categories considered. The excellent environmental behaviour of PP twin wall sewer piping system is again an evidence on the innovative nature of plastics. Figure 4 presents the environmental comparison.

Figure 4: Comparative environmental profiles: PP structured twin wall versus concrete sewer pipe systems



5.2. Water and gas distribution applications

The functional unit of the water and gas distribution pipe systems that have been studied has been defined as: “the below ground transportation of gas/drinking water, over a distance of 100 m (from the exit of the water plant to the water meter of the building), by a typical public European plastic pipe gas/water distribution system and its alternative ductile iron pipe system over their complete reference service life of 100 years, calculated per year.”

PVC-U water pipe system

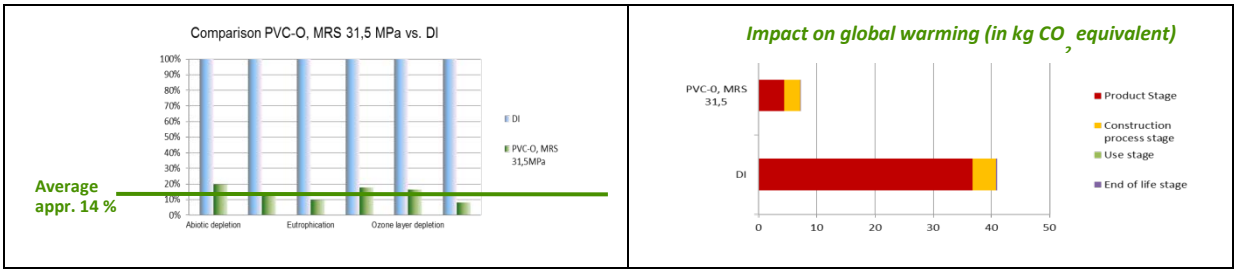
The environmental profiles of the PVC-U water pressure pipe system is mainly caused the raw materials (PVC) during the product stage and by the construction process stage (mainly due to excavation operations at the trench). When considering all environmental impact categories of the LCA, we can conclude that the environmental impact of the PVC-U water distribution pipe system is significantly lower than the ductile iron pipe system that is fulfilling the same function (see Figure 5).

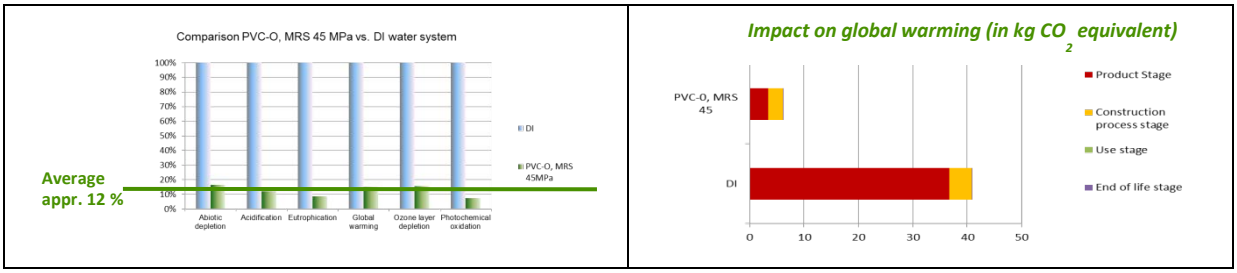
Figure 5: Comparative environmental profiles: PVC-U versus ductile iron water pipe systems

PVC-O water pipe systems (bi-oriented)

Two PVC-O bi-oriented water pipe systems have been assessed: the PVC-O 31,5 MPa pressure and the PVC-O 45 MPa pressure pipe system for water distribution. Both environmental profiles are dominated by the product stage (raw materials production) and by the construction process stage (excavation operations at the trench). When considering all environmental impact categories of the LCA, we can conclude that the environmental impact of both PVC-O water distribution pipe systems is significantly lower than the ductile iron pipe system that is fulfilling the same function (see Figure 6 and Figure 7).

Figure 6: Comparative environmental profiles: PVC-O (31,5 MPa) versus ductile iron water pipe systems





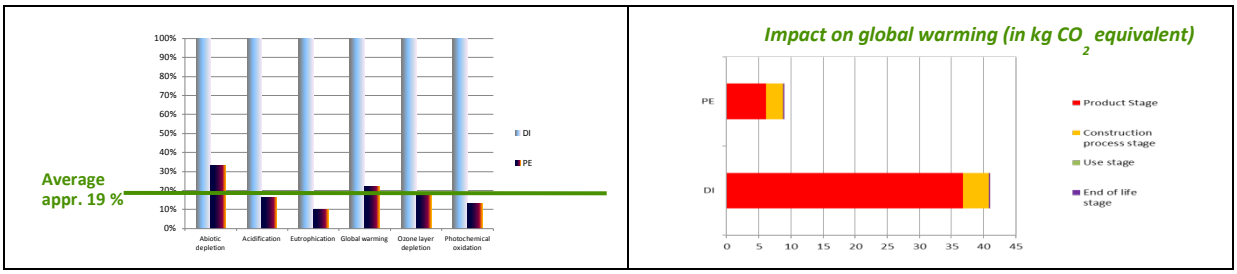


Figure 7: Comparative environmental profiles: PVC-O (45 MPa) versus ductile iron water pipe systems

PE water pipe system

The environmental profiles of the PE water pressure pipe system is mainly caused the raw materials (PE) during the product stage and by the construction process stage (mainly due to excavation operations at the trench). When considering all environmental impact categories of the LCA, we can conclude that the environmental impact of the PE water distribution pipe system is significantly lower than the ductile iron pipe system that is fulfilling the same function (see Figure 8).

Figure 8: Comparative environmental profiles: PE versus ductile iron water pipe systems

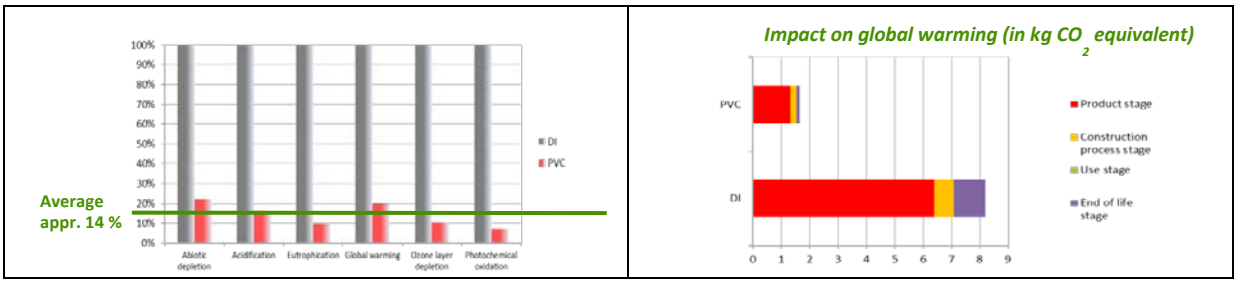
5.3. Soil and waste applications in the building

The functional unit of the soil and waste pipe systems that have been studied has been defined as: “the yearly impact of different soil and waste gravity drainage systems’ installation into a typical European 100 m² apartment, incorporating a bathroom, separate WC, kitchen and washroom, considering the reference service life of the pipe systems to be aligned with the 50 year of reference service life of the apartment”.

Plastic soil and waste pipe system

The environmental profile of the PVC-U and PP soil and waste pipe systems is mainly determined by the product stage and more specifically by the production of the different pipe system components. When considering the environmental impact of a PVC-U and the PP soil and waste pipe systems compared to a ductile iron soil and waste piping system it results in a significantly lower contribution for all the environmental impact categories considered (see Figure 9 and Figure 10).

Figure 9: Comparative environmental profiles: PVC-U versus ductile iron soil and waste pipe systems



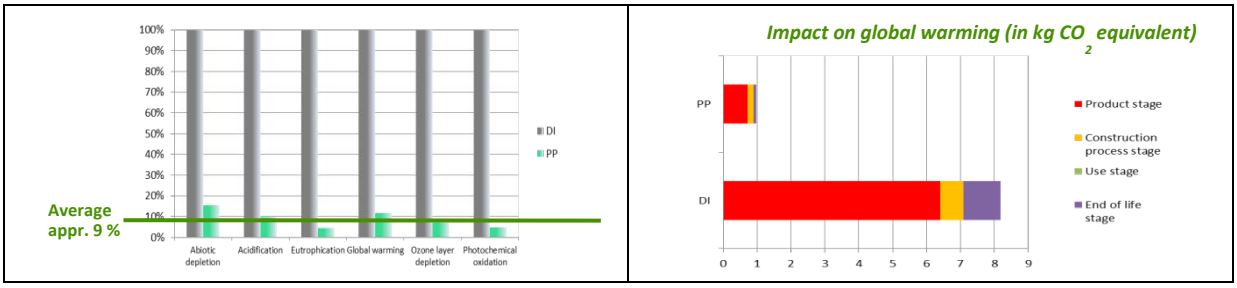


Figure 10: Comparative environmental profiles: PP versus ductile iron soil and waste pipe systems

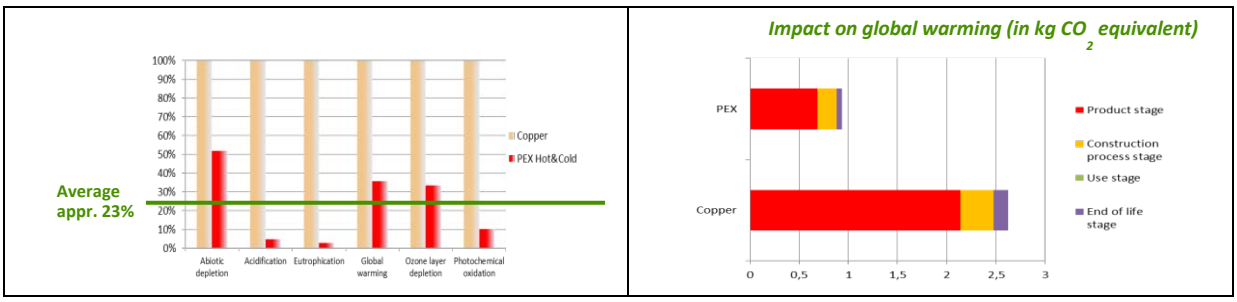
5.4. Plumbing, hot & cold applications in the building

The functional unit of the hot and cold pipe systems that have been studied has been defined as: “the pressure supply and transport of hot and cold drinking water, from the entrance of a well-defined apartment to the tap, by means of a hot and cold drinking water pipe systems’ installation, supplying a 100 m² apartment, incorporating a bathroom, separate WC, kitchen and washroom, considering the reference service life of the pipe systems to be aligned with the 50 year reference service life of the apartment. The environmental profiles are calculated per year.”

Plastic pipe systems for hot and cold

The environmental profile of the PEX solid wall and the polymer – aluminium – polymer multilayer pipe systems for hot and cold water in the building is mainly determined by the product stage and more specifically by the production of the different pipe system components. When considering the environmental impact of the plastic pipe systems for hot and cold water compared to a copper hot and cold pipe system it results in a significantly lower contribution for all the environmental impact categories considered (see Figure 11 and Figure 12).

Figure 11: Comparative environmental profiles: PEX solid wall versus copper hot and cold pipe systems



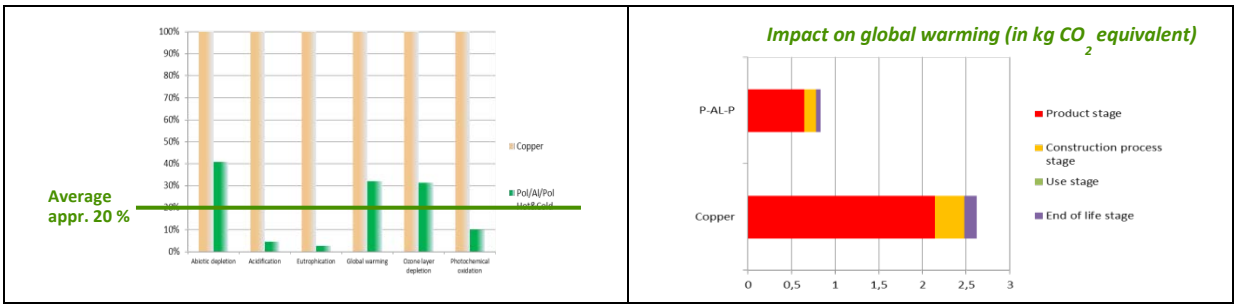


Figure 12: Comparative environmental profiles: Polymer/Al/polymer versus copper hot and cold pipe systems

6. Conclusions

The development of EPDs allows a comprehensive insight in the environmental impact of plastic pipe systems over their entire life cycle.

The results of the LCAs indicate that the impact of plastic pipe systems on the environment is relatively lower compared to the environmental footprint of main non-plastic piping materials.

The contribution of plastic pipe systems to global warming (CO2 footprint) is for all plastic piping systems that have been studied lower in comparison of pipe systems made out of competing materials for the pipes.

TEPPFA is committed to develop new EPDs for other types of plastic pipes and fittings.

TEPPFA members are committed to further reduce the environmental impact of plastic pipe systems.

Short Summary

The project SymBio$_2$ is the research and development of a hybrid façade system that uses the concept of symbiosis of building systems with the controlled and regulated production of microalgae on the building façade. The research explores the behaviour of thin flat panel microalgae photobioreactors in the configuration of a double skin façade where aerolic and fluid exchanges between the building and the photo bioreactors are optimized [4], [5]. The purpose of the research is to demonstrate the economic and technical feasibility of this new approach to producing microalgae. A demonstrator project on an industrial building in Nantes is under development. The project intends to show how this system can be adopted commercially on different building typologies by a large scale demonstrator.

Keywords: Photobioreactor, microalgae, facade, farming, symbiosis

1. Introduction

The building facade is the principle element of communication with the surroundings. It is essential in optimizing the energy performance of buildings both in solar gains, daylight and insulation. The question is whether it can do more whilst still satisfying aesthetical requirements? The future of high performance facades is beyond rendering buildings energy neutral but turning buildings energy positive and productive. Existing systems for transforming energy on building facades include wind turbines, photovoltaic's and solar thermal panels. These take energy and transform it in to other useful forms of energy with differing success.

The principle of using photobioreactors on facades to grow microalgae is very similar to solar thermal panels but instead of only absorbing and converting solar energy it absorbs CO_2 from photosynthesis. The photobioreactors whilst producing microalgae filter waste in symbiosis with the host building. When combined appropriately it can be used to enhance the aesthetics of buildings providing new revenue sources / energy, optimising internal energy performance and processing waste. It is a system that can be adopted for both new and existing buildings.

2. Façade system

2.1 Facades Introduction

The design of a building façade is traditionally the job of the architect and is normally a balance between cost, aesthetics and performance. The choice of façade system varies significantly although environmental regulation has imposed minimum performance criteria in many countries. Initial regulation was very specific about glazing limits and insulation requirements. The regulation is moving towards integrated building performance criteria based on energy performance per m^2. This new approach takes into account the role of the façade as part of the building ecosystems that influences natural ventilation and day lighting.

The role of the façade when designed correctly can help maximize daylight in interiors reducing lighting requirements, reduce cooling and heating loads by minimizing heat losses and gains through the façade whilst at the same time give a building a positive visual identity. In recent years there has been a growing trend in highly glazed building facades to increase transparency. This has posed significant issues for engineers to conform to regulatory requirements on energy performance, thus the advent of the high performance facade which aims to achieve these often contradictory aims. Maximising daylight whilst controlling heat gain is one such contradiction hence the adoption of multi layered facades such as double skin façade systems.

2.2 Microalgae Photobioreactors in a double skin facade

One of the key design criteria of the system we propose for our microalgae photobioreactors is that they are placed in a double façade configuration. There are many benefits of this configuration both on building performance and for the production of microalgae. Aesthetically it also ensures the transparency sought by architects currently. Other than an aesthetic choice, traditional benefits cited of double façade systems over single skin facades include improved thermal comfort, visual comfort and acoustic comfort with the potential of using the cavity to drive natural ventilation as a solar chimney. These benefits help with reducing energy consumption [5], [7]. Negative impacts of these systems are increased costs owing to an additional façade layer and fire regulation problems in certain countries.

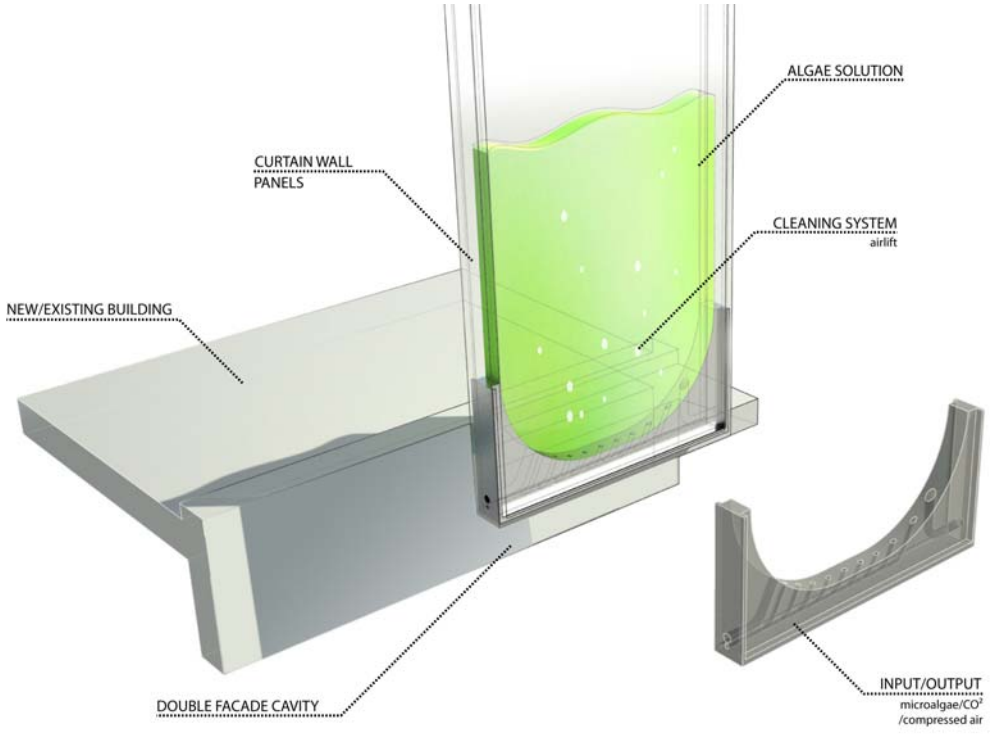

Fig. 1 SymBio$_2$ Photobioreactor configuration

The configuration proposed for our system is to place the photobioreactors in the outer skin layer. This maximizes the solar incidence on the microalgae mixture thus optimising production. The cavity layer is then used as a buffer zone that helps control the temperature of both the microalgae and the office space. The optimal temperature range for the microalgae analysed is between 19°C and 25°C which is very similar to that required by humans. Therefore by controlling the temperature of this zone through temperature exchanges between different areas of the building or evacuation of hot air, the temperature of the microalgae can be controlled [6]. The photobioreactors also act as a natural brise soleil. When the microalgae are in optimum production the photobioreactors are completely opaque preventing any light from passing through the panels. The research has shown that the predominant orientation of the photobioreactors should be south facing otherwise the production levels of the microalgae will not be high enough. The research conducted has shown that a 50/50 split between photobioreactor panels and transparent panels will provide the building with enough natural light for balancing daylight and heat gains. This split might vary according to location. In areas with very high solar incidence the ratio of photobioreactors may increase.

The flat photobioreactors act as a form of double glazing except that instead of an air void there is a liquid layer. This liquid layer varies in opacity according to the stage of photosynthesis of the microalgae. The choice of microalgae also impacts the colour of the liquid layer with both red and blue coloured microalgae available. Depending on the growth cycle of the microalgae it might have two phases turning from green to red.

3. Symbiosis with building

The symbiosis with buildings appears as one promising way to reduce capital and operating cost of photobioreactor technologies. Large scale illuminated areas are available, some costs like glasses can be shared, and the configuration in a double skin façade allows aerolic and fluid exchanges between the building and the photobioreactors to reduce needs in thermal regulation and nutrients supply (especially if CO2 sources are available). Optimisation of the symbiosis is here critical, as the final interest of the concept will be the result of mutual benefits obtained between buildings and microalgae needs. As explained previously the correct choice of microalgae will ensure that the building temperature requirements and that of the microalgae are similar to ensure the greatest synthesis between the two systems.

Depending on the type of building the symbiosis varies between the photobioreactors and the host building. Current research has looked into the possible exchanges between residential, commercial and industrial buildings. The first demonstrator project examined in this first stage of research is a waste incineration plant. The symbiosis identified in this project includes significant amounts of CO_2 as waste but also nitrate and heat exchange. Pluvial grey water collection can also be used in the microalgal solution. Therefore according to each situation of the photobioreactors on a building facade a thorough examination both in terms of thermodynamics and effluents needs to be conducted taking in to account all inputs and outputs. When proposed for new buildings rather than existing buildings the needs of the photobioreactors can be combined with that of the host building from the start bringing additional possibilities for symbiosis.

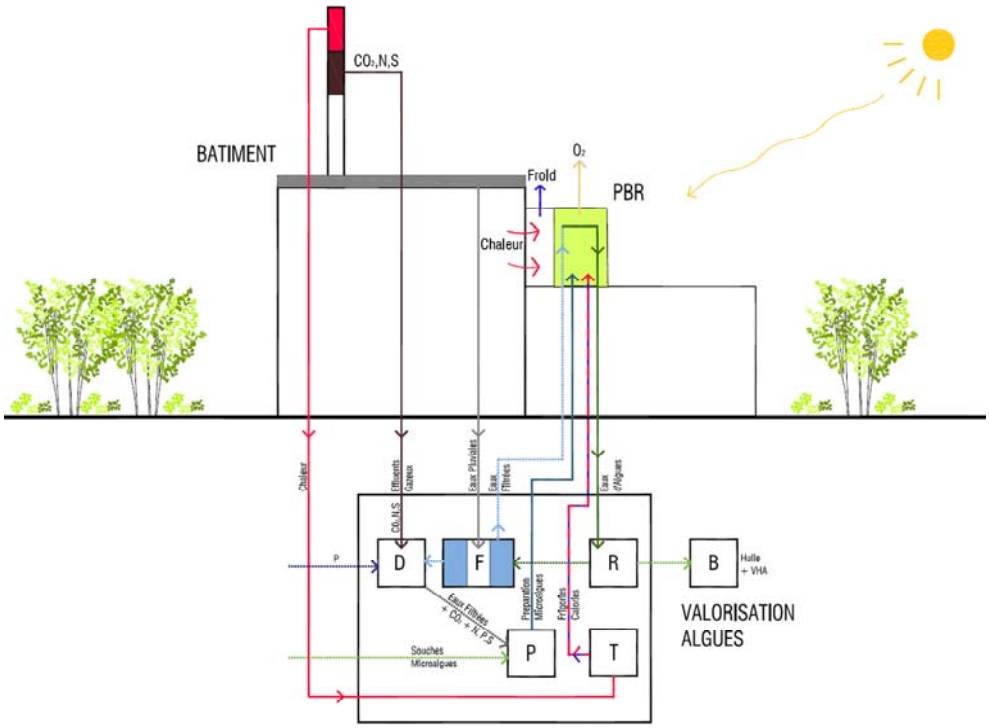

Fig. 2 Symbiosis with industrial plant

4. Flat panel photobioreactors

4.1 Microalgae production

Microalgae growth is based on the photosynthetic assimilation under illumination of inorganic carbon and mineral nutrients dissolved in the medium. The cultivation of photosynthetic microorganisms will thus require:

- A light supply like sunlight,
- An inorganic carbon source (such as dissolved CO2),
- Mineral nutrients (major nutrients such as N, S, P sources and micronutrients as Mg, Ca, Mn, Cu, Fe, etc.),
- Set culture conditions (pH, temperature).

Among all those growing parameters, light has to be considered with special attention, as light is the principal energy source of photosynthesis. Cultivation systems for microalgae are as a consequence characterized by a broad diversity, ranging from open ponds (open systems) to photobioreactor technology (closed systems) [4].The actual microalgae biomass production is mainly based on open systems. Such systems are the cheapest one and they can be easily extended today to a large scale. They suffer however from several limitations which are inherent to their operating principle. Owing to the direct contact with the atmosphere, there is especially a high risk of biological contamination (other microalgae species, bacteria, predators, etc.). Only resistant species can thus be cultivated long-term in such systems. In the opposite, closed geometries reduce risks of external contamination and a better control of culture conditions is obtained. With an optimal design and control, such technology allows reaching the highest productivities which could be achieved with vegetal, including plants and microalgae. In solar condition, the limit will be here

fixed by the solar energy entering the cultivation system and by its use in the culture bulk.

However, closed geometries suffer from several limitations, also inherent to their operating principles. Culture confinement increases the risk of biofilm formation, leads to oxygen accumulation in the culture (toxic effects), and overheating can occur (especially in solar conditions due to the large amount of infrared light collected). Unlike open systems where the only way to prevent external contamination or carbon limitation is to close the systems (working then with photobioreactor technology), the limits of closed geometries can be at least partly overcome by appropriate engineering of photobioreactors (e.g. by adapting mixing conditions to increase heat and gas-liquid mass transfer or to prevent biofilm formation). However, this most often results in increased cost and complexity. As the photobioreactor is the only system that allows maximal productivity to be obtained, great efforts are currently being made to develop new technology devoted to mass scale production. Current mass scale production comes mainly from extensive open systems easier to build and operate, i.e. open ponds or raceway systems. However, it may well be that in the near future a suitable closed technology will be devised that meets the criteria for mass-scale intensified production of photosynthetic microorganisms.

Fig. 3 Examples of raceway technology - open system – on left, and flat panel photobioreactor (closed system) on right (both are here operated in artificial light).

When considering the photobioreactor only, its specific implantation in building façade also introduces technical challenges. The system geometry has to respond to architecture constraints, light capture has to be optimized to guarantee maximal performances, the process has to be robust with ideally a continuous and automated operation during several months. The design of the system reveals here critical, as well as the applied within mixing conditions, or the material used
Regarding all those aspects, recent scientific work has brought new insights into how such systems might be achieved, especially by clarifying the parameters governing photobioreactor productivities and establishing engineering bases to optimize and scale them. Based on those principles and by also introducing constraints of a building integration, a specific photobioreactor has been designed. Thin flat panel photobioreactors were here found to maximize light exposure, while allowing mixing optimisation to avoid progressive biomass fouling on glass surfaces. Thin systems were here retained as photobioreactor depth is a relevant parameter, as it fixes the volumetric productivity which would have also a decisive impact on the global production process [1], [2], [3]. Increasing volumetric productivity will indeed allow high biomass concentration and thus lower harvesting cost, and will also lower the culture volume to be managed and so energy consumption for mixing and thermal regulation. All these aspects will contribute to a positive energy balance at the overall process level.

The fine tuning of all engineering parameters will request a direct evaluation in representative con-

ditions of a building symbiosis. This will be the aim of the demonstrator project which will integrate thin flat panel photobioreactors in a small scale building. Photobioreactors efficiency (biomass production, energy consumption) and robustness (continuous operation during several weeks) will be here assessed in solar outdoor conditions for a microalgae species of economic interest. Results will also be confronted to available models, which have been developed to predict biomass production and energy consumption as a function of meteorological conditions (then feeding the techno-economic model described next). Hydrodynamics conditions will also be optimised to prevent from fouling and to optimise CO2 fixation.

5. Microalgae

5.1 Why microalgae

The aquatic environments still conceal many treasures. At the base of the trophic chains, microalgae implement unique physiological and biochemical strategies to adapt to all environments. They are the biosynthetic progenitors of most of the natural substances of aquatic origin. They produce approximately half of the atmospheric oxygen and use simultaneously the greenhouse gas carbon dioxide to grow photo-autotrophically, i.e. at the expense of light and minerals. Their exceptional biodiversity with species in three out of four kingdoms of eukaryotic live (www.tolweb.org) makes of them a new economical frontier in various fields, namely health and welfare, food, feed and energy. Most of them produce unique products like small bioactive molecules, pigments, antioxidants, fatty acids, polymers, peptides and sterols. Thus, microalgae can offer different valuable compounds or functions which are still unused or underused.

5.2 Microalgae production

Despite fifty years of microalgae prospection, cultivation and the development of many cultivation technologies, the actual level of microalgae derived products remains very limited to few niche markets that can be listed: Astaxanthin from Haematococcus pluvialis, Beta-carotene from Dunaliella sp, Phycocyanin from Spirulina, DHA (Acid Docosahexaenoic - omega 3 fatty acid), EPA from Nannochloropsis sp (The American microalgae producer Aurora is now claiming EPA from Nannochloropsis sp cultivation), Dry Biomass from Spirulina, Chlorella, Aphanizomenon Flos-Aquae (AFA), Odontella, Aquaculture Special food from cultivation of strains such as Nannochloropsis, Phaeodactilum, Skeletonema T-iso, Pavlova, Tetraselmis .Bioactive compounds for cosmetic niches from cultivation of strains such as Porphyridium, Neochloris, Thalassossieraa and many others with production volumes of several hundred kg per year.

5.3 Microalgae costs

The reason for the low volumes is mainly due to the high costs of algae biomass and algae derived products with respect to competitors from natural or chemical origin. Therefore a number of active molecules identified in microalgae have not entered large markets because business models for their commercialization have never proven economic viability. That is the case for instance of Biofuels : C14-C18 saturated/mono-unsaturated. In addition, other active molecules are present in such limited quantities that the cultivation of microalgae for their sole and unique extraction is also uneconomic. Natural carotenoids commonly found in the 1% range in many microalgae, such as lutein or b carotenoid may fetch very high prices reaching thousands of $ per kg. Fucoxanthin and astaxanthin of nutraceutical quality may even fetch prices in the range of $ 7500 – 14000, so that microalgal biomass containing 1% or more of such carotenoids may be worth hundred dollars or more, if the carotenoids can be adequately extracted and marketed. But the corresponding volumes are low, as shown in figure 4.

Product	$/kg Pure	2010 Market Value ($M)	2010 MT (Pure)
Beta-carotene	300	250	833
Lutein	4000	87	22
Astaxanthin *	14000	40	3
Lycopene	4000	66	17
Total		443	874

Table1, : Table illustrating the potential value added by the extraction of carotenoids from microalgal biomass (source BGU – GIAVAP market report)

Similarly, long chain PUFA such as EPA, DHA or Arachidonic Acid sell for several hundred dollars per kg with 3 – 4% biomass content, adding further to the value of algal biomass (source: GIAVAP market report). This value must be gained by a clever processing of a biomass that has been cultivated optimally for this purpose. However applying physiological induction for the hyper accumulation of one component (i.e nitrogen stress, light stress) may have an impact on quantity of the other valuable components.

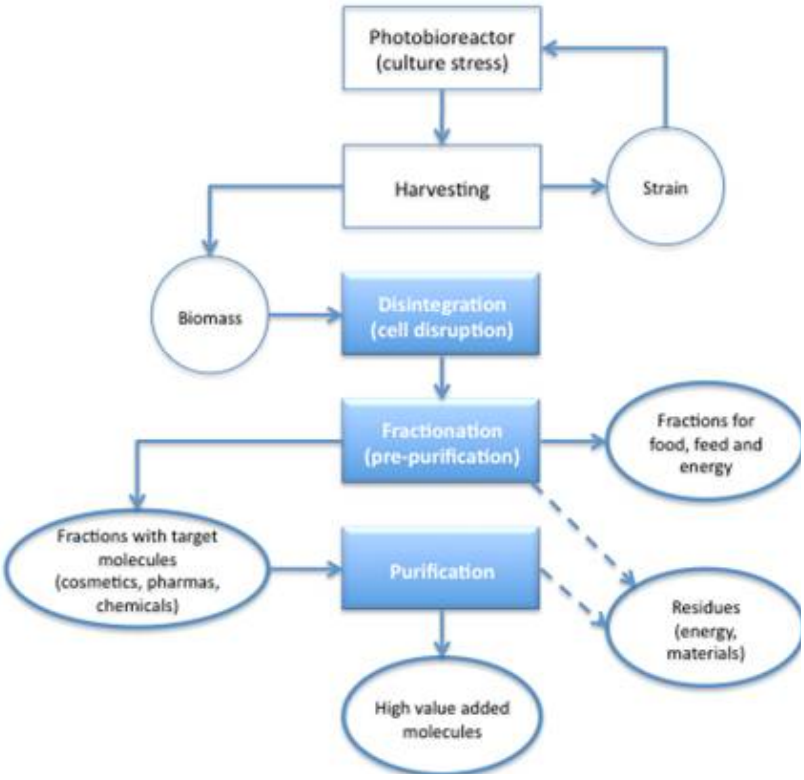

Fig 4 : The overall process of microalgae production and refining

6. Results

The research has shown the feasibility in technical economic terms of growing microalgae in photobioreactor systems. It has identified the optimal configuration of the photobioreactors with estimated production figures for different types of microalgae.

Thermodynamic modelling of the photobioreactors has demonstrated that placing the photobioreactors in a double façade system is the optimum way of growing the microalgae. It has identified the key areas of symbiosis with the building including grey water, CO2 and heat sharing. The production of microalgae in different solar orientations have been modelled to identify which façade orientations are feasible. Predominant south facades are recommended. The research on the photobioreactors themselves have identified the ideal thicknesses for the microalgae culture and functioning requirements to prevent fouling of the system thus the introduction of the airlift system. In order that the system can be justified economically specific microalgae have been identified that already have market potential and have been demonstrated to be cultivable with minimum problems in photobioreactor (closed) systems.

7. Discussion

The future of buildings in the urban environment is more than just being energy neutral but to be energy positive. This objective has taken many forms, as energy harvesting systems such as photovoltaic cells and wind turbines get cheaper and more efficient there has been a large growth in their adoption fuelled by state subsidies. Urban farming and the greening of buildings is seen recently by mayors and planners as one of the most desirable ways of becoming energy positive. Vegetation is seen to symbolise a healthy environment in a city, it helps absorb CO2 and reduce the urban heat island effect.

So what about growing microalgae as a form of urban farming? The benefits are very similar to that of vegetation apart from the aesthetic result. Futuristic tanks on the facades of buildings replace the traditional vegetation. The production of microalgae is one of the most efficient ways of converting solar energy through photosynthesis into biomass. Doubling in quantity every day under the correct conditions, microalgae is seen as the potential answer to the disparition of crude oil if it can be produced cheap enough. Growing microalgae in thin layers is the most efficient way of producing microalgae as it optimises solar exposure. Therefore units similar to that of double glazed systems are optimal. The question is whether architects and clients will adopt the new look and whether it is flexible enough aesthetically to allow them to express themselves sufficiently.

Success will not be just about the design and construction of photobioreactor facades but will rely on the creation of an ecosystem that will support and exploit the microalgae afterwards. Traditional building developers will seek guarantees on the maintenance and exploitation of the photobioreactors during the life of the building.

8. Conclusion

The research has highlighted the key elements of the symbiosis between the photobioreactors and the different typologies of host building. Different scenarios have been modelled in order to optimise the biofacade configuration as well as identify the key economic constraints. The $SymBio_2$ project optimizes the production in the photobioreactor and the harvesting phase by creating a symbiosis between the building and microalgae production. The integration of photobioreactors in a double façade system minimises the impact on net façade costs as well as maximising the symbiosis with the host building. The target is to reduce the cost of microalgae production in order to produce high value molecules at the price of their existing competitor: synthetic molecules from fossil carbon origin or other natural molecules. Doing so the symbiosis between microalgae production and building construction will open new markets for the microalgae industry. The additional environmental benefits of growing microalgae in urban areas is the absorption of CO_2 and the reduction of the urban heat island effect.

Short summary

The lead indicator should be a combined resource score that incorporates both the quantities and residual lives of the abiotic, fossil fuels, biotic and secondary resources used in a product. Water use should be reported as a separate indicator. At present there is no agreed way of reporting land use, but this is something that should, in the future, be an additional indicator. EN 1990 sets minimum design working lives for various types of structure and if a particular component of a structure is not expected to achieve the intended working life, the life cycle analysis should take into account the impacts of replacement. If the term 'environmentally compatible' is taken to mean that the structure does not release or emit significant levels of dangerous substances, this is already covered by BRCW3: *Hygiene, health and the environment.*

Key words: Construction Products Regulation**,** BRCW7, resource indicators, sustainability, fossil fuels, abiotic resources, biotic resources, water.

1. Introduction

The Construction Products Regulation [1] has introduced a new Basic Requirement for Construction Works (BRCW7) on the topic of the sustainable use of natural resources. The key text of the CPR is:
'*The construction works must be designed, built and demolished in such a way that the use of natural resources is sustained and in particular ensure the following:*
(a) Reuse or recyclability of the construction works, their materials and parts after demolition;
(b) Durability of the construction works;
(c) Use of environmentally compatible raw and secondary materials in the construction works.'

At present there is no guidance at the European level on how producers should implement BRCW7 and provide the relevant information. The basic rule is that a producer is only obliged to provide information if there is a notified regulation requiring this information; in all other cases they may use the 'no-performance determined' option. At present there are few, if any, relevant notified regulations but this may change in the future. The expectation is that the requirement for information on BRCW7 will be driven by industry, for example by an architect who wishes to design a sustainable building or an engineer assessing different options for specifying infrastructure materials.

This paper sets out a view as to the information that should be supplied by a product/materials producer when required or asked to provide information with respect to BRCW7. The reasoning for the proposals is set out and it is recognised that the meaning of words can be interpreted in different ways. The methodology described in this paper should, therefore, be treated as a developed starting point for implementing BRCW7 and it may in time be refined to take into account different interpretations of the words given above.

2. Implementation of BRCW7

The problem with lists is that many readers are busy and often this results in skipping the relevant narrative and simply concentrating on the items in the list. With BRCW7 the most important words are in the text before the list and they are '*the use of natural resources is sustained*'. This most important aspect of BRCW7 is to ensure the availability of a resource to future generations and therefore an indicator that includes both quantity and scarcity of a resource is required. Such an indicator has been developed [2] and it is described briefly in Section 4.

2.1 Re-use and recyclability

Most construction products are recyclable at the end of their life (although there are some exceptions such as plastics). Metals have a high intrinsic value and, as a consequence, a high recycling rate but with lower value recyclable products, such as brick, concrete and plasterboard, the achieved recycling rate is controlled by legislation (e.g. banning certain materials from landfill) or by financial means (taxes and incentives). The scope for re-use of a product as opposed to recycling is more limited. Bricks might be re-used in a heritage area to maintain the look of an area. With more utilitarian products, the probability that a building will be found within an economic radius that can re-use elements from a demolished building is low and so the majority of such elements will be recycled rather than re-used. The re-use/recyclability of a structure at the end of its life is more in the hands of the designer/building owner than in the hands of the product suppliers to the original building. Under the declaration of performance, most product producers will be able to claim that their product is fully re-useable or recyclable at the end of its life in the structure, but there are some exceptions, e.g. paint, and some products are only recyclable in a different form. For example, the constituents of concrete are not recyclable in their original form, but only in the form of products, e.g. a precast beam, or as recycled-concrete aggregate. The declaration of performance for a constituent standard is likely to include wording such as 'Products made with (constituent)' are, with rare exceptions, fully recyclable at the end of their intended working life'.

2.2 Durability

EN 1990 [6] defines minimum design working lives for different types of structures. If the declaration of performance or the technical specification indicates that a component of a structure is unlikely to achieve the intended working life, the life-cycle analysis should include the impacts of replacement, including the resources required for such replacement.

2.3 Environmentally compatible

The exact intent of the bullet point '*Use of environmentally compatible raw and secondary materials in the construction works'* is more subjective. Our interpretation of this wording is that there are two points within the one phrase. The first is that the materials used should be environmentally compatible and this is taken to mean that they do not release or emit significant levels of dangerous substances during construction, during the in-use phase or during the end of life phase. This aspect of performance is already covered by BRCW3: *Hygiene, health and the environment*. A series of amendments to product mandates have been or are being issued by the European Commission that requires the producer to provide information on the potential release, emission or content of dangerous substances if the product is to be placed on a market with a notified regulation. The same approach may be used to provide information to satisfy non-notified

regulations and customer requests for information. Consequently this aspect of performance is already adequately covered and further information under BRCW7 is not needed.

The second point relates to the use of secondary materials. Secondary materials may be by-products of industrial processes, e.g. fly ash from burning coal to produce electricity, or recycled materials. The lead indicator described in the Section 4 takes into account the use of secondary materials. The use of recycled materials may, or may not, be the most environmentally compatible solution.

3. Resource Indicators in EN 15804

CEN/TC350 is pushing strongly to have its suite of indicators used as the measure of satisfying BRCW7. The resource indicators for the environmental pillar of sustainability are given in EN 15804 [3] and listed in Table 1. While the abiotic depletion potential (ADP) indicator for non-fossil resources give an obscure measure of sustainability, i.e. relative to antimony, the ADP-fossil fuels treats all fossil fuels as being equally (un)sustainable and simply reports the net calorific value. When information is provided in this format, different specifiers and users cannot make consistent comparisons of the 12 indicators and select the most sustainable materials or products.

Table 1: Resource indicators given in EN 15804

Indicator	**Unit per functional or declared unit**
Abiotic depletion potential (ADP-elements) for non fossil resources	kg Sb equiv
Abiotic depletion potential (ADP-fossil fuels) for fossil resources	MJ, net calorific value
Use of renewable primary energy excluding renewable primary energy resources used as raw materials	MJ, net calorific value
Use of renewable primary energy resources used as raw Materials	MJ, net calorific value
Total use of renewable primary energy resources (primary energy and primary energy resources used as raw materials)	MJ, net calorific value
Use of non-renewable primary energy, excluding non-renewable primary energy resources used as raw materials	MJ, net calorific value
Use of non-renewable primary energy resources used as raw materials	MJ, net calorific value
Total use of non-renewable primary energy resources (primary energy and primary energy resources used as raw materials)	MJ, net calorific value
Use of secondary material	kg
Use of renewable secondary fuels	MJ, net calorific value
Use of non renewable secondary fuels	MJ, net calorific value
Use of net fresh water	m^3

CEN/TC350 has no product specific indicators for the social and economic pillars of sustainability. Without such indicators, it is likely to be concluded that bio-fuel is the answer to energy needs and this is likely to have a devastating effect on the food supply/price in third world countries and the loss of habitat to native people.

As manufacturers of products are likely to be required to provide EN 15804 compliant Environmental Product Declarations (EPDs) in the future, it is assumed that the information on the indicators given in Table 1 will be provided by the product manufacturer and the raw data needed to generate these indicators is available. It is, therefore, proposed that the raw data used to

generate the first 11 resource indicators is also used to provide a Combined Resource Score (CRS). This will provide a rational and transparent way of comparing solutions and demonstrating how well in relative terms they satisfy BRCW7. The procedure for undertaking this calculation is described in Section 4.

The one indicator kept separate in this proposal is the net use of fresh water. This EN 15804 indicator is unsuitable for providing information with respect to BRCW7 as it is the measure of net water use with no factor taking into account the sustainability of the water supply; BRCW7 has to include a measure of the sustainability of the water use.

In our previous paper [2], water-use was combined with the other resources, but subsequent discussions show that the majority of those who expressed a view prefer to keep it as a separate indicator. There is some logic in this approach as the way the characterisation factors are determined is different to those for the other resources. In the longer term it will be necessary to combine all the indicators for the three pillars of sustainability into a single score. Our aim is to have the water-use score set at such a level that it can simply be added to the CRS.

A way of including the sustainability of the water use is given in Table 2. The net water use is multiplied by a characterisation factor based on the availability of water and the impact on other users to give a water-use impact score. The factors given in Table 2 are tentative and they may be refined as a result of further analysis of the impact of such factors and in the process of reaching a consensus on the values.

Table 2: Characterisation factors applied to water

Region	**Characterisation Factor per cubic metre**
Water is always plentiful	5
Irrigation water having no consequences on water availability or quality to downstream users	14.6
Periods of restriction on non-essential water use, e.g. watering domestic gardens, washing cars	20
Irrigation water creating shortages or water quality issues to downstream users	60
Months of water shortages to industry or agriculture every year	130
Water availability is always a critical issue	250

An EN 15804 compliant EPD also contains no measure of bio-diversity or land-use. The authors believe bio-diversity is not a measure of resource sustainability and therefore it should not be included under this element of an EPD, but it must be included in an EPD as soon as there is an agreed measure. Land is a resource and a resource that is not infinite. At present there is no agreed measure of land-use, but when a suitable indicator is agreed, this should be part of the package that is used to measure performance with respect to BRCW7.

4. Lead Indicator: Combined Resource Score

The University of Dundee has developed a methodology for combining 11 of these indicators into a single ‘Combined Resource Score’. In the published paper [4] the term ‘Current Scarcity Score’ was used, but the word ‘scarcity’ was not liked by industry and in the context of use with EN 15804 the term ‘Combined Resource Score’ seems more appropriate.

Industry will be expected to produce EN 15804 compliant EPDs in the future and so pragmatism dictated that this reality is accepted and that we should modify our approach, i.e. not require the reporting of the quantities and residual lives of the resources used, and accept that this information will be provided indirectly via the EN 15804 indicators. It is our view that the input information used to calculate the EN 15804 indicators should also be used to determine a Combined Resource

Score, which is a transparent and rational way of combining 11 of the resource indicators. This Combined Resource Score could be used as the key measure for reporting information with respect to BRCW7.

4.1 Residual life

The Combined Resource Score (CRS) is based on the concept of residual life (as is the abiotic depletion potential). There are several measures of residual life, Table 3, and the 'Mineral resource' used in the determination of the residual life should be regarded as providing the current best estimate of the availability of primary resources to future generations.

Table 3: Measures of a mineral resource's availability

Mineral reserve	Part of the resource that has been fully geologically evaluated and is commercially and legally mineable
Reserve base	Mineral reserve plus those parts of the resources that have a reasonable potential for becoming economically available within planning horizons beyond those that assume proven technology and current economics
Mineral resource	All identified resources that have a natural concentration of the mineral or a body of rock that is, or may become, of potential economic interest as a basis for the extraction of a mineral commodity
Hypothetical resource	Unidentified resources which are similar to known mineral bodies and may be reasonably expected to exist in the same producing district or region under analogous geological conditions
Speculative resource	Unidentified resources that may occur either in known types of deposits in favourable geological settings where mineral discoveries have not been made, or in types of deposits as yet unrecognised for their economic potential

The global use of a resource is the sum of the extracted resource plus the resource obtained from recycling less the resource placed in strategic stockpiles. For primary resources it is the rate of extraction that matters, as this is the measure of depletion of reserves. While the reserves of key resources have increased over the last 50 years [5], so has the rate of use.

Predicting future rate of use is fraught with difficulties:

- Will it be a function of the increasing population?
- Will we become more resource efficient?
- Will there be alternative materials?
- Will innovation create new demands or replace existing demands?
- Will economics force changes?

Consequently residual life should not be regarded as a 'tablet of stone' but the best current estimate and it is accepted that these values must be periodically reviewed and updated. A review of the residual lives should be undertaken every few decades or when there is a significant change in reserves or rate of use.

The current estimates of reserves and rates of extraction have been used for the determination of the residual lives in this methodology. The reality is resource availability will, in the view of the authors, be a significant issue (and could even be a cause for conflict) in the future and Europe should start now to use less of the resources that are predicted to become scarce over the next centuries.

Reporting the quantity of resources with relatively short residual lives is important in focussing the mind on the need to preserve resources, and unfortunately the abiotic depletion potential does not provide such a focus. The quantities of resources include wastage, as is normal in life-cycle analysis.

4.2 Combining quantities with different residual lives

If the sustainability of different solutions is to be compared, it is essential to be able turn these quantities of resources into a single CRS. The CRS is a single numerical value that reflects the impact of resource use on future availability. It is the sum of the quantities of resources used times their characterisation factor per unit volume of resource. The CRS may be calculated for a unit of product, a functional unit, or the structure over part or all of the life-cycle; however, it is only sensible to compare structures over the life-cycle, as comparisons at other stages may give misleading conclusions. Product information on BRCW7 provides the building blocks for making such as assessment. As is normal with environmental indicators, a low CRS is better for the environment/society than a high CRS.

The details of the method of calculation are given in reference [2].

As is normal in life-cycle analysis, the resources used to provide the facilities employed to manufacture energy or products (the capital goods) are not taken into account on the assumption that these will be a secondary effect.

A number of potential characterisation models were assessed [4]. It is appropriate that the characterisation factor per unit volume of resource should be proportionally greater for resources with the shorter residual lives, as these should be the priority for reducing their use. Given the uncertainties with predicting very long residual lives, particularly with respect to patterns of use, the ideal characterisation model should have modest changes in values at residual lives over, say, 2000 years. If for construction it is accepted that the most concern should be for those resources with residual lives less than, say, 750 years, and that the residual life of all resources used in construction is likely to be proven in time as being at least 100 years, a wide range of characterisation factors per unit volume of resource between these residual lives is appropriate. These characterisation factors are the CRSs per unit volume of resource.

For these reasons, the hyperbolic curve (Figure 1) has the best properties of a number of models that were assessed.

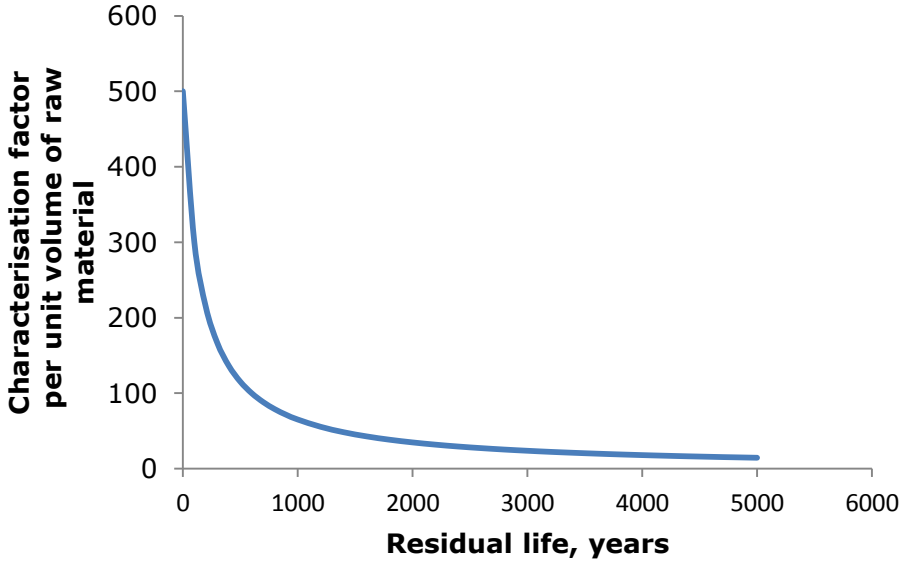

Figure 1: CRS per unit volume of resource

The value of the characterisation factor increase rapidly for residual lives of less than 850 years, i.e. discouraging the use of the scarcer resources, and change little at long residual lives, with their very large uncertainty. With such a curve, the CRS per unit volume of resource will never be zero. As there may be small impacts of resource use that are not covered by the other indicators, always having a positive CRS has merit. The characterisation factor per unit of resource is given by the equation:

Characterisation factor per unit of resource = 75000/(150 + residual life in years) [Eq 1]

This equation gives characterisation factors of 300.0, 65.2, 34.9, 23.8, 18.1 and 14.6 for residual lives of 100, 1000, 2000, 3000, 4000 and 5000 years respectively. Given the uncertainties associated with such long residual lives caused mainly by uncertainty in the rate of use, there should be no significant differences in the characterisation factors between resources with long residual lives. This is achieved by assuming a maximum residual life; any resource that has a residual life longer than this value has the same characterisation factor. As stated previously, the prime purpose of the resource indicator is a measure of availability to future generations; other impacts of resource extraction and processing are covered by other indicators.

It is the author's view that there should be a single master list of residual lives that is freely accessible and the list is maintained by an independent body such as one of the European Joint Research Centres. This list together with the publically-available characterisation curve means that the system is transparent to users.

4.3 Energy use

If energy is taken from the national grid, the resources used are based on the European/national average [7]. Table 4 gives the resources used to generate 1kW/h of electricity and these resources are used to determine the CRS when power use is based on the European average. If a national fuel mix is not available, the European fuel mix should be used in calculations. If however, the power comes from a documented greener source, e.g. hydroelectricity, the producer may use this for determining the CRS.

Table 4: Combined Resource Score (CRS) for 1 kW/h of power based on the European average

Energy Source	Quantity of Resource per kW/h, m^3	Characterisation Factor	CRS
Hard coal	$3.16x10^{-5}$	$5.56x10^{-2}$	$1.76x10^{-6}$
Brown coal	$2.32x10^{-5}$	$1.09x10^{-2}$	$2.53x10^{-7}$
Crude oil	$5.23x10^{-6}$	$5.00x10^{-2}$	$2.61x10^{-7}$
Natural gas	$2.31x10^{-5}$	$3.33x10^{-2}$	$7.71x10^{-7}$
Biomass	$3.86x10^{-6}$	0	0
Hydroelectricity	-	0	0
Nuclear (Uranium)	$9.66x10^{-13}$	$6.25x10^{-2}$	$6.04x10^{-14}$
Other	-	0	0
Total CRS per kW/h			**$3.04x10^{-6}$**

4.4 Secondary materials

Many secondary materials, which include recycled materials, have a finite residual life. For example, blastfurnace slag will only be produced when iron is made from primary ores. The current political will in Europe is that secondary resources are preferable to primary resources and to reflect this will, the characterisation factor per unit volume of resource is the lowest used in this system and independent of the residual life. As there is an additional benefit in the reduction of waste, the characterisation factor is set at 5.0, which is lower than the minimum of 14.6 used with primary resources.

It should be noted that the resources needed to process and transport secondary resources are taken fully into account in an identical way to primary resources. Consequently using secondary materials may not always provide a lower CRS, e.g. when the energy requirement to process and transport them is significantly greater than those needed for primary resources.

A principle of the system is that the benefits of a reduced CRS go to the manufacturer that actually uses the secondary resources. For example if on average p% of a resource is recycled materials, all users of that resource cannot claim p% recycled materials: they can only claim what they use. The aims of this approach are to reward manufacturers who use secondary materials with a lower CRS and create markets for such materials.

4.5 Biotic resources

The CRSs applied to biotic resources where there is a residual life ≥ 5000 years is the minimum value (14.6). This CRS per unit volume of resource is to cover the impacts not covered by the other indicators. The resources used to plant, fertilise, cultivate, harvest, process and transport are taken into account in the same way as for primary resources.

Water use is recorded in a separate indicator and this can be significant factor with respect to the impact of using biotic resources in areas of water stress.

Land use and biodiversity are two significant issues with respect to using biotic resources but there is no agreed way of including land use at present and biodiversity should be covered by a separate indicator (it is not yet included in the EN 15804 indicators).

4.6 Raw Materials Initiative

The system also takes into account the recommendations of the Raw Materials Initiative [5] by converting the supply risk and economic importance of a natural resource into an equivalent residual life and this equivalent residual life is used when it is shorter than the one described here. This process is detailed in reference [2]. Other parts of the world may have similar issues and a similar approach could be taken with resources that are of concern to them. There is also a case for excluding such a refinement from the analysis from globally-sourced products.

5. Example

An example application of the Combined Resource Score to a product is given in Table 5. The CRS calculations for a DN 300 polyethylene pipe were undertaken and the results are shown in Table 5. It should be noted that this example is for the pipe itself and not for the complete piping system.

Oil, gas and hard coal make the largest contribution to the CRS. Water use is also significant in the manufacturing of the pipe, although this is not part of the product CRS. It should be noted that when presented in terms of score-per-length of pipe, the scores are very much sensitive to the mass per unit length value used. The resulting product CRS plus water is similar in value to that of a concrete pipe [2].

One issue is that the pipe CRS is not a ‘functional unit’, i.e. it does not represent the impact of the ‘pipe in the ground’. A pipe of this type requires a bedding layer and a capping layer and the equivalent concrete or cast iron pipes do not normally require these layers. This illustrates why comparisons should never be made at the product level.

*Table 5: Resources used and CRSs for DN 300 polyethylene pipe**

Resource[A)]	Quantity, m^3/m length of pipe	Residual Life, yrs	CRS
Oil	$2.65x10^{-2}$	100	8.42
Gas	$2.74x10^{-2}$	150	7.68
Hard coal	$2.62x10^{-3}$	90	1.31
Brown coal	$5.11x10^{-8}$	460	$6.64x10^{-2}$
Sulfur	$9.29x10^{-7}$	70	$3.17x10^{-4}$
Iron	$7.99x10^{-7}$	100	$2.40x10^{-4}$
NaCl	$1.62x10^{-4}$	5000	$8.71x10^{-5}$
Limestone	$1.82x10^{-6}$	5000	$2.64x10^{-5}$
Sand	$1.17x10^{-6}$	5000	$1.70x10^{-5}$
Bauxite	$5.00x10^{-8}$	280	$8.72x10^{-6}$
Zinc	$1.33x10^{-8}$	170	$3.12x10^{-6}$
Bentonite	$1.10x10^{-7}$	5000	$1.61x10^{-6}$
Gypsum	$1.43x10^{-6}$	5000	$7.68x10^{-7}$
Dolomite	$7.39x10^{-7}$	5000	$3.98x10^{-7}$
Olivine	$4.82x10^{-7}$	5000	$2.60x10^{-7}$
Shale	$1.46x10^{-8}$	5000	$2.13x10^{-7}$
Uranium	$5.55x10^{-11}$	80	$3.87x10^{-8}$
Biomass	$8.90x10^{-4}$	5000	0.00
TOTAL CRS	**$5.75x10^{-2}$**	**-**	**17.48**
Water[B)C)]	$2.43x10^{-1}$	3600	4.85
Product CRS plus water			**22.33**

6. Conclusions

6.1 Information on the sustainable use of natural resources (BRCW7) is best provided using a Combined Resource Score that encompasses 11 of the 12 resource indicators given in EN 15804.

6.2 The proposed lead indicator:

- is policy relevant, e.g. it provides information with respect to BRCW7;
- is coherent and complete as a resource indicator except for land-use, which has no agreed indicator;
- uses a principle (residual life) fully accepted by CEN/TC350;
- includes the impact of using secondary (including recycled) materials;
